9. Dye sensitivity test media: a 0.1% solution of basic fuchsin or thionine is prepared in distilled water and heated at 100°C for 1 h. Portions of this stock solution are then added to molten basal media such as SDA or TSA so as to produce a final dye concentration between 10 and 40 μg/ml. The exact concentration required to produce satisfactory differentiation of biovars must be determined for each batch of dye medium by use of *Brucella* reference strains. The plates should be incubated overnight at 37°C before use, to reveal any contaminants. Dyes from National Aniline Division, Allied Chemical and Dye Co., New York, NY, USA were originally recommended but are no longer available. Dyes from other sources may be used but each batch must be validated before use. Basic fuchsin is now difficult to obtain and has been replaced by *p*-rosaniline.

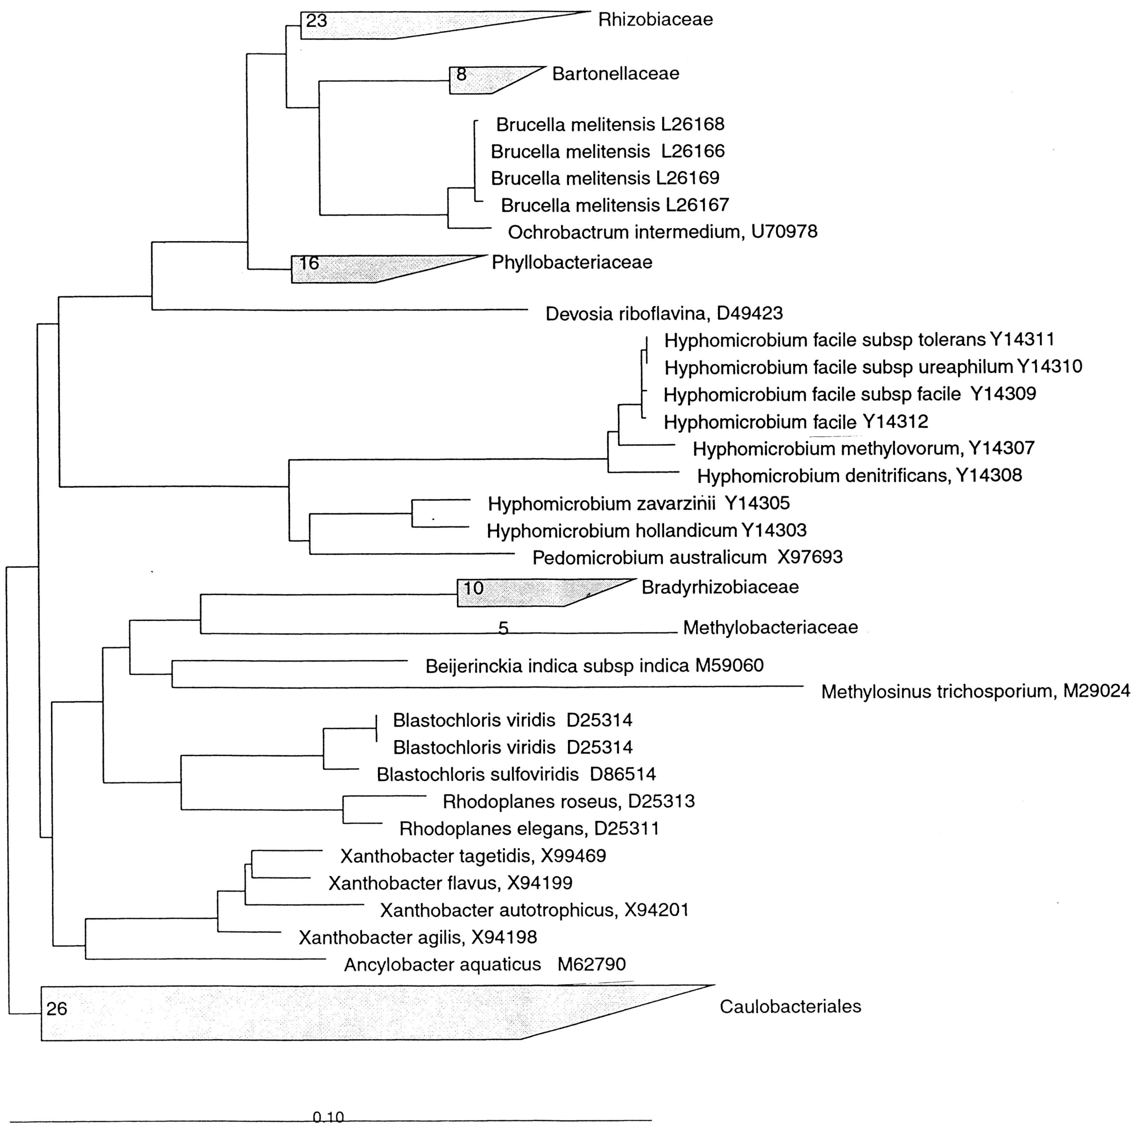

FIGURE BXII.α.138. Phylogenetic tree showing the relationships between the families of *Rhizobiaceae, Bartonellaceae, Bradyrhizobiaceae, Methylobacteriaceae,* and the order *Caulobacterales,* prepared using the weighted least squares method implemented by PAUP, with inverse-squared weighting. Distances were calculated using 1182 positions and corrected according to the HKY85 model (Courtesy of the Ribosomal Database Project).

by gene sequencing and genome mapping as indicated above. These have shown that the various nomenspecies share an essentially similar genomic structure, the main differences being in arrangement rather than content. Current evidence suggests that the presently recognizable subdivisions evolved from a precursor monochromosomal strain resembling *B. suis* biovar 3. The double chromosomes present in the other nomenspecies and biovars contain very similar genes to those represented in the single chromosome, suggesting that they arose through scission of the latter. This emphasizes the essential unity of the genus. Nevertheless significant differences in the genetic, biochemical, cultural, and pathogenic properties of the strains corresponding to its recognized subdivisions do exist, and these are correlated with host specificity (Fig. BXII.α.139). While the concept of separate species is not tenable, it is clear that subdivision at a level higher than biovar should be maintained. To minimize the confusion that would be likely to result from the adoption of a completely novel nomenclature, it is proposed that the current division into nomenspecies should be retained until an adequate genetically based classification is devised.

The present system of classification was devised by the Subcommittee on Taxonomy of the genus *Brucella* at its first meeting (Stableforth and Jones, 1963), with amendments introduced at its subsequent meetings (Jones, 1967; Jones and Wundt, 1971; Wundt and Morgan, 1975). Although a number of studies have produced suggestions for modifications of this scheme, none of the proposed changes has yet emerged as entirely satisfactory. Any improved system needs to take into account the genetic evidence indicating the monospecific nature of the genus, but at the same time acknowledge the significant divisions which exist below species level, particularly in relation to genomic arrangements and host specificity. At this level, the main problem is one of terminology, as clearly differences are discernible within the genus at a higher level than that of the conventionally defined biovars. The application of genetic typing methods has not resolved this problem; rather it has added a further dimension of

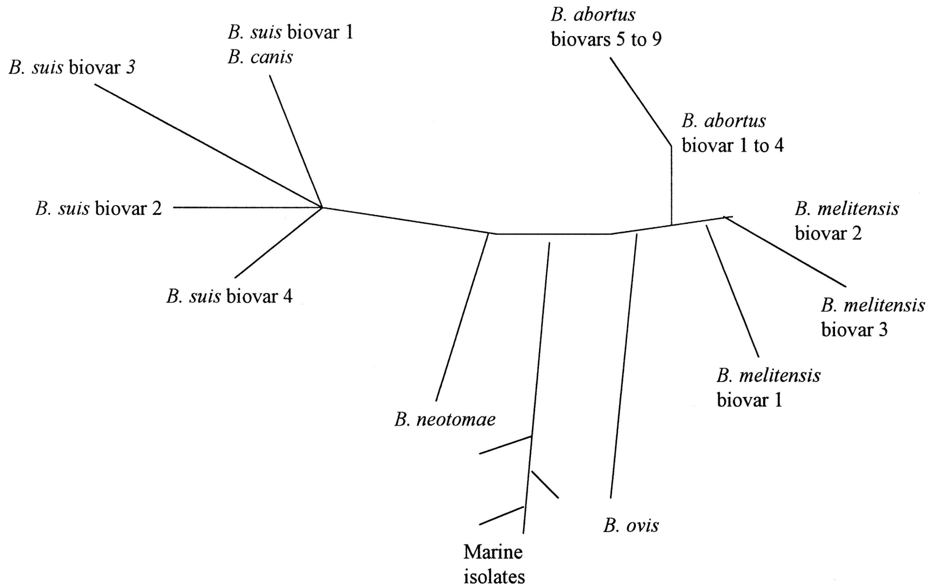

FIGURE BXII.α.139. Phylogenetic tree of the *Brucella* species.

complexity as the level of subdivision can be increased progressively by increasing the number of gene polymorphisms examined.

The biovars defined by conventional biotyping tests correspond to epidemiologically significant variants and this scheme is still useful, although it is evidently incomplete. It is also internally inconsistent, as the number of differential characteristics necessary to define a biovar is variable. For example, the conventional scheme identifies only three biovars of *B. melitensis* based on serology. In fact, strains of this organism may show a similar range of sensitivity to basic fuchsin and thionine to that shown by *B. abortus* strains and this extends the number of possible biovars to twelve, all of which have been detected at some time (Banai et al., 1990; Corbel, 1991; Bardenstein et al., 2002). Similarly, strains of the other nomenspecies that do not fit into the current biotyping scheme have also been described but not accorded separate status.

The conventional scheme also needs to be extended to accommodate the strains isolated from marine mammals. These differ from the currently recognized nomenspecies by as much as the latter differ from each other. It is also clear that distinct groups exist within the marine strains, corresponding to isolations from seals, porpoises, dolphins, or whales (Ross et al., 1996; Clavareau et al., 1998; Miller et al., 1999). These distinctive types may need to be regarded as separate nomenspecies. They show some divergence from the "mainstream" nomenspecies and quite clearly form a distinct branch of the genus (Fig. BXII.α.139).

At one point, the designation *"B. maris"* was suggested for the marine isolates. However, both conventional and genotyping methods indicate the heterogeneity of the group. The marine strains break down into four clear subgroups corresponding to oxidative metabolism pattern and preferred host species. These are distributed across seven marine-specific genotypes according to *omp2* and *omp25* PCR-RFLP typing. The official status of these isolates has yet to be decided but they undoubtedly comprise a novel subdivision within the genus *Brucella.*

List of species of the genus Brucella

1. **Brucella melitensis** (Hughes 1893) Meyer and Shaw 1920, 179[AL] (*Streptococcus melitensis* Hughes 1893, 235).
me.li.ten′sis. L. adj. *Melitensis* of or pertaining to the Island of Malta (Melita) where first isolated (Bruce, 1893).

The morphological and cultural characteristics are as described for the genus. Other characteristics of the species and its biovars are indicated in Tables BXII.α.120 and BXII.α.121. The usual natural hosts are sheep and goats, but other species, including cattle, pigs, and humans, may be infected. Smooth cultures are usually pathogenic for the guinea pig and the mouse. In general, smooth cultures of *B. melitensis* tend to be more virulent for laboratory animals than *B. abortus* and may cause fatal infections. Nonsmooth cultures are usually avirulent for both laboratory animals and the natural hosts.

The mol% G + C of the DNA is: 58 (T_m).
Type strain: 16M, ATCC 23456, NCTC 10094.
GenBank accession number (16S rRNA): L26166.

Additional Remarks: The complete genome of strain 16M has been published by DelVecchio et al. (2002). Strain 16M is also the reference strain for biovar 1. The reference strain for biovar 2 is 63/9 (ATCC 23457; NCTC 10508), and that for biovar 3 is Ether (ATCC 23458; NCTC 10509).

2. **Brucella abortus** (Schmidt 1901) Meyer and Shaw 1920, 176[AL] (*Bacterium abortus* Schmidt *in* Schmidt and Weiss 1901, 266.)
a.bor′tus. L. gen. n. *abortus* of abortion, miscarriage; first isolated by Bang (1897).

The morphological and cultural characteristics are as described for the genus. Other characteristics of the species and its biovars are indicated in Tables BXII.α.120 and BXII.α.121. The usual natural hosts are cattle and other bovidae. Horses, camels, sheep, deer, dogs, man, and other species may also be infected. Placentitis and abortion are usually produced in the pregnant animal. Pathogenic for

laboratory animals including rabbits, guinea pigs, and mice; the guinea pig is probably the most susceptible. Rough strains are usually avirulent, but mice retain the organisms in the spleen for some time after inoculation.

The mol% G + C of the DNA is: 56 (Bd) or 57 (T_m).

Type strain: 544, ATCC 23448, NCTC 10093.

Additional Remarks: ATCC 23448 is also the reference strain for biovar 1. For biovar 2 (referred to as "dye-sensitive *B. abortus*" by Wilson, 1933) the reference strain is 86/8/59 (ATCC 23449; NCTC 10501). For biovar 3 (referred to as "Rhodesian abortus", "non-CO_2-requiring, thionine-resistant *B. abortus*" (Bevan, 1930) or "CO_2-requiring, thionine-resistant *B. abortus*" (Van der Schaaf and Rosa, 1940), the reference strain is Tulya (ATCC 23450; NCTC 10502). The reference strain for biovar 4 is 292 (ATCC 23451; NCTC 10503). For biovar 5 (referred to as British *melitensis* [Stableforth, 1959]) the reference strain is B3196 (ATCC 23452; NCTC 10504). The reference strain for biovar 6 is 870 (ATCC 23453; NCTC 10505). The reference strain for biovar 7, 63/75 (ATCC 23454; NCTC 10506), was reported to be a mixture of both A- and M-dominant strains and this biovar has been suspended. For biovar 9 (referred to as "H_2S-producing *B. melitensis*" by Taylor et al., 1932) the reference strain is C68 (ATCC 23455; NCTC 10507). Biovar 8 was originally described as "CO_2-requiring *B. melitensis*" by Taylor et al. (1932), but as no cultures of this biovar are known to exist, the status of this biovar was suspended by the Subcommittee on the Taxonomy of the genus *Brucella* in 1978 (Corbel, 1982).

3. **Brucella canis** Carmichael and Bruner 1968, 579[AL]
ca'nis. L. gen. n. *canis* of the dog.

The morphological and cultural characteristics are as described for the genus. Other characteristics are indicated in Tables BXII.α.120 and BXII.α.121. No biovars are recognized. On incubation for more than a few days, the colonies become very tenacious and viscous. The growth is almost impossible to emulsify and forms a ropy agglutinate in physiological saline. In *Brucella* broth incubated at 37°C for seven days, a moderate turbidity is produced, with a ropy or viscous sediment that cannot be uniformly resuspended. Older cultures may form a fine surface pellicle, which is easily disrupted. In serum-dextrose broth or well-buffered media, the ropy sediment or pellicle is often not produced. Cultures are always in the rough or mucoid phase on primary isolation. A smooth phase is not known. Cultures are not agglutinated by antisera monospecific for the A and M antigens, but do agglutinate with antiserum to the R antigen of *B. ovis.* Cross-reactions with the surface antigens of nonsmooth strains of other *Brucella* species also occur. Internal antigens are shared with smooth and nonsmooth strains of all *Brucella* strains. Metabolic activity is very similar to *B. suis* biovar 1, but urocanic acid is oxidized.

Pathogenic for the dog, producing chronic bacteremia and localizing granulomatous lesions. Epididymo-orchitis and prostatitis are produced in the male, and metritis, placentitis, and abortion are produced in the pregnant female. The infection is occasionally transmitted to humans; natural infections in other species have not been authenticated. Infection in guinea pigs and mice may be established by inoculation of large doses of organisms. The mouse retains the infection longer than the guinea pig.

The mol% G + C of the DNA is: 56 (T_m).

Type strain: RM6/66, ATCC 23365, NCTC 10854.

Additional Remarks: Genetic and other evidence suggests *B. canis* is a stable rough variant of *B. suis* biovar 1.

4. **Brucella neotomae** Stoenner and Lackman 1957, 947[AL]
ne.o.to'mae. M.L. fem. n. *Neotoma, Neotoma lepida* generic name of the desert wood rat of the Western U.S.A (Thomas); M.L. fem. gen. n. *neotomae* of the desert wood rat, the host from which the organism was first isolated.

The morphological and cultural characteristics are as described for the genus. Other characteristics are indicated in Tables BXII.α.120 and BXII.α.121. Nonpathogenic for cattle, sheep, goats, and pigs. Not proven to be pathogenic for humans. Does not apparently produce disease in its natural host (the desert wood rat) and shows minimal pathogenicity for laboratory animals. Guinea pigs develop slight splenomegaly, and sometimes epididymo-orchitis or testicular abscesses following intraperitoneal inoculation. Small granulomatous lesions develop in the liver and spleen. Mice are more susceptible to infection, and lesions may be produced by frequently passaged strains.

The mol% G + C of the DNA is: 56–57 (T_m).

Type strain: 5K33, ATCC 23459; NCTC 10084.

5. **Brucella ovis** Buddle 1956, 351[AL]
o'vis. L. gen. n. *ovis* of the sheep.

The morphological and cultural characteristics are as described for the genus. Although other species of *Brucella* stain red by modified Köster's stain, *B. ovis* stain blue. Other characteristics are listed in Tables BXII.α.120 and BXII.α.121; no biovars are recognized. L-alanine, L-aspartic acid, L-glutamic acid, adonitol, and DL-serine are oxidized. Cultures are known to exist only in the nonsmooth colonial phase. They do not agglutinate with antisera monospecific for A and M surface antigens, but are agglutinated by antisera to the R surface antigen of *B. ovis.* Cross-reactions occur with the surface antigens of nonsmooth strains of other *Brucella* species. Many of the internal antigens are shared with other *Brucella* species, irrespective of colonial phase.

Pathogenic for sheep, producing epididymo-orchitis in the male and placentitis and abortion in the pregnant female. Goats may be infected experimentally and subclinical infections may be produced in cattle, guinea pigs, rabbits, mice, and gerbils.

The mol% G + C of the DNA is: 57–58 (T_m).

Type strain: 63/290, ATCC 25840, NCTC 10512.

GenBank accession number (16S rRNA): L26168.

Additional Remarks: The *B. ovis* genome contains many more copies of the insertion sequence IS*6501* than the genomes of the other nomenspecies.

6. **Brucella suis** Huddleson 1929, 12[AL]
su'is. L. gen. n. *suis* of the pig.

The morphological and cultural characteristics are as described for the genus. Other characteristics of the species and its biovars are indicated in Tables BXII.α.120 and BXII.α.121. Biovars 1, 2, and 3 are naturally pathogenic for pigs. Biovar 2 also naturally infects hares. Strains resembling biovar 3 have also been isolated from various species of rodents. Biovar 4 is naturally pathogenic for reindeer (Davydov, 1961). Biovar 5 has only been isolated from rodents

(Corbel, 1982; 1988). All biovars, with the possible exception of biovar 2, are pathogenic for humans. Other species, including dogs, horses, and many species of rodents, may also be infected. In the natural hosts, generalized infections are produced, with localizing lesions, particularly in the genitalia. The testes, epididymides, and seminal vesicles are usually severely affected in the male. Metritis, placentitis, and abortion are produced in the pregnant female.

Pathogenic for laboratory animals including rabbits, guinea pigs, and mice. Splenomegaly and widespread granulomatous and suppurative lesions are produced. Biovars 1 and 3 are usually the most virulent, and heavy inocula may produce fatal infections in guinea pigs.

The mol% G + C of the DNA is: 56–57 (T_m).

Type strain: 1330, ATCC 23444, NCTC 10316.

GenBank accession number (16S rRNA): L26169.

Additional Remarks: ATCC 23444 is also the reference strain for biovar 1 (referred to as "American *suis*"). For biovar 2 (referred to as "Danish or European *B. suis*" by Thomsen, 1929), the reference strain is Thomsen (ATCC 23445; NCTC 10510). For biovar 3 (referred to as "American *melitensis*" or "dye-resistant *B. suis*" [Huddleson, 1957]), the reference strain is 686 (ATCC 23446; NCTC 10511). This biovar is unique in having a single chromosome of 3.2×10^6 base pairs. For biovar 4 (formerly "*Brucella rangiferi tarandi*" [Davydov, 1961]), the reference strain is 40 (ATCC 23447; NCTC 11364). For biovar 5 the reference strain is 513 (NCTC 11996). Biovar 3 is probably closest to the ancestral prototype of the genus. It is believed that the double chromosomes of the other nomenspecies and biovars arose because of rearrangements during replication.

Other Organisms

"Brucella maris"

The designation *"Brucella maris"* has been suggested for strains of *Brucella* isolated from marine mammals. However, it is now clear that these comprise at least four distinct groups, according to conventional typing and host range, and at least seven types based on restriction fragment polymorphism of the *omp2a*, *2b*, and *omp25* genes. Three new nomenspecies have been proposed to cover the known variants. These are *"B. phocae"* with two biovars, associated with seals, *"B. phoecoenae"* and *"B. delphini"* with one biovar each, isolated from porpoises and dolphins, respectively. All strains oxidize D-glutamic acid, ribose, and xylose, whereas none oxidize L-alanine, L-aspartic acid, L-arginine, L-ornithine, or L-lysine. Strains of *"B. phocae"* biovars 1 and 2 oxidize *i*-erythritol but only biovar 2 oxidizes urocanic acid. Both *"B. phocoenae"* and *"B. delphini"* oxidize D-galactose; the former oxidizes *i*-erythritol but not urocanic acid, whereas the latter shows the reverse pattern. Nearly all strains are lysed by Bk_2 phage and none are lysed by phage R/Cat-RTD. Strains of *"B. phocae"* biovar 2 and *"B. delphini"* are lysed by Tb and Fi phages at RTD, whereas *"B. phocae"* biovar 1 and *"B. phocoenae"* are not. Only strains of *"B. phocae"* biovar 2 are usually lysed by Wb phage. There is some variation in phage sensitivity between strains within putative nomenspecies, suggesting that phage typing could be applicable for subgrouping.

Strains of both *"B. phocae"* biovars require CO_2, but the other nomenspecies do not. None produce H_2S, but all are urease positive and grow in the presence of basic fuchsin and thionine. European isolates obtained to date have been A-antigen dominant, but North American strains dominant for M antigen have also been described. The latter may correspond to an additional nomenspecies. Pathogenicity for natural host species has not been clearly defined; subclinical infection seems the usual outcome. Potentially pathogenic for humans (Brew et al., 1999).

The status of this group requires resolution. It is clear that it represents a novel subdivision within the genus, but with considerable internal diversity.

Genus II. **Mycoplana** *Gray and Thornton 1928, 82^AL emend. Urakami, Oyanagi, Araki, Suzuki and Komagata 1990d, 439*

Teizi Urakami and Paul Segers

My.co.pla′ na. Gr. *mykes* fungus; Gr. *plane* a wandering; M.L. fem. n. *Mycoplana* fungus wanderer.

Cells are **curved or irregular rods** with rounded ends, 0.5–0.8 × 2.0–3.0 μm. Occur singly or rarely in pairs. The cells form **branching filaments** prior to fragmentation into irregular rods. Gram negative and nonsporeforming. **Motile by means of peritrichous flagella**.

Colonies are white to light yellow.

Aerobic, with a **strictly respiratory** type of metabolism; not fermentative. Grow well on standard culture media, between pH 6 and 8, at 30°C, but not in medium containing 3% NaCl and not at 42°C. The methyl red test is negative. Indole and hydrogen sulfide are not produced. Hydrolysis of gelatin and starch does not occur. Ammonia is produced. Denitrification is negative and litmus milk is not changed. Acid is produced only oxidatively from sugars. Urease and oxidase are produced. A water-soluble fluorescent pigment is not produced on King A or King B media. The cells **accumulate granules of poly-β-hydroxybutyrate**. **Occur in soil**. The major fatty acids are octadecenoic acid ($C_{18:1}$), in large amounts, hexadecanoic acid ($C_{16:0}$), and hexadecenoic acid ($C_{16:1}$). The major hydroxy fatty acid is $C_{14:0\ 3OH}$. They contain Q-10 as major ubiquinone.

The mol% G + C of the DNA is: 63–65.

Type species: **Mycoplana dimorpha** Gray and Thornton 1928, 82 emend. Urakami, Oyanagi, Araki, Suzuki and Komagata 1990d, 440.

Further descriptive information

The genus *Mycoplana* as emended and described by Urakami et al. (1990d) is paraphyletic, as shown by rRNA gene sequence analysis (Abraham et al., 1999, see also the chapter on *Brevundimonas*). *Mycoplana dimorpha* and *Mycoplana ramosa* belong to a separate lineage within the family *Brucellaceae*, whereas the type strains of *Mycoplana bullata* and *Mycoplana segnis* belong to the

family *Caulobacteraceae*. Furthermore, *M. bullata* was shown to belong to the genus *Brevundimonas* and *M. segnis* was reclassified as *Caulobacter segnis* (Abraham et al., 1999). Since the last two species belong to other genera, the authentic genus *Mycoplana* contains only the species *M. dimorpha* (the type species) and *M. ramosa*. Therefore, in this chapter, a corresponding restrictive description is given for the genus. *M. bullata* and *Caulobacter segnis* (*M. segnis*) are described in the chapters on the genera *Brevundimonas* and *Caulobacter*, respectively, the genera in which they are presently classified.

Colonies of the genus *Mycoplana* are not mucous. Voges–Proskauer and catalase tests are positive. Ammonium salts, urea, peptone, Casamino acids, and, for most strains, nitrate are utilized as nitrogen and or carbon sources. Biotin or thiamine is required for growth. They utilize as sole source of carbon L-arabinose, D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, D-sorbitol, D-mannitol, glycerol, L-glutamic acid, L-aspartic acid, acetic acid, putrescine, spermidine, and spermine. Lactose, trehalose, inositol, soluble starch, citric acid, formic acid, methanol, ethanol, butanol, monomethylamine, methane, and butane are not utilized.

In an extensive comparative study between members of the *Rhizobiaceae*, assimilation of 147 carbohydrates by the type strains of *M. dimorpha* and *M. ramosa* (NCIB 9440) was shown (de Lajudie et al., 1994). In this study, the assimilation of maltose, sucrose and succinate was shown to be negative for *M. dimorpha*, and it was demonstrated that the assimilation of ribose, L-sorbose, inositol, 2-ketogluconate, butyrate, DL-3-hydroxybutyrate, L-valine, betaine, spermine, and glucosamine can be used to distinguish the two species *M. dimorpha* and *M. ramosa*.

In the emended description of *Mycoplana* (Urakami et al., 1990d), strains of *M. dimorpha* and *M. ramosa* were shown to produce oxidatively acid from L-arabinose, D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, D-sorbitol, D-mannitol, and glycerol, but not from maltose, sucrose, lactose, trehalose, inositol, and soluble starch. Hydrolysis of gelatin and starch was not observed. Contradicting the results of Gray and Thornton (1928), *Mycoplana* strains produced no acid from carbohydrates, and hydrolysis of starch and gelatin liquefaction were variable features.

The ability to decompose aromatic compounds, such as phenol and *m*-cresol, is included in the original description (Gray and Thornton, 1928).

Mycoplana strains that are diazotrophic under microaerobic conditions have been described. Several *M. dimorpha* and *M. bullata* strains showed nitrogenase activity and ^{15}N enrichment when grown on N-free media (Pearson et al., 1982).

Q-10 is the major ubiquinone; also detected were small amounts of Q-9 and traces of Q-11.

Enrichment and Isolation Procedures

Isolation of *Mycoplana* strains was originally described by Gray and Thornton (1928): inoculate 100 ml of a solution of mineral salts, to which 0.05–0.1% phenol or 0.05% *m*-cresol is added, with soil (0.5–1 g). If growth occurs, make transfers into fresh flasks of the same medium. After further plating and purification on an agar medium, *Mycoplana* strains can be isolated.

Maintenance Procedures

Cultures can be maintained on most common media. Abundant growth occurs in nutrient broth, PYG broth, and peptone water, and on these solid media, when grown at 30°C in air. Cultures can be stored at room temperature or in the refrigerator, but should be transferred weekly, although longer storage in a refrigerator is possible.

Cultures may be stored for many years by lyophilization, freezing at −80°C, or in liquid nitrogen. Cryoprotective agents such as 10% glycerol or DMSO should be added to cultures before freezing, and heavy cell concentrations should be used.

Differentiation of the genus *Mycoplana* from other genera

Mycoplana belongs phylogenetically to the family *Brucellaceae*, which also contains the genera *Brucella* and *Ochrobactrum*. *Mycoplana* can easily be differentiated from the other genera by the ability to form branching filaments (Fig. BXII.α.140), motility (*Brucella* is nonmotile), accumulation of granules of poly-β-hydroxybutyrate, utilization and acid production from several carbohydrates (Holmes et al., 1988; de Lajudie et al., 1994; see Table BXII.α.123 in the chapter on *Ochrobactrum*), and the hydrolysis of L- isoleucyl-β-naphthylamide and L-prolyl-β-naphthylamide hydroxychloride (API-ZYM test, Holmes et al., 1988).

The former *Mycoplana* species *M. bullata* and *C. segnis* can be distinguished from the authentic *Mycoplana* species *M. dimorpha* and *M. ramosa* by their phylogenetic position, mucoid colonies, requirement for growth of special unknown growth factors or peptone, no production of acid from several carbohydrates, occurrence of $C_{12:0\ 3OH}$, and only small amounts of $C_{14:0\ 3OH}$ and larger amounts of hexadecanoic acid ($C_{16:0}$), and the higher mol% G + C content (66–68), (Urakami et al., 1990d).

Mycoplana strains resemble *Methylobacterium*, *Xanthobacter*, and *Oerskovia* strains based on branching filament formation and/or a few chemotaxonomic properties. One can easily differentiate those taxa by their different phylogenetic position, Gram stain, the fine structure of the cells, colony color, utilization of methanol, and hydroxy fatty acid composition (Urakami et al., 1990d).

Taxonomic Comments

In 1928, Gray and Thornton created the genus *Mycoplana* for branching bacteria isolated from soil and able to decompose aromatic compounds. They classified this new genus with two species, *M. dimorpha* (the type species) and *M. bullata*, in the family *Mycobacteriaceae*.

The ability of the strains to form branching filaments prior to breaking up into motile rods has led several workers to place the genus *Mycoplana* in the order *Actinomycetales*, although they have a cell wall of the Gram-negative type, containing *meso*-DAP and numerous amino acids (Sukapure et al., 1970; Cross and Goodfellow, 1973; Lechevalier and Lechevalier, 1981a, c). In different editions of *Bergey's Manual of Determinative Bacteriology*, the genus was placed in the family *Mycobacteriaceae* or in the family *Pseudomonadaceae* (Breed, 1957) or even, in the eighth edition, left out (Buchanan and Gibbons, 1974). In the first edition of *Bergey's Manual of Systematic Bacteriology*, it was mentioned in the section "Nocardioform Actinomycetes", as a comment, supplementary to the genus *Oerskovia* (Lechevalier and Lechevalier, 1981b).

Mycoplana, *M. dimorpha*, and *M. bullata* are valid names since they appear on the Approved Lists of Bacterial Names (Skerman et al., 1980).

The genus description was emended in 1990, and two new species, *M. ramosa* and *M. segnis*, were proposed by Urakami et

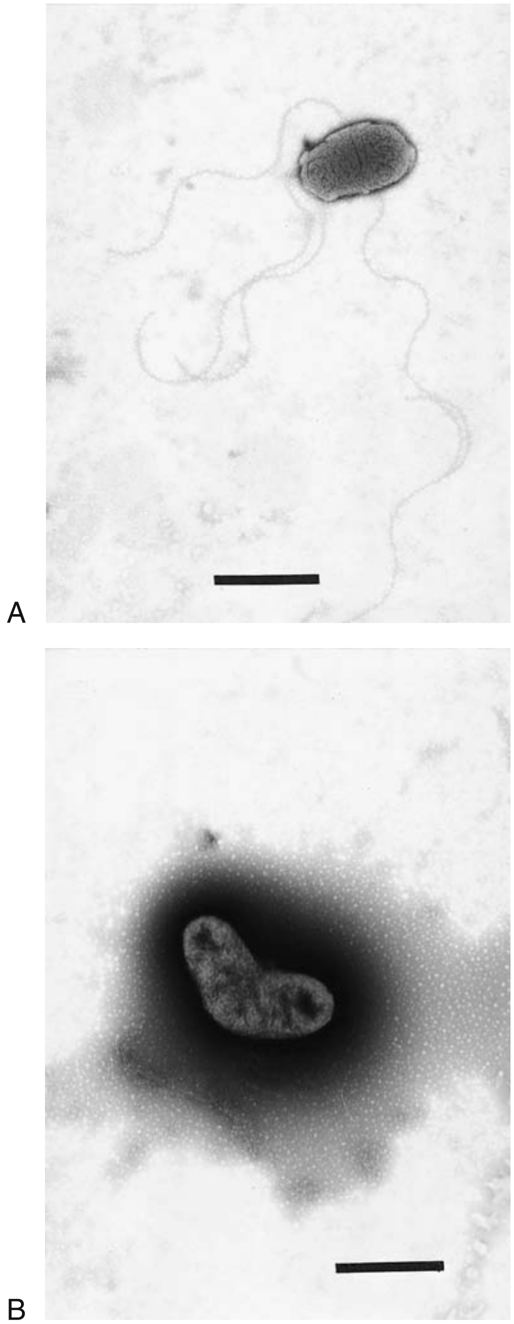

FIGURE BXII.α.140. Negatively stained cells of *Mycoplana dimorpha* ATCC 4279^T (Bar = 1 μm). (*A*) peritrichous flagella; (*B*) exhibiting branching.

al. (1990d). In a polyphasic approach, they recharacterized and clarified the authenticity of the type strains of *M. dimorpha* and *M. bullata* from different origins as well as a few other *Mycoplana* strains. From the strains of *M. bullata*, received from different culture collections, only ATCC 4278^T (IFO 13290^T) was, based on strain authenticity investigations, identified as the original type strain for *M. bullata*. *M. bullata* strain NCIB 9440, supposedly originating from the same source, differs from this species. A new species, *M. ramosa*, was proposed for this strain. *M. segnis* was proposed as a new taxon with two strains.

Recent rRNA similarity studies showed that the genus *Mycoplana* is paraphyletic (Yanagi and Yamasato, 1993; Abraham et al., 1999; see Fig. BXII.α.122 in the chapter on *Brevundimonas*). With two species, *M. dimorpha* and *M. ramosa*, *Mycoplana* constituted a separate branch, closely related to *Brucella* and *Ochrobactrum* in the family *Brucellaceae*. 16S rRNA gene sequencing studies showed *M. bullata* to cluster in the *Caulobacteraceae* as a separate branch within the emended genus *Brevundimonas* (Abraham et al., 1999; see chapter *Brevundimonas*). It can be considered as a *Brevundimonas* species. *M. segnis*, a member of the same rRNA family, is more closely related to the type species of *Caulobacter* and has been reclassified as *Caulobacter segnis* (see Fig.BXII.α.122 and Table BXII.α.107 in the chapter *Brevundimonas*; Abraham et al., 1999). The unexpectedly high level of interrelationship of both former *Mycoplana* species with the emended genera *Brevundimonas* and *Caulobacter* was also confirmed by polar lipid and fatty acid analysis, mol% G + C content, and phenotypic characterization.

Sensitivity to the rhizobial peptide antibiotic trifolitoxin was found in *Mycoplana* species and in organisms of related genera (Triplett et al., 1994).

Lipopolysaccharides were isolated and characterized from *M. dimorpha*, *M. ramosa*, *M. bullata*, and *C. segnis* (Tharanathan et al., 1993). Similarities in chemical composition between related organisms could be shown. *M. ramosa* and *M. dimorpha* expressed ladder-like patterns on DOC-PAGE, albeit weakly, indicating some S-type lipopolysaccharides and lipid A of the D-glucosamine type. *M. bullata* and *M. segnis* showed an R-type on DOC-PAGE and had lipid As of the lipid A-DAG-type, which exclusively contained 2,3-diamino-2,3-dedeoxy-D-glucose as lipid A sugar (Tharanathan et al., 1993).

"Mycoplana rubra" (Devries and Derx, 1953), a pink methylamine-utilizing bacterium was deposited in the National Collection of Industrial Bacteria (Aberdeen, UK). This organism is now classified in the facultative methylotrophic genus *Methylobacterium* (Urakami and Komagata, 1984; Bousfield and Green, 1985).

Differentiation of the species of the genus *Mycoplana*

Characteristics useful in distinguishing the two authentic *Mycoplana* species *M. dimorpha* and *M. ramosa* are the ability of the first species to assimilate maltose, sucrose, and succinic acid, and its requirement of biotin for growth. *M. ramosa* requires thiamine for growth (Urakami et al., 1990d). Differences in the utilization and acid production from other carbohydrates between the two species have also been shown (Holmes et al., 1988; de Lajudie et al., 1994).

List of species of the genus Mycoplana

1. **Mycoplana dimorpha** Gray and Thornton 1928, 98[AL] emend. Urakami, Oyanagi, Araki, Suzuki and Komagata 1990d, 440.
di.mor′pha. Gr. adj. *dimorpha* two forms.

Morphology and characteristics are as given for the genus.

Reduction of nitrate is variable. Biotin is required for growth. Maltose, sucrose, and succinic acid are also assimilated.

The mol% G + C of the DNA is: 64–65 (HPLC).

Type strain: ATCC 4279, IFO 13291, NCIB 9439, LMG 4061.

2. **Mycoplana ramosa** Urakami, Oyanagi, Araki, Suzuki and Komagata 1990d, 441[VP]
ra.mo′sa. M.L. *ramosa* ramous, ramose, branched, branch-like.

Morphology and characteristics are as given for the genus.

Reduction of nitrate and the Voges–Proskauer test are weakly positive. Thiamine is required for growth. Maltose, sucrose, and succinic acid are not assimilated.

The mol% G + C of the DNA is: 64 (HPLC).

Type strain: ATCC 49678, NCIB 9440, IFO 15249, LMG 3026.

Genus III. **Ochrobactrum** *Holmes, Popoff, Kiredjian and Kersters 1988, 412[VP]*

Barry Holmes

O.chro.bac′trum. Gr. adj. *ochros* pale, colorless; Gr. neut. n. *baktron* a staff or stick; M.L. neut. n. *Ochrobactrum* a colorless rod.

Rods with parallel sides and rounded ends, typically 1.0 × 1.5–2.0 µm; shorter oval forms, 1.0–1.5 µm in length, may occur. Cells usually occur singly. **Gram negative**. **Motile** by means of peritrichous flagella. **Obligately aerobic**, having a strictly **respiratory** type of metabolism. Optimal growth temperature in the range 20–37°C. Colonies on nutrient agar are smooth, low convex, and translucent (opaque and mucoid, quickly becoming confluent in *O. tritici*). Chemoorganotrophic, using a variety of amino acids, organic acids, and carbohydrates as carbon sources. Acid is produced from glucose, arabinose, ethanol, fructose, rhamnose, and xylose. **Oxidase positive**. **Catalase positive**. Indole is not formed. **Nitrates usually reduced**. Growth occurs on MacConkey agar. Urease usually positive. Ornithine decarboxylase (ODC) negative. Occur in human clinical specimens, also in soil samples and wheat roots. Parameters of DNA–rRNA hybrids indicate that *Ochrobactrum* belongs to the *Brucella* branch within rRNA superfamily IV. 16S rRNA gene sequence analysis places *Ochrobactrum* in the group of bacteria known as the α-2 subclass of the *Proteobacteria*. At the suprageneric level, *Ochrobactrum* is related to *Brucella*, *Phyllobacterium*, *Rhizobium*, and *Agrobacterium*.

The mol% G + C of the DNA is: 56–59.

Type species: **Ochrobactrum anthropi** Holmes, Popoff, Kiredjian and Kersters 1988, 412.

Further descriptive information

Cells of *Ochrobactrum* grown on nutrient agar are monomorphic straight rods and have rounded ends. The usual cell dimensions are 1.0 × 1.5–2.0 µm. Shorter oval forms, 1.0–1.5 µm in length, may occur.

Sudanophilic bodies have not been detected with the use of Sudan Black B.

After incubation for 24 h at 37°C on nutrient agar, colonies are <0.5 mm in diameter, circular, low convex, smooth, moist, glistening, translucent, and butyrous, and have an entire edge; pigment is not produced.

Growth at 20°C and 37°C is equally good. Few strains grow at 42°C, and while clinical strains have not been reported to grow at 5°C, environmental isolates will grow at 4°C.

Immunological cross-reactions between *O. anthropi* and *Brucella* spp. are apparent in animals infected by *Brucella* spp. Pulsed-field gel electrophoresis and polymerase chain reaction genome fingerprinting based on repetitive chromosomal sequences (rep-PCR) have been applied to the typing of strains of *O. anthropi* (van Dijck et al., 1995). Two chromosomes are present.

Clinical strains have been reported as resistant to ampicillin, amoxicillin + clavulanic acid, aztreonam, cefamandole, cefonicid, cefoperazone, cefoxitin, cefsulodin, ceftazidime, cefuroxime, cephalothin, chloramphenicol, erythromycin, fosfomycin, kanamycin, mezlocillin, pipemidic acid, piperacillin, pristinamycin, streptomycin, and ticarcillin. Strains are said to be sensitive to amikacin, cefoperazone, ceftriaxone, ciprofloxacin, gentamicin, imipenem, netilmicin, nalidixic acid, pefloxacin, rifampicin, tetracycline, and vancomycin; most are also susceptible to moxalactam. However, different authors find different results with cefotaxime, colistin, newer fluoroquinolones, and trimethoprim-sulfamethoxazole. Monotherapy with an appropriate aminoglycoside or an appropriate β-lactam (such as ceftriaxone) has yielded a good clinical response in the treatment of bacteremia. However, despite determining *in vitro* susceptibility to imipenem in initial isolates, treatment of two patients with this agent failed to eradicate the organism (Kern et al., 1993).

In humans, *O. anthropi* has been reported from various clinical specimens, mostly as a cause of bacteremia but also of endophthalmitis, meningitis, necrotizing fasciitis, pancreatic abscess, and puncture wound osteochondritis of the foot. *O. anthropi* is apparently often community acquired and can be pathogenic in critically ill or immunocompromised patients, with or without indwelling catheters; although it can produce clinically significant infections, it appears to be of relatively low virulence. The organism has also been reported from activated sludge, biofilm in water supply lines, soil, and the termite gut. *O. intermedium* has also been isolated from human blood and soil. *O. grignonense* and *O. tritici* have so far been reported predominantly from soil and wheat roots, respectively.

Enrichment and Isolation Procedures

Special procedures are not required for the isolation of *Ochrobactrum* strains.

Maintenance Procedures

Stock cultures can be maintained for several months on a slant of Dorset egg medium (Barrow and Feltham, 1993) in a metal screw-capped bijou bottle stored at 4°C. Cultures can be maintained for longer periods by suspending growth from an 18-h-old agar slant culture in defibrinated rabbit blood, transferring to a small tube (capped or plugged), and freezing in a mixture of dry ice and alcohol prior to storage at −50°C. Strains of *Ochrobactrum* may also be preserved by lyophilization.

Procedures for Testing Special Characters

A major feature of *Ochrobactrum* strains is their motility by means of from two to several subpolar peritrichous flagella. Motility should be determined in hanging-drop preparations after overnight growth in nutrient broth, incubated at either 37°C or room temperature (18–22°C). The peritrichous nature of the flagella and their lateral attachment are best demonstrated by electron microscopy.

The saccharolytic ability of strains must be determined in a medium with either a low peptone content, such as Hugh and Leifson medium, or with no peptone, such as ammonium salt sugars. In high peptone-content media, alkali production from the peptone will mask the acid produced by oxidation of the carbohydrate.

Differentiation of the genus *Ochrobactrum* from other genera

Characteristics for the differentiation of *Ochrobactrum* from closely related and phenotypically similar genera are given in Table BXII.α.123.

Taxonomic Comments

Holmes et al. (1988) found two DNA hybridization groups among the 56 strains for which they proposed the name *O. anthropi*. The majority of strains tested grouped around the proposed type strain of the species (NCTC 12168 LMG 3331), with an average relative binding ratio of 80.5% ± 7.2%. A second, smaller group of strains formed around reference strain NCTC 12171 (= LMG 3301), with an average relative binding ratio of 87% ± 11%. Two further reference strains occupied a somewhat separate position. The two DNA hybridization groups hybridized at an average degree of relative binding of 45% ± 4%. The major hybridization group of 32 strains could be divided into biovars A and D (corresponding to the *Achromobacter* Groups A and D of Holmes and Dawson 1983). The DNA–DNA hybridization data, however, clearly demonstrated that the three strains constituting biovar D showed a high degree of DNA relatedness (≥90%) to the strains of biovar A, despite having phenotypic differences. The second DNA hybridization group of five strains contained two which formed biovar C (corresponding to the *Achromobacter* Group C of Holmes and Dawson 1983). However, the remaining three strains of the second DNA hybridization group (including LMG 3301) corresponded to biovar A, as did the two strains which occupied an intermediate hybridization position.

In summary, Holmes et al. (1988) found *O. anthropi* to be phenotypically homogeneous except for five strains; three of these represented a separate biovar but were genotypically indistinguishable from the major group of strains. *O. anthropi* was also genotypically homogeneous, except for seven strains, but only two of these could be distinguished phenotypically from the major group of strains. Holmes et al. (1988) proposed recognition of their group of strains as a single species. This view was not accepted by Velasco et al. (1998), who re-examined LMG 3301 (= NCTC 12171) and some additional strains, and found them more closely related to *Brucella* than to the group containing the type strain of *O. anthropi*, NCTC 12168 (= LMG 3331). The two groups could be differentiated by 16S rRNA gene sequence analysis and by 16S rRNA PCR with *Brucella*-specific primers. It was specifically recommended that distinct genomic groups not be proposed as named species until adequate phenotypic characters for differentiation from related genomic groups (Wayne et al., 1987) are available. Despite the fact that the two groups differed only in susceptibility to colistin, Velasco et al. (1998) considered this sufficient to propose a separate species, *O. intermedium*, for the group containing LMG 3301 (= NCTC 12171).

Subsequently, Lebuhn et al. (2000) studied isolates of *Ochrobactrum* from soil samples and wheat roots. They described two new species, *O. grignonense* and *O. tritici*, and found additional phenotypic characters to distinguish *O. intermedium* from *O. anthropi*. They also countenanced the future transfer of *O. intermedium* to a new genus, in order to yield monophyletic lineages that correspond to results from genotyping.

Differentiation of the species of the genus *Ochrobactrum*

Phenotypic differentiation among the four named species of *Ochrobactrum* is given in Table BXII.α.124.

List of species of the genus Ochrobactrum

1. **Ochrobactrum anthropi** Holmes, Popoff, Kiredjian and Kersters 1988, 412[VP]
an.thro′pi. Gr. n. *anthropos* a human being; N.L. gen. n. *anthropi* of a human being.

The characteristics are as described for the genus. Additional characteristics are listed in Table BXII.α.125. The species was originally divided into three biovars A, C, and D, corresponding to the *Achromobacter* groups A, C, and D, respectively, of Holmes and Dawson (1983). On genomic grounds, however, only biovars A and D can be retained for *O. anthropi*; strains of biovar A differ from those of biovar D in producing acid from adonitol and sucrose, also in failing to utilize L-arabitol.

The mol% G + C of the DNA is: 56–59 (T_m).

Type strain: NCTC 12168, CIP 82.11, CIP 14970, DSM 6882, IAM 14119, LMG 3331.

GenBank accession number (16S rRNA): D12794.

2. **Ochrobactrum grignonense** Lebuhn, Achouak, Schloter, Berge, Meier, Barakat, Hartmann and Heulin 2000, 2221[VP]
gri.gno.nen′se. Fr. n. *Grignon* a location in France; L. neut. suff. *-ense* indicating provenance; N.L. neut. adj. *grignonense* pertaining to Grignon, region from which the strains were isolated.

The characteristics are as described for the genus. Additional characteristics are listed in Table BXII.α.125. The principal diagnostic phenotypic characteristics of *O. grignonense* are production of acid from arabinose and melibiose, assimilation of mannose but not maltose, and utilization of malonic acid but not adonitol or D-glucosaminic acid.

The mol% G + C of the DNA is: 58 (T_m).

Type strain: OgA9a, LMG 18954, DSM 13338.

GenBank accession number (16S rRNA): AJ242581.

3. **Ochrobactrum intermedium** Velasco, Romero, López-Goñi, Leiva, Díaz and Moriyón 1998, 767[VP]
in′ter.me′dium. L. neut. adj. *intermedium* of intermediate position.

The characteristics are as described for the genus. Additional characteristics are listed in Table BXII.α.125. There are few phenotypic tests to differentiate *O. intermedium* from *O. anthropi*, but strains of the former are said to differ from those of the latter in being resistant to both colistin and polymyxin B, in failing to produce urease, and in failing to utilize quinic acid.

The mol% G + C of the DNA is: 58 (T_m).

Type strain: NCTC 12171, LMG 3301.

GenBank accession number (16S rRNA): U70978.

4. **Ochrobactrum tritici** Lebuhn, Achouak, Schloter, Berge, Meier, Barakat, Hartmann and Heulin 2000, 2222[VP]
tri′ti.ci. M.L. gen. n. *tritici*, from *Triticum*, generic name for wheat, from which the strains were isolated.

The characteristics are as described for the genus. Additional characteristics are listed in Table BXII.α.125. The principal diagnostic phenotypic characteristics of *O. tritici* are assimilation of gluconate, and utilization of sebacic acid but not γ-hydroxybutyric acid.

The mol% G + C of the DNA is: 59 (T_m).

Type strain: SCII24, LMG 18957, DSM 13340.

GenBank accession number (16S rRNA): AJ242584.

Family IV. **Phyllobacteriaceae** *fam. nov.*

JORIS MERGAERT AND JEAN SWINGS

Phyl.lo.bac.teri.a′ce.ae. M.L. neut. n. *Phyllobacterium* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Phyllobacteriaceae* the *Phyllobacterium* family.

Rod-shaped, ovoid, or reniform cells when cultured *in vitro*. **Nonsporeforming. Gram negative. Aerobic.** Cells cultured *in vitro* are motile by means of polar, subpolar, or lateral flagella. Strains grow well on complex solid media at 28°C. **Occur in leaf nodules and the rhizosphere of higher plants.**

The mol% G + C of the DNA is: 60–62 (De Smedt and De Ley, 1977).

Type genus: **Phyllobacterium** (ex Knösel 1962) Knösel 1984b, 356 (Effective publication: Knösel 1984a, 254.)

TAXONOMIC COMMENTS

The family presently contains seven genera. Based on 16S rRNA gene sequence analysis the type genus, *Phyllobacterium*, is closely related phylogenetically to the genus *Mesorhizobium*. Together these genera form a separate branch in the *Alphaproteobacteria* and are phylogenetically related to the genera *Rochalimaea*, *Mycoplana*, *Bartonella*, *Rhizobium*, *Agrobacterium*, *Sinorhizobium*, *Allorhizobium*,* *Ochrobactrum*, and *Brucella* (Yanagi and Yamasato, 1993; de Lajudie et al., 1994, 1998a, b; Jarvis et al., 1997). Apart from 16S rRNA gene similarities, there are as yet no other arguments available to unite the genera *Mesorhizobium* and *Phyllobacterium* in a single family. Both genera are very different, not only on the basis of habitat, plant interactions, and biochemical characteristics, but also chemotaxonomically. By analysis of total cellular fatty acid composition, the genera *Phyllobacterium*, *Mesorhizobium*, and members of the *Agrobacterium–Rhizobium–Sinorhizobium* group form clearly separated entities, as exemplified in Fig. BXII.α.141 (see also Table BXII.α.126, and Jarvis et al., 1996). Unlike *Mesorhizobium* and other rhizobia, *Phyllobacterium* shows no evidence of nitrogen fixation (Lersten and Horner, 1976; Van Hove, 1976), and the genus lacks the *nif* HFK-like genes (Lambert et al., 1990), which occur in all the classical nitrogen-fixing bacteria.

Some differential features permitting differentiation of *Phyllobacterium* and *Mesorhizobium* are given in Table BXII.α.126.

*Editorial Note: *Allorhizobium* has been moved to the family *Rhizobiaceae* and is no longer listed in *Phyllobacteriaceae*.

JORIS MERGAERT AND JEAN SWINGS

Phyl.lo.bac.te' ri.um. Gr. n. *phyllos* leaf; Gr. dim. neut. n. *bakterion* a small rod; M.L. neut. n. *Phyllobacterium* leaf bacterium.

Cells cultured *in vitro* are **rod-shaped, ovoid, or reniform**. Clumping and/or **star formation** occurs when cells are grown in carrot juice medium. **Gram negative. Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Cultures are **motile** by means of polar, subpolar, or lateral flagella. Optimal temperature for growth, 28–34°C. After 1–2 days of incubation on nutrient agar, *Phyllobacterium* colonies are whitish-gray, punctiform or circular, with a colony diameter of <1 mm, and regularly edged. Most cultures are mucoid and confluent. After 4 d, colonies reach a maximum diameter of 4 mm. **Oxidase and catalase positive. Chemoorganotrophic**, using a variety of sugars or salts of organic acids as carbon sources. Do not hydrolyze starch, pectin or cellulose. **Occur in leaf nodules and the rhizosphere of higher plants.**

The mol% G + C of the DNA is: 60.3–61.3 (De Smedt and De Ley, 1977).

Type species: **Phyllobacterium myrsinacearum** (ex Knösel 1962) Knösel 1984b, 356 (Effective publication: Knösel 1984a, 254) (*Phyllobacterium rubiacearum* Knösel 1984a, 254.)

FURTHER DESCRIPTIVE INFORMATION

Phyllobacterium within leaf nodules of plants develop into pleomorphic cells that are rod shaped, ellipsoidal, or branched (Fig. BXII.α.142). In liquid media, especially in carrot juice medium[1], the cells appear as motile, straight rods, which form characteristic star clusters (Fig. BXII.α.143) after an initial phase of intensive swimming.

The maximum temperature at which growth occurs is 36°C; the minimum is 4–5°C. Cells heated in saline are killed within 10 min at 52°C.

Whole-cell fatty acid extracts of cells grown on modified TY medium[2] are composed of mainly octadecenoic acids ($C_{18:1}$) and cyclopropaneoctadecanoic acid ($C_{19:0\ cyclo}$), lower amounts of hydroxylated straight-chain fatty acids ($C_{16:0\ 3OH}$ and $C_{18:1\ 2OH}$) and hexadecanoic acid ($C_{16:0}$), and minor amounts of other fatty acids.

Acid is produced from a wide range of carbohydrates without gas formation: pentoses, hexoses, maltose, inulin, glycerol, adonitol, sorbitol, and dulcitol. Starch, pectin, and cellulose are not hydrolyzed. Ammonium salts, nitrates, and most amino acids can serve as nitrogen sources. Strains may or may not reduce nitrate to nitrite.

Growth of *Phyllobacterium* is inhibited by deoxycycline, novobiocin, framycetin, and tetracycline (Lambert et al., 1990). Sensitivity towards the rhizobial peptide antibiotic trifolitoxin has been reported (Triplett et al., 1994).

Although over 400 plant species of three genera of Rubiaceae and one genus of Myrsinaceae have been reported to have bacterial leaf nodules (see Lersten and Horner, 1976), *Phyllobacterium* has been isolated by Knösel (1962) only from *Pavetta zimmermanniana* (Rubiaceae), *Ardisia crispa*, and *Ardisia crenata* (Myrsinaceae). Although Knösel (1984a) has stated that *Phyllobacterium* is able to induce nodules on leaves, there is still no proof for the leaf nodulation capacity of *Phyllobacterium* (Swings et al., 1992), despite more than a century of research on leaf nodulation (reviewed by Lersten and Horner, 1976).

It has been suggested that leaf-nodule bacteria produce plant growth hormones, particularly cytokinins, which are necessary for the normal function of the plant (Rodrigues-Pereira et al., 1972; Fletcher and Rhodes-Roberts, 1976). The auxin indolyl-3-acetic acid has been isolated from the growth medium of a *Phyllobacterium* strain (Lambert et al., 1990).

It has long been claimed that leaf-nodule bacteria can fix nitrogen, but this has been contested by Van Hove (1976) and Lersten and Horner (1976). The lack of the ability to fix nitrogen is also indicated by the absence of the *nif* HFK-like genes (Lam-

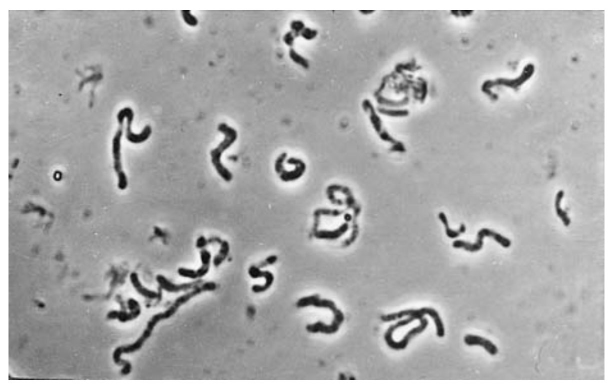

FIGURE BXII.α.142. Phase-contrast photomicrograph showing bacteroids of *Phyllobacterium myrsinacearum* (synonym *Phyllobacterium rubiacearum*) from leaf nodules of *Pavetta zimmermanniana* (× 2000).

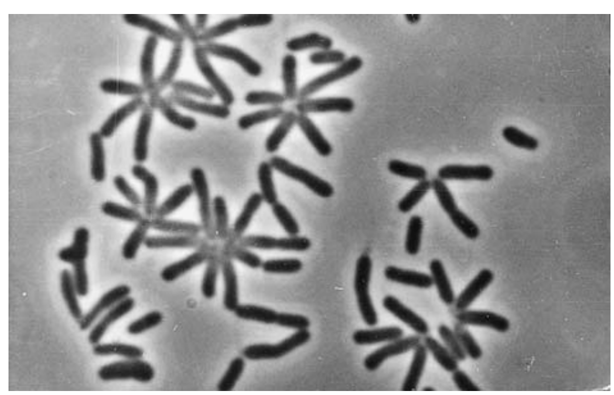

FIGURE BXII.α.143. Phase-contrast photomicrograph showing star clusters of cells of *Phyllobacterium myrsinacearum* (synonym *Phyllobacterium rubiacearum*) in carrot juice medium after incubation at 28°C for 24 h (× 2000)

1. Carrot juice medium has the following composition: fresh carrot juice, 500 ml; water, 500 ml; $FeSO_4 \cdot 7H_2O$, 0.1 g; $MnSO_4 \cdot H_2O$, 0.1 g; pH 7.2. The medium is sterilized by fractional sterilization. For a solid medium, add 15.0 g/l agar. (Knösel, 1984a).

2. According to the methods described by Jarvis et al. (1996) and Sasser (1990a).

bert et al., 1990), which occur in all the classical nitrogen-fixing bacteria.

Phyllobacterium is able to interact with plant tissues, as demonstrated by the tumor induction on *Kalanchoe* plants by a Ti plasmid-carrying *Phyllobacterium* strain (Lambert et al., 1990). Tumor induction involves the attachment of bacterial cell wall sites to plant cell wall sites prior to the induction of T-DNA transfer. The chromosomal genes *chv*A, *chv*B, *exo*C, and *att* are the only ones found to be involved in attachment, but these cannot be detected in *Phyllobacterium* strains, suggesting that other genes with similar functions are present. There are no data indicating that *Phyllobacterium* is pathogenic or deleterious to plants.

A number of *Phyllobacterium* isolates show antifungal and antibacterial activities (Lambert et al., 1990). The fact that *Phyllobacterium* is a predominant bacterium on the root surface of sugar beet plant tissues, its capacity to communicate with plant tissues, and its nonpathogenic status make this bacterium an interesting new candidate for use in plant-growth promotion or biological control of soil-borne diseases. Indeed, some of the sugar beet isolates exert broad antibacterial and antifungal activity (Lambert et al., 1990). It has also been shown that a *Phyllobacterium* strain is able to reduce the symptoms of vascular *Fusarium* wilt when artificially introduced in seedlings of cotton plants prior to inoculation with *Fusarium oxysporum* f. sp. vasinfectum (Chen et al., 1995a).

Enrichment and Isolation Procedures

To isolate strains from leaf nodules, Knösel (1984a) used the following procedure. Washed leaf pieces showing nodules are macerated by rubbing and placed in saline. After shaking, dilutions are plated onto carrot juice agar containing yeast extract. After incubation at 28°C, typical colonies are transferred into liquid carrot juice medium for micromorphological characterization. The cultures should be observed by phase-contrast microscopy after 24–48 h to confirm the presence of star clusters (Fig. BXII.α.143).

Lambert et al. (1990) described a procedure for isolating strains from the rhizosphere of sugar beets. The entire root system of the plant is carefully washed to remove adhering soil, then vigorously shaken for 15 minutes using a flask shaker in a phosphate-buffered saline solution containing 0.025% Tween 20. Serial dilutions of the resulting suspensions are plated on 10% trypticase soy agar. After 2 d incubation at 28°C, *Phyllobacterium* colonies are beige-colored, ~5 mm large, convex with entire margins, and very mucoid and glistening.

To extract vascular sap from cotton plants for the subsequent isolation of *Phyllobacterium*, the use of the Scholander pressure bomb has been shown to be a successful technique (Hallmann et al., 1997).

Maintenance Procedures

Stock cultures on trypticase soy agar or nutrient agar may be maintained at 4°C for 2–3 months. Long-term preservation can be achieved by lyophilization or by storing cell suspensions in 25% glycerol at −70°C (Swings et al., 1992).

Differentiation of the genus *Phyllobacterium* from other genera

The genus *Phyllobacterium* is phenotypically most similar to the genus *Ochrobactrum* (Swings et al., 1992). *Phyllobacterium* is isolated from plants or the rhizosphere, whereas *Ochrobactrum* is typically of clinical origin. Table BXII.α.127 shows useful characteristics for the differentiation of the two genera from each other.

Taxonomic Comments

The genus *Phyllobacterium* was originally restricted to bacteria that develop within leaf nodules of the tropical ornamental plants. Two species, *Phyllobacterium myrsinacearum* (from *Ardisia* leaf nodules) and *Phyllobacterium rubiacearum* (from *Pavetta* leaf nodules), have been defined on the basis of plant source, nitrate reduction, and flagellar characteristics. However, conflicting results have been obtained with regard to the nitrate-reduction capability by Lambert et al. (1990). It has become evident that the natural habitat of these bacteria is not limited to leaf nodules, and that these microorganisms are also very common on the rhizoplane and phylloplane of other plants (including sugar beet roots and *Polymnia* leaves) and in roots of cotton plants (Lambert et al., 1990; Hashidoko et al., 1994; Chen et al., 1995a; Hallmann et al., 1997). The phyllobacteria from *Ardisia*, *Pavetta*, and sugar beet roots are phenotypically very similar (Lambert et al., 1990) and the 16S rRNA sequences of the type strains of *P. myrsinacearum* and *P. rubiacearum* differ from each other by only 2 nucleotides (Yanagi and Yamasato, 1993). The sugar beet isolates show whole-cell protein-electrophoretic patterns almost identical to those of the type strain of *P. rubiacearum* and very similar to those of *P. myrsinacearum* strains (Lambert et al., 1990). Strains from these three different habitats also show very similar fatty acid compositions (see Fig. BXII.α.141 in *Phyllobacteriaceae*). DNA pairing data are not available to draw definite conclusions about speciation within the genus. Based upon their phenotypic and chemotaxonomic resemblance and for practical reasons of identification, all the phyllobacteria are united here within a single species, *Phyllobacterium myrsinacearum* (subjective synonym *Phyllobacterium rubiacearum*) (Mergaert et al., 2002).

Genus II. **Aminobacter** Urakami, Araki, Oyanagi, Suzuki and Komagata 1992, 90[VP]

TEIZI URAKAMI

Am.i.no.bac'ter. M.L. n. *aminum* amine; M.L. n. *bacter* rod, staff; M.L. masc. n. *Aminobacter* amine rod.

Rods, 0.5–0.9 × 1.0–3.0 μm, with rounded ends. Occur singly (rarely in pairs). Motile by means of subpolar flagella. Nonsporeforming. Gram negative. **Reproduction occurs by budding.** Poly-β-hydroxybutyrate granules are accumulated in the cells. Colonies are white to light yellow. Aerobic, having a strictly respiratory type of metabolism. Cells grow abundantly in nutrient broth and PYG broth. No water-soluble florescent pigment is produced. Methyl red and Voges–Proskauer negative. Indole and H_2S are not produced. Gelatin and starch are not hydrolyzed. **Ammonia is produced.** Denitrification does not occur. Litmus milk is not changed. Acids are produced from sugars oxidatively but not fermentatively. Monomethylamine, trimethylamine, trimethylamine-*N*-oxide, and sugars are utilized as carbon sources. Methanol, methane, and hydrogen are not utilized. Growth factors are not required. Ammonia, nitrate, urea, peptone, and methylamine are utilized as nitrogen sources. Oxidase and catalase positive. Urease negative. Good growth occurs between pH 6.0 and 8.0. No growth above pH 9.0 or below pH 5.0. Good growth occurs at 30 and 37°C; no growth at 42°C. No growth in the presence of 3% NaCl. The cellular fatty acids include a large amount of straight-chain, unsaturated $C_{18:1}$ acid. The hydroxy acids include a large amount of $C_{12:0\ 3OH}$. The ubiquinone system is ubiquinone Q-10.

The mol% G + C of the DNA is: 62–64.

Type species: **Aminobacter aminovorans** (den Dooren de Jong 1926) Urakami, Araki, Oyanagi, Suzuki and Komagata 1992, 90 (*Pseudomonas aminovorans* den Dooren de Jong 1926, 161.)

Enrichment and Isolation Procedures

Aminobacter strains are isolated from soils at 30°C by the enrichment culture technique, using methylamine compounds or methylformamide compounds (Urakami et al., 1990a, c). Monomethylamine, dimethylamine, trimethylamine, trimethylamine-*N*-oxide, and tetramethylammonium (TMAH) are used as methylamine compounds and *N*-methylformamide and *N,N*-dimethylformamide (DMF) are used as methylformamide compounds.

Maintenance Procedures

Working stock cultures should be transferred every 7 d to ensure viability. This requirement for frequent transfer appears to be independent of the type of maintenance medium or temperature of storage. Stock strains may be preserved indefinitely by lyophilization in 10% skim milk. Strains may also be preserved for at least 5 years by storage at −70°C in glycerol–PYG broth (PYG broth supplemented with 15% glycerol). Organisms are cultivated approximately 24 h in PYG broth medium, and glycerol is added to culture broth (final glycerol concentration, 15%). 1.0 ml of dense suspension of organisms is transferred to an autoclaved half-dram vial and stored in a −70°C freezer.

Procedures for Testing Special Characters

Acid production from carbohydrates Hugh and Leifson oxidation–fermentation basal medium (Difco) is used with each of the carbohydrates. The carbohydrates (5 g/l) are added aseptically to the autoclaved, cooled basal medium from a 10% stock solution that has been sterilized by filtration.

The GasPak™ anaerobic system is used for anaerobic conditions. Acidification of the media is investigated up to 4 weeks.

Urease, oxidase, and catalase test Urease activity is determined on Christensen medium incubated for 7 d. The oxidase test is performed with cytochrome oxidase test paper (Nissui Seiyaku, Tokyo, Japan). Catalase activity is detected by the production of bubbles upon addition of a 3% hydrogen peroxide solution to cultures grown on agar slants of PYG medium, which consists of 0.5% peptone, 0.5% yeast extract, and 0.5% glucose (pH 7.0).

Utilization of carbon compounds Utilization of carbon compounds is carried out at a concentration of 0.15% (w/v). Utilization of methane is tested under an atmosphere containing $CH_4/O_2/CO_2$ (5:4:1) with a rotary shaker in a tightly stopped conical flask containing carbon compound-free medium. Utilization of hydrogen is tested in the same manner, but in an atmosphere containing $H_2/O_2/CO_2$ (8:1:1).

Differentiation of the genus *Aminobacter* from other genera

The minimal characteristics for differentiating the genus *Aminobacter* from related genera are shown in Table BXII.α.129.

Aminobacter strains resemble *Blastobacter aggregatus* and *Blastobacter denitrificans* in motility and colony pigmentation, but are differentiated from *B. aggregatus* on the basis of acid production from mannitol under aerobic conditions, utilization of ethanol and succinic acid, tolerance of NaCl, and DNA base composition, and from *B. denitrificans* on the basis of acid production from mannitol under aerobic conditions, utilization of methanol, ethanol, and sucrose, tolerance of NaCl, and denitrification (Hirsch and Muller, 1985; Urakami et al., 1992).

Aminobacter strains resemble *Hyphomicrobium* strains in that they are nonpigmented, Gram-negative, methylamine-utilizing bacteria that metabolize C_1 compounds via the serine pathway (Bellion and Hersh, 1972; Wagner and Lecvitch, 1975). However, *Aminobacter* strains are distinguished from *Hyphomicrobium* species based on formation of hyphae, utilization of methanol and carbohydrates, quinone system, and hydroxy acid composition (Hirsch, 1984; Urakami and Komagata, 1986b, 1987a, b).

Taxonomic Comments

In his classical work, den Dooren de Jong (1926) isolated from soil enrichments with various amines (methylamine, trimethylamine, tetramethylammonium (TMAH), ethylamine, and ethylurea) a group of organisms, among which seven strains were placed in the genus *Pseudomonas*. den Dooren de Jong created the name *Pseudomonas aminovorans* for the group because of the ability of the strains to utilize various amines as sole carbon and energy sources. *Pseudomonas aminovorans*, which is a typical species of methylamine-utilizing bacteria, was included in Section V in *Bergey's Manual of Systematic Bacteriology* (Palleroni, 1984) with other *Pseudomonas* species whose natural relationships were unknown. These methylamine-utilizing bacteria were distinguished clearly from genus *Pseudomonas sensu stricto*, i.e., from the *Pseudomonas fluorescens* rRNA branch (De Vos et al., 1989), by the following characteristics: motility by subpolar flagella, multipli-

cation by budding (Green and Gillis, 1989), utilization of methylamine, quinone system, cellular fatty acid composition, hydroxy fatty acid composition, DNA–DNA hybridization, and rRNA–DNA hybridization (De Ley et al., 1987; De Vos et al., 1989).

De Ley et al. (1987) studied the rRNA cistron similarities of *Pseudomonas* and *Pseudomonas*-like strains and reported that the type strain of *Pseudomonas aminovorans* was actually a member of the *Rhizobium loti* rRNA branch, not of the genus *Pseudomonas*. Furthermore, Green and Gillis (1989) pointed out the phenotypic resemblance between *Pseudomonas aminovorans* strains and the genus *Blastobacter*, which contains heterotrophic, rod-shaped, budding bacteria that do not fix nitrogen.

In 1990, the tetramethylammonium (THAH)-utilizing strain TH-3 of Urakami et al. (1990a) and the *N,N*-dimethylformamide (DMF)-utilizing strain DM-81 of Urakami et al. (1990c) were isolated and found to resemble *P. aminovorans*. Urakami et al. (1992) studied the chemotaxonomic characteristics of five methylamine-utilizing bacteria, including strains TH-3 and DM-81, and proposed the transfer of these strains and *Pseudomonas aminovorans* to a new genus, *Aminobacter*. *Pseudomonas aminovorans* became *Aminobacter aminovorans*, and two additional species were created: *Aminobacter aganoensis* for strain TH-3^T and *Aminobacter niigataensis* for strain DM-81^T.

Although *Aminobacter* is actually a member of the *Rhizobium loti* rRNA branch as determined by rRNA–DNA hybridization (Jarvis et al., 1986; De Ley et al., 1987), it can be differentiated from *R. loti sensu stricto* on the basis of the viscosity of the colonies, utilization of methylamine, production of extracellular gum (Jordan, 1984b), hydroxy fatty acid composition (Yokota, 1989), and rRNA–DNA hybridization data (De Ley et al., 1987; De Vos et al., 1989). In addition, the failure of representative *Aminobacter* strains to reduce acetylene has been described by Green and Gillis (1989). Furthermore, these methylamine-utilizing bacteria have been isolated from soils enriched with various amines, which serve as sole carbon and energy sources.

Differentiation of the species of the genus *Aminobacter*

Characteristics useful in differentiation of the species of *Aminobacter* are listed in Table BXII.α.130.

List of species of the genus Aminobacter

1. **Aminobacter aminovorans** (den Dooren de Jong 1926) Urakami, Araki, Oyanagi, Suzuki and Komagata 1992, 90^VP (*Pseudomonas aminovorans* den Dooren de Jong 1926, 161.)
am.i.no' vo.rans. M.L. n. *aminum* amine; L. v. *voro* to devour; L. part. adj. *aminovorans* amine-devouring, digesting.

The characteristics are as described for the genus and as given in Tables BXII.α.129 and BXII.α.130. In addition, it has the following characteristics. Growth occurs in peptone water. Nitrate is not reduced to nitrite. Acids are produced oxidatively from L-arabinose, D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, maltose, sucrose, trehalose, D-sorbitol, D-mannitol, inositol, and glycerol. No acid production from lactose or soluble starch. Carbon sources for growth include L-arabinose, D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, maltose, sucrose, trehalose, D-sorbitol, D-mannitol, inositol, glycerol, succinic acid, acetic acid, monomethylamine, trimethylamine, and trimethylamine-*N*-oxide. Lactose, soluble starch, citric acid, formic acid, ethanol, methanol, dimethylamine, formamide, *N*-methylformamide, DMF, TMAH, methane, and H_2 are not utilized.

The type strain was isolated from soil enrichments containing various amines by de Dooren de Jong in 1926.

The mol% G + C of the DNA is: 62.5 (HPLC).

Type strain: ATCC 23314, DSM 7048, JCM 7852, NCIB 9039, NCTC 10684.

GenBank accession number (16S rRNA): AJ011759.

Additional Remarks: Reference strain MS, ATCC 23819, NCIB 11591.

2. **Aminobacter aganoensis** Urakami, Araki, Oyanagi, Suzuki and Komagata 1992, 91^VP
a.ga.no.en' sis. M.L. masc. adj. *aganoensis* coming from the Agano River, Niigata, Japan.

The characteristics are as described for the genus and as given in Tables BXII.α.129 and BXII.α.130. In addition, it has the following characteristics. Poor growth occurs in peptone water. Nitrate is weakly reduced to nitrite. Acids are produced oxidatively from D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, maltose, sucrose, trehalose, D-sorbitol, D-mannitol, inositol, and glycerol. Weak acid production from D-glucose, D-mannose, maltose, sucrose, trehalose, D-sorbitol, D-mannitol, and inositol. No acid production from L-arabinose, lactose, or soluble starch. L-Arabinose, D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, maltose, sucrose, trehalose, D-sorbitol, D-mannitol, inositol, glycerol, succinic acid, acetic acid, monomethylamine, dimethylamine, trimethylamine, trimethylamine-*N*-oxide, and TMAH are utilized as carbon sources. Acetic acid is utilized weakly. Lactose, soluble starch, citric acid, formic acid, ethanol, methanol, formamide, *N*-methylformamide, DMF, methane, and H_2 are not utilized.

The mol% G + C of the DNA is: 63.8 (HPLC).

Type strain: Strain TH-3, DSM 7051, JCM 7854.

GenBank accession number (16S rRNA): AJ011760.

3. **Aminobacter niigataensis** Urakami, Araki, Oyanagi, Suzuki and Komagata 1992, 91^VP
ni.i.ga.ta.en' sis. M.L. masc. adj. *niigataensis* coming from the Niigata region of Japan.

The characteristics are as described for the genus and as given in Tables BXII.α.129 and BXII.α.130. In addition, it has the following characteristics. Poor growth occurs in peptone water. Nitrate is weakly reduced to nitrite. Acid is produced oxidatively from D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, maltose, sucrose, trehalose, D-sorbitol, D-mannitol, inositol, and glycerol. No acid production from L-arabinose, lactose, or soluble starch. L-arabinose, D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, maltose, sucrose, trehalose, D-sorbitol, D-mannitol, inositol, glycerol, succinic acid, acetic acid, monomethylamine, dimethylamine, trimethylamine, trimethylamine-*N*-oxide, *N*-methylformamide, and DMF are utilized as carbon sources. Formamide is utilized weakly. Lactose, soluble starch, citric acid, formic acid, ethanol, methanol, TMAH, methane, and H_2 are not utilized.

The type strain was isolated as a DMF-utilizing bacterium from soil by Urakami et al. (1990c).

The mol% G + C of the DNA is: 63.2 (HPLC).

Type strain: Strain DM-81, DSM 7050, JCM 7853.

GenBank accession number (16S rRNA): AJ011761.

Genus III. Aquamicrobium *Bambauer, Rainey, Stackebrandt and Winter 1998b, 631^VP (Effective publication: Bambauer, Rainey, Stackebrandt and Winter 1998a, 300)*

THE EDITORIAL BOARD

A.qua.mi.cro' bi.um. L. n. *aqua* water; L. n. *microbium* a microbe; *Aquamicrobium* a bacterium living in water/wastewater.

Gram negative, pleomorphic or regularly formed short **rods**. Motile or nonmotile. Respiratory metabolism using either O_2 or nitrate under anoxic conditions. **Nitrate reduced to nitrite or N_2.** Mesophilic. Optimal pH 6–9. Salt tolerant, up to 3% NaCl. Utilize sugars, fatty acids, and heterocyclic aromatic compounds as carbon sources. Utilize nitrate or O_2 as electron acceptors.

The mol% G + C of the DNA is: 59–65.

Type species: **Aquamicrobium defluvii** Bambauer, Rainey, Stackebrandt and Winter 1998b, 631 (Effective publication: Bambauer, Rainey, Stackebrandt and Winter 1998a, 300.)

ENRICHMENT AND ISOLATION PROCEDURES

Aquamicrobium defluvii strain NKK was isolated from activated sewage sludge, using thiophene-2-carboxylate as the sole carbon source and nitrate as the electron acceptor, as described in Bambauer et al. (1998a). Sludge (10% v/v) was added to mineral salts medium containing 2 mM thiophene-2-carboxylate and 10 mM nitrate. The enrichment culture was incubated at 37°C for 3 weeks, and 1 ml was transferred to fresh medium. Pure cultures were obtained after several transfers.

List of species of the genus Aquamicrobium

1. **Aquamicrobium defluvii** Bambauer, Rainey, Stackebrandt and Winter 1998a, 631[VP] (Effective publication: Bambauer, Rainey, Stackebrandt and Winter 1998a, 300.)
de.flu′vi.i. M.L. neut. n. *defluvium* wastewater; *defluvii* from waste water.

Gram-negative rods, 0.5–0.8 × 1.5–2.5 μm. Motile. Do not form spores. Catalase and oxidase positive. Colonies are white, circular, convex, 2–4 mm in diameter after 3–5 d. Optimal temperature 30–37°C. Optimal pH 7.5–8.5. Growth occurs at 41°C and with 2% NaCl. Vitamins required for growth. Respiratory metabolism with O_2 or nitrate as electron acceptors. Nitrate reduced to nitrite. Chemoorganotrophic, utilizing thiophene-2-carboxylate, acetate, propionate, butyrate, crotonate, glucose, fructose, mannose, xylose, mannitol, and sorbitol as carbon sources.

The mol% G + C of the DNA is: 61.7.

Type strain: NKK, CIP 105610, DSM 11603.

GenBank accession number (16S rRNA): Y15403.

Genus IV. Defluvibacter *Fritsche, Auling, Andreesen and Lechner 1999b, 1325[VP] (Effective publication: Fritsche, Auling, Andreesen and Lechner 1999a, 202)*

THE EDITORIAL BOARD

De.flu.vi.bac′ter. M.L. n. *defluvium* waste water; Gr. hyp. masc. n. *bacter* rod; M.L. masc. n. *Defluvibacter* referring to its origin from activated sludge of a waste water treatment plant.

Gram-negative **rods**, occurring as single cells. Motile. **Strictly aerobic.** Oxidase and catalase positive. Does not reduce nitrate. Utilizes the following carbohydrates: D-glucose, D-fructose, D-mannose, D-ribose, D-xylose, and L-lyxose. Some amines and amino acids used as carbon sources. **Major ubiquinone is ubiquinone 10.** Major fatty acid is $C_{18:1}$. $C_{12:0\ 3OH}$ is present in small amounts. Spermidine is the major polyamine. The genus belongs in the *Alphaproteobacteria* and is most closely related to *Pseudaminobacter*, *Mesorhizobium*, and *Phyllobacterium*.

Type species: **Defluvibacter lusatiensis** Fritsche, Auling, Andreesen and Lechner 1999b, 1325 (Effective publication: Fritsche, Auling, Andreesen and Lechner 1999a, 202)

List of species of the genus Defluvibacter

1. **Defluvibacter lusatiensis** Fritsche, Auling, Andreesen and Lechner 1999b, 1325[VP] (Effective publication: Fritsche, Auling, Andreesen and Lechner 1999a, 202)
lu.sa.ti.en.sis. M.L. gen. n. *lusatiae* referring to the German province of Lausitz (Latin name *Lusatia*), where the organism was isolated.

Short rods, 0.6–0.8 × 1.5–3 μm, occurring singly. Motile by means of a single polar flagellum. Do not form spores. Colonies are grayish white, circular, and mucoid, with a diameter of 2 mm after 2 d on nutrient agar. Can reach 4 mm after prolonged incubation. Optimal temperature 30–37°C (range 12–44°C). Optimal pH 7.0–7.7 (range 6.0–9.2). Grows in peptone medium. Does not form indole. Does not hydrolyze urea, starch, gelatin, casein, DNA, Tween 80, or esculin. Utilization of carbohydrates requires yeast extract or growth factors. Carbohydrates utilized are DL-α-amino-*n*-valerate, putrescine, L-tryptophan, malonate, glutarate, and 2-ketoglutarate. Can utilize the following as carbon sources: 4-chloro-2-methylphenol, 2,4-dichlorophenol, and 4-chlorophenol. Phenol is degraded by a different set of enzymes. Does not degrade benzoate, *m*- and *p*-hydroxybenzoate, 3,4-dihydroxybenzoate, gentisate (2,5-dihydroxybenzoate), and phenylacetate. Isolated from activated sludge of an industrial waste water plant at Schwarzheide.

The mol% G + C of the DNA is: 61.4.

Type strain: S1, CIP 106844, DSM 11099.

GenBank accession number (16S rRNA): AJ132378.

Genus V. ***Candidatus*** **Liberibacter** *Jagoueix, Bové and Garnier 1994, 385 (Candidatus* Liberobacter *(sic) Jagoueix, Bové and Garnier 1994, 385)*

MONIQUE GARNIER

Li.be.ri′bac.ter. L. n. *liber* phloem; Gr. n. *bakterion* a small rod; N.L. masc. n. *Liberibacter* rod in the phloem.

Filamentous bacteria occurring in the phloem sieve tubes of plants (Fig. BXII.α.146). Round forms are also observed but have been shown to correspond to degenerating bacteria. The bacteria are also present in the hemolymph and salivary glands of insect vectors (Psyllidae) responsible for the transmission. Like most phloem-restricted bacteria, *Candidatus* Liberibacter spp. have resisted *in vitro* cultivation (Garnier and Bové, 1993). The characterized species originated from sweet orange (*Citrus sinensis*). The original description is based on bacteria present in the phloem sieve tubes of sweet orange trees affected by huanglongbing (ex. greening disease) in Poona (India) and Nelspruit (South Africa).

Type species: *Candidatus* Liberibacter asiaticus Jagoueix, Bové and Garnier 1994, 385 (*Candidatus* Liberobacter asiaticum (sic) Jagoueix, Bové and Garnier 1994, 385.)

Further descriptive information

Phylogenetic treatment Phylogenetic analyses of the 16S rRNA gene indicated *Candidatus* Liberibacter spp. belong to the *Alphaproteobacteria*; their closest cultivated relatives are members of the group of bacteria known as the alpha-2 subgroup belonging to the genera *Bartonella*, *Bradyrhizobium*, *Agrobacterium*, *Brucella*, and *Afipia* (Fig. BXII.α.147) (Jagoueix et al., 1994).

Based on sequence comparisons of ribosomal protein genes of the beta operon, and on biological properties, two species have been recognized: *Candidatus* Liberibacter asiaticus and *Candidatus* Liberibacter africanus.

Strain morphology Electron microscopy measurements on thin sections show that the filamentous forms of the liberibacteria have a diameter of 0.2–0.3 µm. Variations in diameter occur between organisms and sometimes within a single organism. Round forms are larger (0.5 µm) with a less dense cytoplasm and often show plasmolysis (Figs. BXII.α.146 and BXII.α.148). The *Candidatus* Liberibacter spp. envelope is a membranous wall characteristic of Gram-negative bacteria (Fig. BXII.α.149), but the peptidoglycan layer is hardly visible (Garnier et al., 1984). There is no evidence for flagella or pili. *Candidatus* L. asiaticus and *Candidatus* L. africanus cannot be distinguished on the basis of morphology.

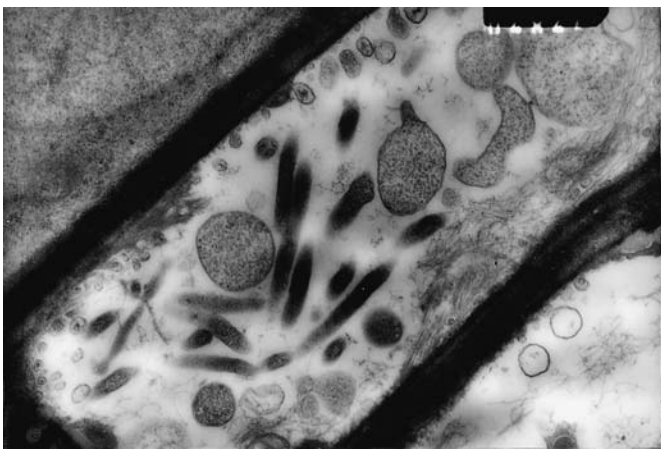

FIGURE BXII.α.146. *Candidatus* Liberibacter cells in a phloem sieve tube of huanglongbing-affected sweet orange leaves (× 12,000).

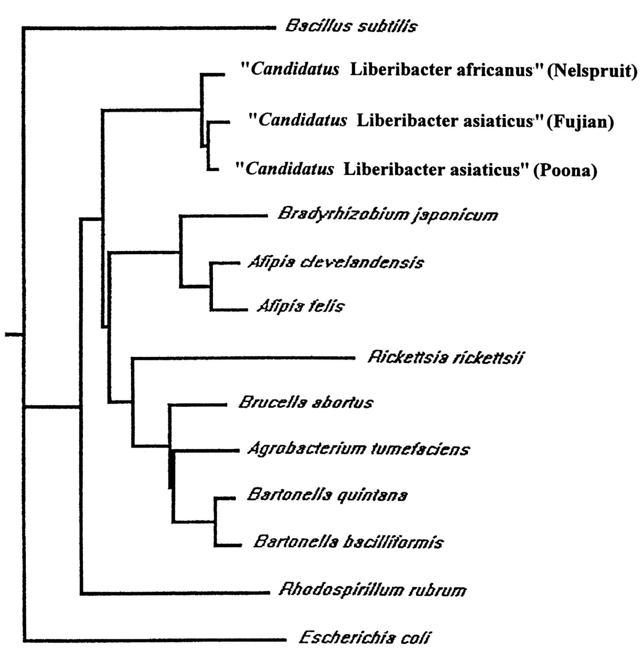

FIGURE BXII.α.147. Phylogenetic tree constructed with 16S rDNA sequences from GenBank.

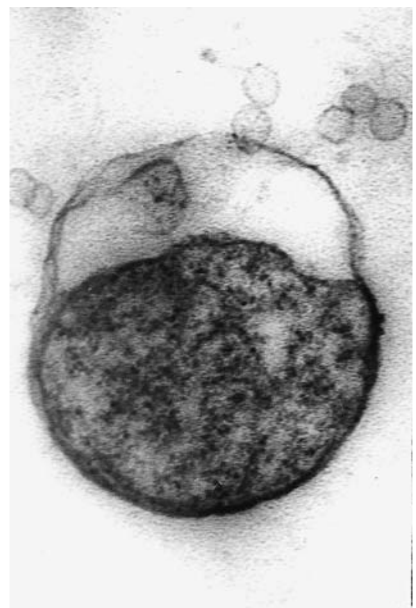

FIGURE BXII.α.148. Round plasmolyzed *Candidatus* Liberibacter (× 100,000).

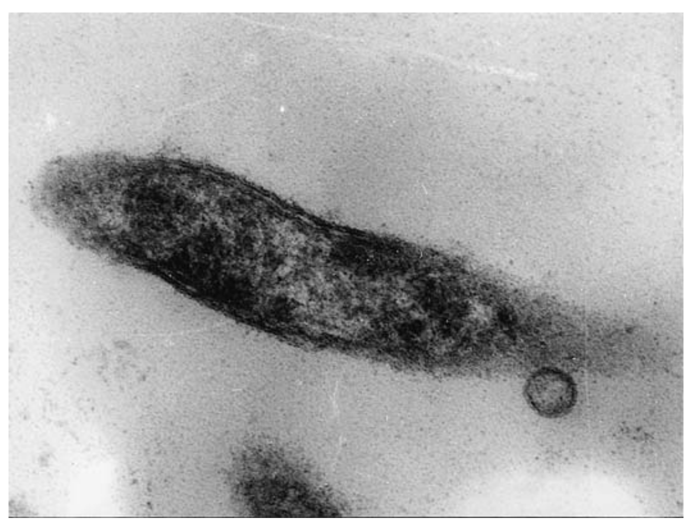

FIGURE BXII.α.149. Filamentous *Candidatus* Liberibacter cell showing the membranous cell wall (× 80,000).

Ecological data, host range *Candidatus* Liberibacter spp. are phytopathogenic bacteria affecting most, if not all, *Citrus* species and some other genera and species in the Rutaceae family. They are responsible for huanglongbing (ex. greening disease). Natural infections are limited to members of the Rutaceae plant family, but experimental transmissions by dodder (*Cuscuta* sp.) to periwinkle (*Catharanthus roseus*, Apocynaceae) and tobacco (*Nicotiana* sp., Solanaceae) have been achieved (Garnier and Bové, 1983; Bové and Garnier, 1992). *Candidatus* Liberibacter asiaticus is present in Asia (from Pakistan to China) and induces symptoms in a temperature range of 25–40°C, while *Candidatus* Liberibacter africanus is present in South and Eastern Africa as well as Cameroon and does not induce symptoms when temperatures are above 30°C (Bové et al., 1974; Garnier and Bové, 1996).

Psyllids become contaminated by feeding on infected plants; they remain infective all their life. *Candidatus* Liberibacter cells can cross the insect gut membranes and multiply into the hemolymph, from which they reach salivary glands. From there on, they can be reinoculated into plants. There is no evidence of transovarial transmission of the liberibacteria. Two psyllids, *Diaphorina citri* in Asia (Capoor et al., 1967) and *Trioza erytreae* in Africa (McLean and Oberholzer, 1965), are vectors of the liberibacteria.

Diaphorina citri has also been present in South and Central America for many years; it has recently reached Florida and the West Indies. Liberibacteria, however, are not present in the American continent and the West Indies. Recently *D. citri* has also been reported from Iran. In the Arabian Peninsula (South Western Saudi Arabia, Yemen), Mauritius, and Reunion islands, both psyllid vectors and the two *Candidatus* Liberibacter spp. are present (Garnier and Bové, 1996).

Enrichment and Isolation Procedures

To date, all attempts to grow liberibacteria in axenic cultures have failed.

In periwinkle plants, the *Candidatus* Liberibacter cells reach higher titers than in citrus. Purified preparations of phloem tissue from infected periwinkle plants are enriched in *Candidatus* Liberibacter cells.

Maintenance Procedures

Strains are maintained in citrus or periwinkle plants by repeated graft-inoculations.

Procedures for Testing Special Characters

Specific identification Cells belonging to *Candidatus* Liberibacter can be identified by amplification and sequencing of the 16S rDNA. The complete sequence of the 16S rRNA gene is deposited in GenBank under the accession number L22532 for *Candidatus* Liberibacter asiaticus and L22533 for *Candidatus* Liberibacter africanus. Primers for specific amplification of the *Candidatus* Liberibacter 16S rDNA have been developed and yield a 1160 bp amplicon with both species (Jagoueix et al., 1996). The oligonucleotide sequences complementary to unique regions of the 16S rDNA are 5′-GCGCGTATGCAATACGAGCGGCA-3′ for *Candidatus* Liberibacter asiaticus and 5′-GCGCGTATTTTATACGAGCGGCA-3′ for *Candidatus* Liberibacter africanus. Digestion of the amplified DNA with *Xba*I is required for species identification.

Primers A2 (5′-TATAAAGGTTGACCTTTCGAGTTT-3′) and J5 (5′-ACAAAAGCAGAAATAGCACGAACAA-3′) defined in the ribosomal protein genes *rplA* and *rplJ* of the *Candidatus* Liberibacter spp. yield amplicons of 703 bp and 669 bp for *Candidatus* Liberibacter asiaticus and *Candidatus* Liberibacter africanus, respectively (Hocquellet et al., 1999).

DNA probes specific for each species or for strains within species have also been obtained (Villechanoux et al., 1992; Hocquellet et al., 1997).

Seven serovars have been demonstrated in the *Candidatus* Liberibacter spp. with the 12 monoclonal antibodies available so far (Gao et al., 1993).

Acknowledgments

Monique Garnier-Semancik died suddenly in May, 2003. She was Director of Research at INRA Bordeaux and served as director of a "Joined Research Unit" in which INRA researchers and University teachers work together. Most of her scientific contributions were to the field of phloem- and xylem-restricted plant pathogenic bacteria, which won her respect both in France and internationally.

List of species of the genus Candidatus Liberibacter

1. *Candidatus* Liberibacter asiaticus Jagoueix, Bové and Garnier 1994, 385 (*Candidatus* Liberobacter asiaticum (sic) Jagoueix, Bové and Garnier 1994, 385.)
as.iat′i.cus. M.L. adj. *asiaticus* from Asia.

The type strain Poona was isolated from a sweet orange tree in India.

The mol% G + C of the DNA is: not determined.
GenBank accession number (16S rRNA): AY192576, L22532.

2. *Candidatus* Liberibacter africanus Jagoueix, Bové and Garnier 1994, 379.
afr.ic′a.nus. M.L. adj. *africanus* from Africa.

The type strain Nelspruit was isolated from a sweet orange tree in South Africa.

The mol% G + C of the DNA is: not determined.
GenBank accession number (16S rRNA): L22533.

a. *Candidatus* Liberibacter africanus subsp. capensis Garnier, Jagoueix-Eveillard, Cronje, le Roux and Bové 2000, 2124.

Detected in an ornamental rutaceous tree (*Calodendrum capense*) in South Africa. 16S rDNA and ribosomal protein gene sequence analysis revealed that it is different from the two previously described species but more closely related to *Candidatus* L. africanus.

The mol% G + C of the DNA is: not determined.
GenBank accession number (16S rRNA): AF137368.

Genus VI. **Mesorhizobium** *Jarvis, van Berkum, Chen, Nour, Fernandez, Cleyet-Marel and Gillis 1997, 897*[VP]

WEN XIN CHEN, EN TAO WANG AND L. DAVID KUYKENDALL

Me.so.rhi.zo' bi.um. Gr. adj. *mesos* middle; M.L. neut. n. *Rhizobium* bacterial generic name; M.L. neut. n. *Mesorhizobium* the *meso*-growing rhizobium, referring to the growth rate intermediate between those of the genera *Rhizobium* and *Bradyrhizobium*.

Rods 0.4–0.9 × 1.2–3.0 μm. Commonly pleomorphic under adverse growth condition or in the root nodules as bacteroids. Usually contain granules of poly-β-hydroxybutyrate, which are refractile by phase-contrast microscopy. Nonsporeforming. Gram negative. **Motile** by one polar or subpolar flagellum or by peritrichous flagella. Aerobic, possessing a respiratory type of metabolism with oxygen as the terminal electron acceptor. Optimal temperature 25–30°C. Optimal pH 6–8. Growth in yeast extract–mannitol agar (YMA)[1] produces colonies that are circular, convex, semitranslucent, raised, and mucilaginous, 2–4 mm diameter within 5–6 d for some species or 1 mm after a 7-d incubation for other species. **The generation times of *Mesorhizobium* strains range from 4–15 h.** Chemoorganotrophic, utilizing a wide range of carbohydrates and salts of organic acids as carbon sources without gas production. Cellulose and starch are not utilized. **Produces an acidic reaction in YMA.** Ammonium salts, nitrates, urea, and most amino acids are utilized as nitrogen sources. Peptone is poorly utilized. *Mesorhizobium* strains are only weakly proteolytic, but can produce a slow digestion in litmus milk; some strains form a clear serum zone. Some strains require thiamin, nicotinamide, and riboflavin for growth. **The organisms are characteristically able to invade the root hairs of a wide range of temperate, subtropical, and tropical leguminous plants, inciting production of root nodules where the bacteria reduce atmospheric nitrogen into a combined form available for the host plants.** All strains exhibit host specificity.

The mol% G + C of the DNA is: 59–64.

Type species: **Mesorhizobium loti** (Jarvis, Pankhurst, and Patel 1982) Jarvis, van Berkum, Chen, Nour, Fernandez, Cleyet-Marel and Gillis 1997, 898 (*Rhizobium loti* Jarvis, Pankhurst, and Patel 1982, 378.)

FURTHER DESCRIPTIVE INFORMATION

In young cultures, the cells are short rods of various cell sizes. The cell width of some strains is 0.25 μm, and the cell length of some strains is 4.0 μm (de Lajudie et al., 1998b). In old cultures, or under adverse environmental conditions, the cells are usually pleomorphic, swollen, club-shaped, or branched.

In host nodules, the bacteroids of *M. huakuii* are mostly club-shaped and approximately 40–50 times larger than the rod-shaped cells in the infection threads or *in vitro* culture. The invaded nodule cell contains many swollen bacteroids and a few rod-shaped bacteria. Microculture of bacteroids and bacteria released from bacterial nodule protoplasm reveals that only the rod-shaped cells multiply; the club-shaped bacteroids do not (Fig. BXII.α.150). (Cao et al., 1984). The ratio of viable (may multiply) counts and total counts of bacteroids released from protoplasts of *Astragalus sinicus* is 0.27:100 for *M. huakuii*, which is between the values reported for *Sinorhizobium meliloti* in *Medicago sativa* (0.11:100) and for *Bradyrhizobium japonicum* in *Glycine max* (81.08:100) (Cao et al., 1984).

The unique phenotypic characters of this genus are the moderately slow or slow growth rate of the strains and their acid production in YMA. The generation times (4–15 h) of *Mesorhizobium* strains (Table BXII.α.131) are generally slower than those of fast growers classified in the genera *Rhizobium* and *Sinorhizobium* (<6 h) and overlap those of *Bradyrhizobium* species (>6 h). *Mesorhizobium* species produce acid in mineral medium, such as YMA, which is a characteristic of *Rhizobium* and *Sinorhizobium*; they do not produce an alkaline reaction like that characteristic of *Bradyrhizobium* (Chen et al., 1995c; Wang et al., 1998). The temperature ranges are highly strain dependent and vary between 4–42°C. Growth at 4°C and 10°C has been observed only with strains of *M. tianshanense*, and growth at 42°C is documented only for strains of *M. plurifarium*, a bacterium from tropical regions. The maximum temperature is 37–40°C for strains from temperate regions. The pH range for the genus is 4.0–10.0, except for *M. tianshanense*, which originated from an alkaline environment and can grow only in the narrow range of pH 6.0–8.0. *M. loti* is the most acid-tolerant species and grows at pH 4.0.

Mesorhizobium strains tested produce a slow digestion in litmus milk with a slightly alkaline reaction.

The bacteria in this genus fix nitrogen only in root nodules. No stem-nodule formation nor nitrogen-fixation in free-living conditions has been reported for any *Mesorhizobium* strain.

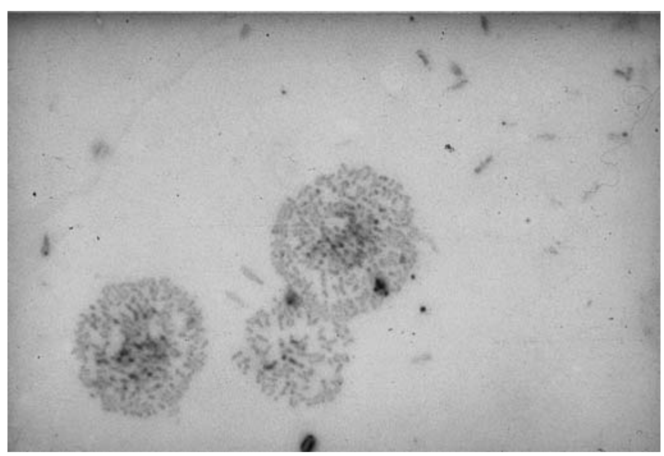

FIGURE BXII.α.150. Photomicrograph showing a microculture of bacterioids and bacteria released from bacteroidal host protoplast. There are 3 microcolonies in the lower left corner, which were developed from regular rods after a 3–4-d incubation in wet chamber. The club-shaped bacteroids elsewhere in the picture could not grow. 1. Yeast extract–mannitol agar (YMA): mannitol, 10.0 g; KH_2PO_4, 0.5 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; NaCl, 0.1g; $CaCO_3$, 4.0 g; yeast water, 100 ml (or yeast extract [Difco], 0.4 g); agar, 15.0 g; and distilled water, 1 liter; pH 6.8–7.0. Sterilize at 121°C for 15 min. The $CaCO_3$ is omitted in the preparation of pour plates or of liquid medium (YMB) used for turbidimetric measurement of growth. The yeast water is prepared by mixing 100 g of baker's compressed yeast with 1 liter of cold water, allowing the mixture to stand at room temperature for 1–2 h, and then steaming for 40–60 min. After the mixture has been centrifuged or allowed to settle, the clear supernatant fluid is autoclaved at 121°C for 15 min (Kleczkowska et al., 1968).

[b]Data from Jarvis et al. (1982).

[c]Data from Wang et al. (1999b).

[d]Data from Nour et al. (1994a, 1995).

[e]Data from Chen et al. (1991b, 1995c).

[f]Data from de Lajudie et al. (1994, 1998b).

Strains contain 1–5 plasmids, with molecular sizes ranging from 60–940 kb, depending on the species and strain. Symbiotic plasmids carrying the *nod* and *nif* genes have been reported in *M. huakuii* (Chan et al., 1988; Xu and Murooka, 1995; Zou et al., 1997) and *M. amorphae* (Wang et al., 1999b). In other species, the symbiotic genes might be carried on the chromosome, as in *Bradyrhizobium*, since no symbiosis-controlling plasmids have been identified (Wang et al., 1998). Novel and complex chromosomal arrangements have been reported for the nodulation genes of *M. loti* (Scott et al., 1996). The gene *nodB* is separated from *nodACIJ* in *M. loti*, but they are in the same operon in other legume-nodulating bacteria. Lateral transfer of symbiotic genes in the field has been reported between *M. loti* and other related bacteria (Sullivan et al., 1995), and a transferable chromosomal element carrying the symbiotic genes has been identified for *M. loti* (Sullivan and Ronson, 1998).

M. loti strains produce extracellular polysaccharides, which contain uronic acid, galactose, and glucose (Jarvis et al., 1982). Somatic antigens are highly strain specific, but internal antigens show a reaction of identity among strains and can be used to distinguish *M. loti* from other *Rhizobium* species (Jarvis et al., 1982). No serological crossreactions (immunofluorescence) have been observed among chickpea rhizobia and other rhizobia (Kingsley and Bohlool, 1983). As analyzed by the method of Vincent (1982), antisera to strains of *M. huakuii* either do not react or do so only weakly with strains of *Astragalus hamosus* and *A. adsurgens* (Chan et al., 1988).

Most strains are resistant to streptomycin, erythromycin, ampicillin, kanamycin, polymyxin, and nystatin at concentrations of 10–30 μg/ml (Chan et al., 1988; Chen et al., 1991b, 1995c; Wang et al., 1998). Two species isolated from chickpea plants, *M. mediterraneum* and *M. ciceri* (Nour et al., 1994a, 1995), can be differentiated by antibiotic tests: in contrast to *M. ciceri*, *M. mediterraneum* is susceptible to carbenicillin and resistant to chloramphenicol, nalidixic acid, and trimethoprim–sulfamethoxazole (Nour et al., 1995).

Strains of *Mesorhizobium* occur in vast areas from arctic to tropic regions, according to their hosts. The host range of the species within genus *Mesorhizobium* varies from a single legume species to several species in different genera. Some *Mesorhizobium* species share hosts with each other or with bacteria from other rhizobial genera. Four restriction-fragment-length-polymorphism (RFLP) groups of *Cicer*-nodulating bacteria have been identified by Kuykendall et al. (1993a). *Cicer arietinum* is a host for *M. ciceri*, *M. mediterraneum*, and two other genomic species (Nour et al., 1994a, 1995). *Acacia* species have been reported to nodulate with *M. plurifarium*, *Sinorhizobium terangae*, and some as yet unnamed species (de Lajudie et al., 1994). Among *Mesorhizobium* species, *M. tianshanense* has the broadest host range.

Enrichment and Isolation Procedures

Isolation from root nodules and soil is by the techniques described for the genus *Rhizobium*.

Maintenance Procedures

A suitable medium is YMA. Storage recommendations are the same as given for the genus *Rhizobium*.

Procedures for Testing Special Characters

Procedures for testing special characters are the same as given for the genus *Rhizobium*.

Differentiation of the genus *Mesorhizobium* from other genera

Phenotypically, the moderately slow growth rate and acid production in YMA can differentiate *Mesorhizobium* strains from other related bacteria, such as *Agrobacterium*, *Rhizobium*, *Sinorhizobium*, *Allorhizobium*, *Bradyrhizobium*, and *Azorhizobium*.

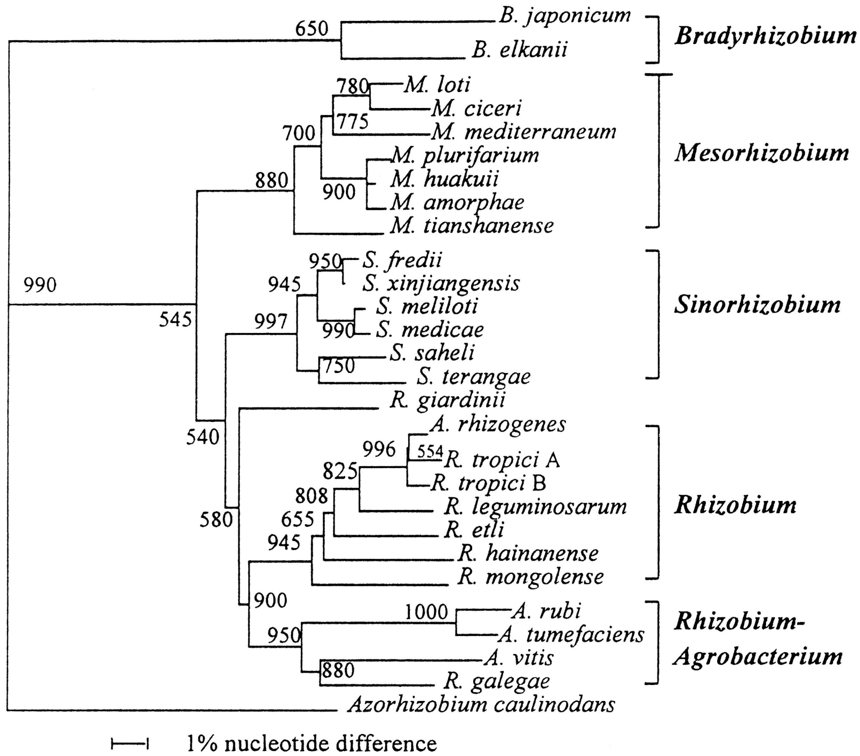

FIGURE BXII.α.151. Dendrogram showing the phylogenetic relationships of species of *Mesorhizobium* and related genera. 16S rRNA gene sequences were obtained from GenBank, DDBJ, and EMBL (analyzed by Z.Y. Tan). The similarity values were calculated with Jukes–Cantor coefficient and the neighbor-joining method was used for construction of the phylogenetic tree and 1000 subsamples were generated for bootstrap analysis using the package of PHYLIP version 3.572c (Felsenstein, 1993).

Analyses of rRNA sequences can differentiate *Mesorhizobium* species from other related bacteria on the phylogenetic basis (Fig. BXII.α.151). Ribotyping or PCR-based RFLP of 16S rRNA genes can serve as a simple and quick method for identification of *Mesorhizobium* strains (Laguerre et al., 1994; Wang et al., 1998). *Mesorhizobium* species have fingerprinting patterns different from other related bacteria and form a group distinct from other bacteria according to cluster analysis of RFLP patterns.

Other differences among the genus *Mesorhizobium* and related bacteria have been demonstrated by numerical taxonomy, SDS-PAGE patterns of total cell proteins, MLEE patterns, PCR-based fingerprinting (ribotyping, ARDRA, RAPD, AFLP), and total DNA–DNA relatedness.

Taxonomic Comments

The genus *Mesorhizobium*, together with some other genera, such as *Agrobacterium*, *Allorhizobium*, *Rhizobium*, and *Sinorhizobium*, constitutes an rRNA cluster in the *Alphaproteobacteria* class. The 16S rRNA sequence similarities between *M. loti* (type species of genus *Mesorhizobium*) and representatives of related genera, specifically *Rhizobium leguminosarum*, *Agrobacterium tumefaciens*, *Sinorhizobium fredii*, *Bradyrhizobium japonicum*, and *Azorhizobium caulinodans*, are 93.2, 93.1, 95.1, 87.7, and 89.4, respectively.

In the first edition of *Bergey's Manual of Systematic Bacteriology*, all of the legume root nodule bacteria were divided into two genera: *Rhizobium* and *Bradyrhizobium* (Jordan, 1984a). *M. loti*, the type species of the genus *Mesorhizobium*, was included in the genus *Rhizobium* as *R. loti* (Jarvis et al., 1982). Several new species phylogenetically related to *R. loti* were later described, including *R. huakuii* from *Astragalus sinicus* (Chen et al., 1991b), *R. ciceri*, and *R. mediterraneum* from *Cicer arietinum* (Nour et al., 1994a, 1995), and *R. tianshanense* from several leguminous plants (Chen et al., 1995c). It was recognized that *R. loti* and its relatives were quite different from both the fast-growing symbiotic species, such as *R. leguminosarum* and *S. meliloti*, and the slow growing bacteria in the genus *Bradyrhizobium*, now in a new family, the *Bradyrhizobiaceae*. Comparative analyses of the complete 16S rRNA sequences from representative strains for the species indicated that all these species clustered in a close branch distinct from related bacteria (Nour et al., 1995; Tan et al., 1997; de Lajudie et al., 1998b). The strains of *Mesorhizobium* produce acid in YMA, and they generally exhibit growth rates slower than those of *R. leguminosarum* and *S. meliloti*. Consequently, there is good agreement that these organisms warrant the designation of a new genus in the family *Rhizobiaceae* (Lindström et al., 1995; Young and Haukka, 1996). The name *Mesorhizobium*, referring to the moderately slow growth rate, was first suggested by W.X. Chen and coworkers and afterwards validly proposed (Jarvis et al., 1997) to include five species: *M. ciceri*, *M. huakuii*, *M. loti*, *M. mediterraneum*, and *M. tianshanense*. Subsequently, three new species have been described: *M. plurifarium*, from the tropical trees *Acacia senegal*, *Leucaena leucocephala*, and *Prosopis juliflora* (de Lajudie et al., 1998b); *M. amorphae*, from *Amorpha fruticosa*, originating from Chinese soils (Wang et al., 1999b); and *M. chacoense* (Velázquez et al., 2001).

Although 16S rRNA gene analysis can differentiate *Mesorhizobium* from other related genera, it is not as useful for defining the species within this genus. For example, *M. loti* is not coherent

and consists of strains with differing phylogenies, since there are more differences among the strains within this species than there are among different *Mesorhizobium* species (Laguerre et al., 1997). Thus, the definition of species within this genus is based mainly upon DNA–DNA hybridization, associated with distinctive features.

Diversity has been investigated for some *Mesorhizobium* species using different methods. Two genomic groups have been distinguished within *M. loti* by DNA–DNA hybridization and by 16S rRNA analyses (de Lajudie et al., 1998b). *M. plurifarium* has been reported to contain two subgroups divided by protein SDS-PAGE and DNA–DNA hybridization (de Lajudie et al., 1998b). *M. amorphae* has been reported as one of the three *Mesorhizobium* groups from *A. fruticosa*, each of which contains strains with different enzyme electrophoretic types (ET) and different plasmid contents. These three groups have different phylogenies within the *Mesorhizobium* branch but share the same symbiotic plasmid (Wang et al., 1998). *M. huakuii* has been described for nine strains isolated from *A. sinicus*, grown in the southern part of China. Recently 200 strains from the same host species growing in seven provinces of China have been divided into four genotypic groups (including *M. huakuii*) by PCR-RFLP of 16S rRNA analysis (Zhong, personal communication). Further taxonomic work would be desirable to clarify the relationships among the defined species and new or unnamed groups.

Acknowledgments

The authors are indebted to Dr. M. Gillis, Dr. E. Martínez-Romero, Dr. K. Lindström, and other members in the International Subcommittee for the Taxonomy of *Rhizobium/Agrobacterium* for their valuable advice.

Differentiation of the species of the genus *Mesorhizobium*

The differential characteristics of the species of *Mesorhizobium* are indicated in Table BXII.α.131.

List of species of the genus Mesorhizobium

1. **Mesorhizobium loti** (Jarvis Pankhurst, and Patel 1982) Jarvis, van Berkum, Chen, Nour, Fernandez, Cleyet-Marel and Gillis 1997, 898^{VP} (*Rhizobium loti* Jarvis Pankhurst, and Patel 1982, 378.)
lo′ ti. M.L. masc. n. *Lotus* generic name of leguminous plants; M.L. gen. n. *loti* of *Lotus.*

The characteristics are as described for the genus and as indicated in Table BXII.α.131. Cells are motile, predominantly by one polar or subpolar flagellum. Bacteroids in nodules are club-shaped and branched and contain inclusion bodies composed of poly-β-hydroxybutyrate (Jarvis et al., 1982). Strains usually lack plasmids, but a plasmid has recently been found in strain NZP 2213 (Wang et al., 1998). All strains utilize one or more of the following carbohydrates as sole carbon sources and form acidic products from them: glucose, galactose, fructose, arabinose, xylose, rhamnose, maltose, sucrose, lactose, trehalose, raffinose, mannitol, and dulcitol (Jarvis et al., 1982).

Strains normally form nitrogen-fixing root nodules on the following hosts: *Lotus corniculatus*, *Lotus tenuis*, *Lotus japonicum*, *Lotus krylovii*, *Lotus filicalius*, and *Lotus schoelleri.* Ineffective nodules are formed on *L. pedunculatus*, *L. huspidus*, and *L. angustissiumus.* Information concerning additional plant hosts is presented by Jarvis et al. (1982).

The mol% G + C of the DNA is: 59–64 (T_m).

Type strain: ATCC 33669, DSM 2626, LMG 6125, NZP 2213.

GenBank accession number (16S rRNA): D14514, X67229.

2. **Mesorhizobium amorphae** Wang, van Berkum, Sui, Beyene, Chen and Martínez-Romero 1999b, 63^{VP}
a.mor′ phae. M.L. gen. n. *amorphae* of *Amorpha*, a genus of plant with which the species forms a nitrogen-fixing symbiosis.

The characteristics are as described for the genus and as indicated in Table BXII.α.131. The cell size is 0.41–0.65 × 0.47–1.68 μm. Produces acid in mineral-salt medium containing mannitol and alkaline in litmus milk. The generation times are from 6–13 h in YM broth. The species can use L-arabinose, D-fructose, D-glucose, rhamnose, sucrose, L-xylose, inositol, fumarate, alanine, and ornithine as sole carbon sources and ammonium salts and tyrosine as sole nitrogen sources. Strains are resistant to cefoperazone (75 μg/ml) and tetracycline (30 μg/ml). Usually, strains harbor one to three plasmids (150–930 kb). The genes for symbiosis reside on the 930-kb plasmids. There is only one *nifH* gene copy. Strains of this species have been isolated from nodules of *Amorpha fruticosa* growing in north China. No nodulation by the reference strain, ATCC 19665, has been observed on any selected host plant of other described microsymbiont species, except its original one, and *Amorpha fruticosa* does not nodulate with any type strains of other described species within the genera *Rhizobium*, *Sinorhizobium*, *Mesorhizobium*, *Bradyrhizobium*, and *Azorhizobium* (Wang et al., 1999b).

The species can be differentiated at the molecular level from other *Mesorhizobium* species and related genera by PCR-RFLP of the 16S rRNA gene, multilocus enzyme electrophoresis (MLEE) patterns, DNA–DNA relatedness, and 16S rRNA sequence.

The DNA–DNA similarity between *M. amorphae* and *M. loti* is 35.0% (Southern blotting method), and sequence similarity of 16S rRNA gene between them is 98.2%.

The mol% G + C of the DNA is: 63–64 (T_m).

Type strain: ATCC 19665.

GenBank accession number (16S rRNA): AF041442.

3. **Mesorhizobium chacoense** Velázquez, Igual, Willems, Fernández, Muñoz, Mateos, Abril, Toro, Normand, Cervantes, Gillis and Martínez-Molina 2001, 1019^{VP}
cha.co.en′ se. N.L. neut. adj. *chacoense* from El Chaco, Argentina, where the type strain was isolated.

Motile Gram-negative rods. Colonies on yeast mannitol agar opaque, white, and convex. Aerobic. Acid produced from adonitol, L-arabinose, galactose, lactose, maltose, melibiose, rhamnose, sucrose, and trehalose in NH_4NO_3-containing media. *N*-acetylglucosaminidases, α-maltosidases, and β-xylosidases produced. Resistant to ciprofloxacin, cloxacillin, and erythromycin. Isolated from trees of the genus *Prosopsis.* Form root nodules and fix nitrogen in association with *P. alba*, *P. chilensis*, and *P. flexuosa.*

The mol% G + C of the DNA is: 62 (HPLC).
Type strain: LMG 19008.
GenBank accession number (16S rRNA): AJ278249.

4. **Mesorhizobium ciceri** (Nour, Fernandez, Normand and Cleyet-Marel 1994a) Jarvis, van Berkum, Chen, Nour, Fernandez, Cleyet-Marel and Gillis 1997, 897[VP] (*Rhizobium ciceri* Nour, Fernandez, Normand and Cleyet-Marel 1994a, 520.)
ci' ce.ri. L. gen. n. *ciceri* of *Cicer*.

The characteristics are as described for the genus and as indicated in Table BXII.α.131. Sole carbon sources are glycerol, arabinose, ribose, D-xylose, D-glucose, D-fructose, D-mannose, rhamnose, inositol, mannitol, *N*-acetylglucosamine, maltose, saccharose, trehalose, D-turanose, L-fucose, D-arabitol, succinate, fumarate, malate, pyruvate, L-histidine, tryptophan, L-glutamate, D,L-kynurenine, L-proline, betaine, D,L-4-aminobutyrate, 2-aminobenzoate, 3-aminobenzoate, 4-aminobenzoate, glucosamine, galactose, D,L-lactate, L-tyrosine, D-lyxose, glycerate, L-asparate, L-ornithine, β-alanine, L-xylose, L-alanine, and L-leucine (Nour et al., 1994b). No serological crossreaction is observed between this organism and 55 strains of *R. leguminosarum*, *B. japonicum*, and others (Kingsley and Bohlool, 1983). Strains of this species are isolated from chickpeas grown in uninoculated fields over a wide geographic range, including Spain, the United States of America, India, Russia, Turkey, Morocco, and Syria. Of 71 chickpea isolates tested, 70 nodulate only the original host plant and do not nodulate the 88 species belonging to Fabaceae and Mimosaceae (Gaur and Sen, 1979). Consequently, this species may be considered a monospecific cross-nodulation system.

This species can be distinguished at the molecular level from other *Mesorhizobium* species and related genera by DNA–DNA relatedness, PCR-RFLP of 16S rRNA, and 16S rRNA sequencing.

The DNA similarity between *M. ciceri* and *M. loti* is 7.5% (S_1 nuclease method). The 16S rRNA sequence similarity between them is 99.8%.

The mol% G + C of the DNA is: 63–64 (T_m).
Type strain: UPM-Ca7, ATCC 51585, DSM 11540, LMG 14898.
GenBank accession number (16S rRNA): U07934.

5. **Mesorhizobium huakuii** (Chen, Li, Qi, Wang, Yuan and Li 1991b) Jarvis, van Berkum, Chen, Nour, Fernandez, Cleyet-Marel, and Gillis 1997, 897[VP] (*Rhizobium huakuii* Chen, Li, Qi, Wang, Yuan and Li 1991b, 278.)
hua.kui' i. N.L. gen. n. *huakuii* in honor of Huakui Chen, a Chinese professor of soil microbiology, who is the pioneer in investigating the microsymbionts isolated from *Astragalus sinicus*.

The characteristics are as described for the genus and as indicated in Table BXII.α.131. Motile by means of a single polar or subpolar flagellum. Cells usually contain granules of poly-β-hydroxybutyrate. The bacteroids in nodules are mostly club-shaped, in vast amounts and approximately 40–50 times larger than the unswollen rod-shaped bacterium (Cao et al., 1984). The generation time of the strains in the species varies from 4–6 h. Strains use D-arabinose, cellobiose, D-fructose, D-glucose, lactose, sucrose, maltose, D-raffinose, L(+)-rhamnose, malate, fumarate, oxalate, or succinate as a sole carbon source. Ammonium nitrate, urea, and many amino acids, including arginine, citrulline, lysine, methionine, ornithine, threonine, tryptophan, and tyrosine, are utilized as sole nitrogen sources. DL-Leucine and valine are not utilized. Some strains require thiamin, nicotinamide, and riboflavin for growth (Chen et al., 1991b). Strains are resistant to the following antibiotics (μg/ml): streptomycin, 10; tetracycline, 10; erythromycin, 20; penicillin, 10; kanamycin, 5; polymyxin, 10; nystatin, 30; neomycin, 10. Most strains contain 1–5 plasmids (66–942 kb). Usually, the *nod* and *nif* genes are carried on the largest plasmid (942 kb) as a gene cluster (Xu and Murooka, 1995; Zou et al., 1997). The other plasmids are also related to symbiosis. A derivative strain cured of the middle-sized plasmid does not nodulate the host plant, has an altered lipopolysaccharide, and grows more slowly than the parent strain. Curing the strain of the smallest plasmid results in delayed nodulation and loss of nitrogen-fixation ability. Curing the strain of each of these plasmids reduces the acid tolerance (Zou et al., 1997). The original host of the species is *Astragalus sinicus*, a green manure crop grown in rice fields in the southern parts of China, Japan, and Korea. This species either cannot nodulate other leguminosarum species or can do so only weakly, and isolates from nodules of 24 species of 8 genera of Leguminoseae cannot nodulate *A. sinicus*, except for isolates from *Desmodium hoterotyllum* (Chen and Shu, 1944). Consequently, the *M. huakuii* symbiosis may be a monospecific cross-nodulation system (Chen et al., 1992).

This species can be differentiated at the molecular level from other *Mesorhizobium* species and related genera by SDS-PAGE of whole-cell proteins, DNA–DNA relatedness, and 16S rRNA sequence.

The DNA–DNA similarity between type strains of *M. loti* and *M. huakuii* is 22.3%. The 16S rRNA sequence similarity between them is 98.3%.

The mol% G + C of the DNA is: 59–64 (T_m).
Type strain: 103, ATCC 51122, CCBAU 2609, DSM 6573, IAM 14158.
GenBank accession number (16S rRNA): D12797.

6. **Mesorhizobium mediterraneum** (Nour, Normand, Cleyet-Marel and Fernandez 1995) Jarvis, van Berkum, Chen, Nour, Fernandez, Cleyet-Marel and Gillis 1997, 898[VP] (*Rhizobium mediterraneum* Nour, Normand, Cleyet-Marel and Fernandez 1995, 647.)
me.di.ter.ra' ne.um. L. adj. *mediterraneum* midland, inland.

Characteristics are as described for the genus and as indicated in Table BXII.α.131. Strains that have been tested can grow at 4°C and cannot grow at pH 5.0 and 10.0; these differentiate them from *M. ciceri*. Sole carbon sources include 39 compounds that are the same as those used by *M. ciceri*. D-Lyxose, DL-glycerate, L-asparate, L-ornithine, β-alanine, L-xylose, L-alanine, and L-leucine are not used (Nour et al., 1994b). Strains comprise a single serological group (Kingsley and Bohlool, 1983). This species may be a monospecific cross-nodulation system (Gaur and Sen, 1979). It can be distinguished at the molecular level from other *Mesorhizobium* species and related genera by DNA–DNA relatedness, PCR-RFLP of the intergenic spacer (IGS) between the 16S and 23S rRNA genes (the average length of the IGS DNA is 1000 bp), and total 16S rRNA sequence analysis.

The DNA–DNA similarity between *M. mediterraneum* and

M. loti is 31%, and the 16S rRNA sequence similarity between them is 97.2%.

The mol% G + C of the DNA is: 63–64 (T_m).

Type strain: ATCC 51670, UPM-Ca36, DSM 11555.

GenBank accession number (16S rRNA): L38825.

7. **Mesorhizobium plurifarium** de Lajudie, Willems, Nick, Moreira, Molouba, Hoste, Torck, Neyra, Collins, Lindström, Dreyfus and Gillis 1998b, 380[VP]

plu.ri.fa′ ri.um. M.L. adj. *plurifarus* from adv. *plurifarium* in a different place, referring to the fact that this species contains strains isolated from several places in East Africa, West Africa, and South America.

The characteristics are described as for the genus and as indicated in Table BXII.α.131. Cells are motile in liquid media. Colonies on YMA are beige, round, convex to drop-like, 0.5–2.0 mm in diameter within 2–3 d at 30°C. Strains utilize glycerol, arabinose, ribose, L-xylose, L-sorbose, D-mannose, rhamnose, inositol, mannitol, sorbitol, *N*-acetyl-glucosamine, D-cellobiose, maltose, lactose, D-melibiose, D-raffinose, xylitol, D-turanose, D-lyxose, succinate, fumarate, glycolate, D,L-lactate, D-malate, L-malate, pyruvate, L-histidine, L-glutamate, L-ornithine, L-arginine, L-proline, betaine, and glucosamine as sole carbon sources. Erythritol, methyl-L-xyloside, amygdalin, glutarate, D-tartrate, D-mandelate, L-mandelate, glycine, D-(−)-alanine, L-norleucine, D,L-norvaline, L-serine, L-cysteine, L-citrulline, creatine, diaminobutane, and spermine are utilized (de Lajudie et al., 1994).

Most of the strains can nodulate *Acacia senegal*, *A. tortilis*, *A. nilotica*, *A. seyal*, *Leucaena leucocephala*, and *Neptunia oleracea*, but not *Sesbania rostrata*, *S. pubescens*, *S. grandiflora*, *Ononis repens*, and *Lotus corniculatus* (Lortet et al., 1996; de Lajudie et al., 1998b). This species can be differentiated at the molecular level from other *Mesorhizobium* species and related genera by SDS-PAGE of whole-cell proteins, DNA–DNA hybridization, and 16S rRNA sequence analysis.

The DNA–DNA similarity between this species and *M. loti* is 10–13%. The 16S rRNA sequence similarity between this species and *M. loti* is 98.0%.

The mol% G + C of the DNA is: 62.6–64.4 (T_m).

Type strain: LMG 11892, ORS 1032.

GenBank accession number (16S rRNA): Y14158.

8. **Mesorhizobium tianshanense** Jarvis, van Berkum, Chen, Nour, Fernandez, Cleyet-Marel and Gillis 1997, 898[VP] (*Rhizobium tianshanense* Chen, Wang, Wang, Li, Chen and Li 1995c, 158.)

tian.shan.en′ se. M.L. adj. *tianshanense* referring to the Tianshan Mountains in the Xingjiang region of the People's Republic of China, where strains were isolated.

The characteristics are described as for the genus and as indicated in Table BXII.α.131. Cells of some strains move by means of peritrichous flagella, others by means of polar and subpolar flagella. The generation time of strains varies from 5–15 h in YM broth. Even the strains with a slow growth rate (generation time >8 h) produce an acid reaction in YMA. All tested strains use D-glucose, mannitol, glycerol, D-xylose, D-fucose, erythritol, D,L-proline, L-(+)-glutamic acid, and rhamnose; some strains can use lactose, maltose, sucrose, pyruvate, raffinose, sorbitol, fructose, mannose, arabinose, citrate, and dulcitol. Tagatose, galactose, melibiose, sorbose, inulin, benzoate, malate, vanillic acid, inositol, salicytol, fumarate, pyrocatechol, starch, and dextrin are not utilized. Sole nitrogen sources are ammonium salts, nitrate, and many kinds of amino acids, including glutamate, glycyl-L-leucine, valine, threonine, arginine, proline, and glycine. No megaplasmid has been detected, but some strains harbor three plasmids (166–468 kb) (Zou and Chen, unpublished). Strains have been isolated from *Glycyrrhiza pallidiflora*, *G. uralensis*, *Glycine max*, *Sophora alopecuroides*, *Swainsonia salsula*, *Caragara polourensis*, and *Halimodendron holodendron* growing in Xinjiang Region of China. Most of these plants are wild and indigenous to that region, except *Glycine max*, a cultivated crop that originated in northeastern China. The type strain A-1BS nodulates all of the original host species of *M. tianshanense* strains but not *Pisum sativum*, *Medicago sativa*, *Phaseolus vulgaris*, *Trifolium repens*, *Lotus corniculatus*, *Leucaena leucocephala*, *Macroptilium atropurpureum*, *Vigna unguiculata*, and *Astragalus sinicus*. Therefore, the hosts of *M. tianshanense* form a single cross-nodulation group (Chen et al., 1995c).

The species can be differentiated from other *Mesorhizobium* species and related genera by phenotypic features, DNA–DNA relatedness, and 16S rRNA sequence.

The DNA–DNA similarity between the type strain of this species and that of *M. loti* is 4.4% (Southern blotting method), and the 16S rRNA gene sequence similarity between them is 97.6%.

The mol% G + C of the DNA is: 59–63 (T_m).

Type strain: A-1BS, CCBAU 3306, DSM 11417.

GenBank accession number (16S rRNA): AF041447, U71079.

Other Organisms

Four unnamed species within the genus *Mesorhizobium* have been reported for some symbiotic or nonsymbiotic strains that were isolated from the rhizosphere of *Lotus corniculatus* (Sullivan et al., 1995, 1996). These isolates have been identified by RFLP of different genes from *M. loti*, including exopolysaccharide genes and symbiotic genes, total DNA–DNA hybridization, MLEE, and 16S rRNA gene sequencing. They are considered to be potential recipients that can acquire and express symbiotic-controlling genes from related microsymbiotic strains.

Two other *Mesorhizobium* groups were also identified when the species *M. amorphae* was described (Wang et al., 1999b). These two groups were also isolated from *Amorpha fruticosa*, and they share moderate DNA–DNA similarity (35–50%) and the same symbiotic plasmid with *M. amorphae* but have distinct phylogenies of their 16S rRNA genes. They also have high phenotypic similarities to *M. amorphae*. These might be included in *M. amorphae* when further evidence is obtained.

Genus VII. **Pseudaminobacter** *Kämpfer, Müller, Mau, Neef, Auling, Busse, Osborn and Stolz 1999, 894*[VP]

Peter Kämpfer

Pseud.ami.no.bac′ter. Gr. adj. *pseudos* false; M.L. *aminobacter* generic name of a bacterium; *Pseudaminobacter* false aminobacters.

Rods 0.5–0.8 × 1.0–2.0 μm, with rounded ends. **Motile**. Gram negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Oxidase and catalase positive**. Colonies on nutrient agar at 25°C are circular, entire, slightly convex and smooth, glistening, and pale beige. Contains ubiquinone Q-10. Major polyamines are spermidine, *sym*-homospermidine, and putrescine. Polar lipid pattern characterized by nearly equal amounts of phosphatidylcholine, phosphatidylglycerol, phosphatidyldimethylethanolamne, phosphatidylmonomethylethanolamine, phosphatidylethanolamine, and diphosphatidylglycerol. The major cellular fatty acid is $C_{18:1}$. The hydroxy acids include the hydroxylated fatty acid $C_{15:0\ iso\ 3OH}$. Isolated from wastewater and river water.

The mol% G + C of the DNA is: 62.9–63.9.

Type species: **Pseudaminobacter salicylatoxidans** Kämpfer, Müller, Mau, Neef, Auling, Busse, Osborn and Stolz 1999, 894.

Further descriptive information

P. salicylatoxidans BN12[T] was described as an aerobic bacterium, able to degrade substituted naphthalenesulfonates and substituted salicylates and originated from a 6-aminonaphthalene-2-sulfonate degrading microbial consortium from the German river Elbe (Nörtemann, 1987). *P. defluvii* THI 051[T] was isolated during a study on thiobacilli (Katayama-Fujimura et al., 1983, 1984b), but it became soon obvious that the organism was not an authentic *Thiobacillus* species.

Growth occurs on nutrient agar (Oxoid), tryptone soya agar (Oxoid), trypticase soy broth (BBL) supplemented with 1.5% (w/v) agar (BBL), and R2A agar (Oxoid).

Differentiation of the genus *Pseudaminobacter* from other genera

Table BXII.α.132 lists the main differential characteristics of the genera belonging to this rRNA group.

Taxonomic Comments

16S rDNA sequence analyses of the type strains of the two *Pseudaminobacter* species clearly place the genus in the family within the *Alphaproteobacteria*. In phylogenetic trees, the highest similarities occur with *Aminobacter* species (>96.7%). Together with the genera *Defluvibacter*, *Mesorhizobium*, *Phyllobacterium*, *Sinorhizobium*, *Ochrobactrum*, and *Aminobacter* (sequence similarities between 16S rRNA genes are above 93%), they form a branch referred to as the group of bacteria known as the alpha-2-subgroup of the *Proteobacteria*. In Fig. BXII.α.152 a phylogenetic tree is presented.

At present, each species is represented by only one strain (Kämpfer et al., 1999).

Differentiation of the species of the genus *Pseudaminobacter*

The two species can be differentiated based on several biochemical tests as indicated in Table BXII.α.133.

TABLE BXII.α.132. Features that differentiate the genus *Pseudaminobacter* from related genera of the *Alphaproteobacteria*[a,b]

Characteristic	*Pseudaminobacter*	*Aminobacter*[c]	*Defluvibacter*	*Mesorhizobium*	*Ochrobactrum*	*Phyllobacterium*

Nitrate reduction			−	−	+	+

[a]Symbols: see standard definitions; blank space, not determined.

[b]Data from Fritsche et al. (1999a) and Kämpfer et al. (1999).

[c]The genus *Chelatobacter* is not listed separately, because it is considered as a later synonym of *Aminobacter* (Kämpfer et al., 2002)

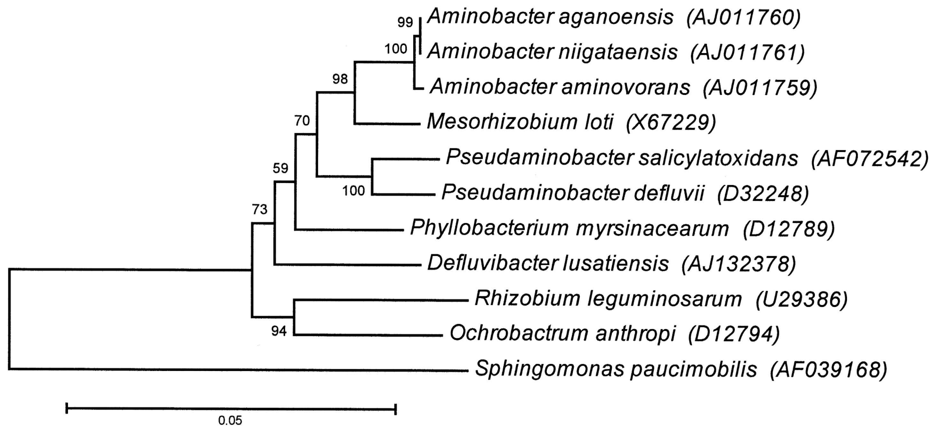

FIGURE BXII.α.152. Phylogenetic tree based on 16S rRNA sequences of *Pseudaminobacter* species and close relatives. The underlying distance matrix has been calculated with the neighbor joining tool of the ARB package using the Jukes-Cantor correction. All gaps in the sequences were excluded. *S. terrae* was used as the outgroup. Accession numbers of the analyzed sequences are indicated. Bar = 10% sequence divergence.

List of species of the genus Pseudaminobacter

1. **Pseudaminobacter salicylatoxidans** Kämpfer, Müller, Mau, Neef, Auling, Busse, Osborn and Stolz 1999, 894[VP]
sa.li.cy.lat.oxi′ dans. N.L. *salicylatoxidans* oxidizing salicylate, because the organism oxidizes salicylate in an unusual manner.

The characteristics are as described for the genus and as listed in Tables BXII.α.132 and BXII.α.133, with the following additional features. Cell size, 0.5–0.8 × 1.0–1.5 μm. Colonies on nutrient agar are circular, entire, slightly convex and smooth, glistening, and beige, 1–3 mm in diameter. Growth occurs at 20–40°C. The major polyamines are spermidine, *sym*-homospermindine, and putrescine. Utilize adonitol, *cis*-aconitate, D-maltose, D-trehalose, glutarate, and L-malate but not L-arabinose, D-cellobiose, D-galactose, D-mannose, sucrose, L-ornithine, and L-serine. Do not hydrolyze *p*-nitrophenyl α-D-glucopyranoside and *p*-nitrophenyl-β-D-glucopyranoside. Isolated from a microbial consortium originating from the river Elbe, Germany.

The mol% G + C of the DNA is: 63.9 (HPLC).
Type strain: BN12, CIP 106963, DSM 6986.
GenBank accession number (16S rRNA): AF072542.

2. **Pseudaminobacter defluvii** Kämpfer, Müller, Mau, Neef, Auling, Busse, Osborn and Stolz 1999, 895[VP]
de.flu′ vi.i. L. neut. gen. n. *fluvius* wastewater, because the organism was isolated from activated sludge.

The characteristics are as described for the genus and as listed in Tables BXII.α.132 and BXII.α.133, with the following additional features. Coccoid to rod-shaped cells, 0.5–0.8 × 0.8–1.2 μm. Colonies on nutrient agar are circular, entire, slightly convex and smooth, glistening, and beige, 1–3 mm in diameter. Growth occurs between 10° and 40°C. No growth occurs at 5° or 45°C. Utilize D-glucose, ribose, D-xylose, acetate, and propionate but not D-maltose, D-trehalose, adonitol, mannitol, sorbitol, L-malate, and L-aspartate. Isolated from a Japanese activated sludge enriched with thiocyanate.

The mol% G + C of the DNA is: 62.9 (HPLC).
Type strain: THI 051, CIP 107185, IFO 14570.
GenBank accession number (16S rRNA): D32248.

TABLE BXII.α.133. Differential characteristics of the type strains of *Pseudaminobacter* species[a]

Characteristic[b]	*P. salicylatoxidans* strain BN12	*P. defluvii* strain THI 051
Acid produced from:[c]		
D-Mannitol	w	−
Dulcitol	w	−
Melibiose	w	−
Utilization of:[d]		
D-Maltose	+	−
D-Trehalose	+	−
Adonitol	+	−
D-Mannitol	+	−
D-Sorbitol	+	−
cis-Aconitate	+	−
Glutarate	+	−
L-Malate	+	−
L-Aspartate	+	−
L-Ornithine	−	+
L-Serine	−	+
4-Hydroxybenzoate	+	−

[a]Symbols: +, positive; −, negative; w, weakly positive. Test results given in the table were read after 72 h of incubation at 30°C.

[b]Tests for hydrolysis of various substrates (not listed in this table) failed to differentiate the two strains. Both type strains hydrolyzed bis-*p*-nitrophenyl-phosphate, *p*-nitrophenyl-phosphorycholine, and L-alanine-*p*-nitroanilide. Neither strain hydrolyzed esculin, *p*-nitrophenyl-β-L-galactopyranoside, *p*-nitrophenyl-β-D-glucuronide, *p*-nitrophenyl-α-D-glucopyranoside, *p*-nitrophenyl-β-D-glucopyranoside, *p*-nitrophenyl-phosphoryl-choline, 2-deoxythymidine-5′-*p*-nitrophenyl-phosphate, and L-glutamate-γ-3-carboxy-*p*-nitroanilide.

[c]Acid formation from carbohydrates in most cases was very weak (even after prolonged incubation). Both strains showed weak acid formation from D-glucose. Neither strain formed acid from lactose, sucrose, salicin, adonitol, inositol, sorbitol, L-arabinose, raffinose, rhamnose, maltose, D-xylose, trehalose, cellobiose, methyl-D-glucoside, and erythritol.

[d]Both strains utilized *N*-acetyl-D-glucosamine, D-glucose, D-ribose, D-xylose, acetate, propionate, 4-aminobutyrate, DL-3-hydroxybutyrate, DL-lactate, oxoglutarate, pyruvate, L-alanine, β-alanine, L-histidine, L-leucine, and L-proline. Neither strain utilized L-arabinose, arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, α-D-melibiose, L-rhamnose, sucrose, salicin, *i*-inositol, maltitol, putrescine, *trans*-aconitate, adipate, azelate, citrate, fumarate, itaconate, mesaconate, suberate, L-phenylalanine, L-tryptophan, 3-hydroxybenzoate, and L-phenylacetate.

Family V. **Methylocystaceae** *fam. nov.*

JOHN P. BOWMAN

Me.thy.lo.cyst.a' ce.ae. M.L. masc. n. *Methylocystis* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Methylocystaceae* the *Methylocystis* family.

Cells are **pyriform, vibrioid, reniform, or rod-like** in shape, sometimes arranged in rosettes. **Reproduce by budding or binary division. Produce heat- and desiccation-resistant exospores or lipoidal cysts.** Motility varies; if present, cells are propelled by a polar and/or subpolar flagellar tuft. Cells contain **type II intracytoplasmic membranes,** which are arranged as layers in parallel to the periphery of the cell wall. Possess an **aerobic, strictly respiratory metabolism**. **Obligately methanotrophic, utilizing only methane and methanol as sole carbon and energy sources.** C_{2+} and other C_1 compounds are not utilized. Fix formaldehyde for cell carbon via the **serine pathway**. Enzymes for the Benson–Calvin cycle pathway are absent. The tricarboxylic acid pathway is complete. **Fix atmospheric nitrogen** by means of an oxygen-sensitive nitrogenase. Mesophilic. Nonhalophilic. Major habitats include soils, freshwater sediments, and groundwater. Primary fatty acids are $C_{18:1\ \omega 8c}$ and $C_{18:1\ \omega 7c}$. Primary quinone is ubiquinone-8 (Q-8).

The mol% G + C of the DNA is: 61–67 (T_m).

Type genus: **Methylocystis** (ex Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993c, 751.

$C_{19:0\ cyclo}$	1.5–4.9	0–3.0

[a]Data from Bowman et al. (1993c).

FURTHER DESCRIPTIVE INFORMATION

Circumscription of the family Bacteria that have the capability to oxidize and utilize methane as a sole carbon and energy source are referred to as methanotrophic bacteria or methanotrophs (Whittenbury et al., 1970b). The original description of the family *Methylococcaceae* (Whittenbury and Krieg, 1984) included two distinct groups of methanotrophs referred to in the literature as "type I" and "type II" methanotrophs. In addition, there is a third group called the "type X" methanotrophs (Hanson and Hanson, 1996), which represents a subgroup of type I methanotrophs. Type I and II methanotrophs possess extensive biological differences, which are morphological, biochemical, chemotaxonomic, and phylogenetic in nature. The order *"Methylococcales"*, which includes the type I methanotrophs, is classified in the *Gammaproteobacteria* and is thus dealt with in another part of this volume. The Family *Methylocystaceae* represents all type II methanotrophs and includes the genera *Methylocystis* and *Methylosinus*. Phenotypic properties and fatty acid components differentiating these genera are shown in Tables BXII.α.134 and BXII.α.135, respectively. The facultative methylotroph *Methylobacterium* represents a distinct taxonomic group and does not have close enough taxonomic association with *Methylocystis* or *Methylosinus* to be included in the family *Methylocystaceae*.

Methane oxidation The major characteristic that separates methanotrophs from other procaryotes is their ability to utilize methane as a sole carbon and energy source. Methanotrophs oxidize methane to CO_2 in a dissimilatory pathway that generates energy and allows access to metabolizable carbon units in the form of formaldehyde. The first step of this pathway is the oxidation of methane to methanol by action of methane monooxygenase (MMO). Methanol is then oxidized to formaldehyde by a pyrrolquinol quinone-containing methanol dehydrogenase. Formaldehyde is then either used for cell carbon (see below) or oxidized to formate and then CO_2, these final steps forming reducing equivalents needed to drive methane oxidation.

In all type II methanotrophs, MMO is present in a membrane-bound form and is referred to as particulate MMO (pMMO) (Semrau et al., 1995). Synthesis of a cytoplasmic version of MMO, referred to as soluble MMO (sMMO) (Dalton, 1992; Murrell, 1992; Lipscomb, 1994), is common in type II methanotrophs but is relatively rare in type I methanotrophs (Bowman et al., 1993a; Bowman and Sayler, 1994; Miguez et al., 1997). Although pMMO and sMMO are genetically distinct (Martin and Murrell, 1995), they are controlled by a common copper-inducible regulatory pathway (Nielsen et al., 1997). Soluble MMO is copper-repressible and contains three components. The first component is a hydroxylase that contains an unusual non-heme iron–oxygen linked active site. The second component is a regulatory protein, and the third is a ferredoxin-based reductase. Particulate MMO has a high affinity to methane, allowing for more efficient growth

yields than with sMMO. sMMO appears to be an adaptation to copper-limiting growth conditions (Hanson and Hanson, 1996). However, sMMO has an exceptionally broad substrate specificity and can co-metabolize an extraordinarily wide range of aliphatic, aromatic, and heterocyclic compounds (Haber et al., 1984). This property has been exploited biotechnologically, with methanotrophs being proposed for organic transformation applications in industrial applications (Lidstrom and Stirling, 1990) and as bioremediation agents (Hanson and Hanson, 1996).

The amino acid sequences of the polypeptides and the nucleotide sequences of the genes (*mmo*A, *mmo*B, *mmo*C and *mmo*X) of sMMO of type I and II methanotrophs show a high degree of conservation (Stainthorpe et al., 1991; Murrell, 1992). These genes have been used to develop general oligonucleotide probes that are specific for different types of methanotrophs (Holmes et al., 1995b; McDonald and Murrell, 1997a, b; Miguez et al., 1997; Dedysh et al., 1998b). Several physiological comparisons have been drawn between methanotrophs and ammonia-oxidizing bacteria because both groups are capable of oxidizing methane and ammonia by similar means (Hanson and Hanson, 1996). For example, type II methanotrophs are able to oxidize ammonia to nitrite and nitrous oxide, although the oxidation rates are lower than those in ammonia-oxidizing bacteria (Yoshinari, 1985). An evolutionary link has been drawn between type I methanotrophs and ammonia-oxidizers (such as *Nitrosococcus oceani*) owing to the similarity of pMMO (*pmo*A gene) and ammonia monooxygenase genes (Holmes et al., 1995a). However, the *pmo*A sequences from type II methanotrophs are comparatively more divergent compared to *pmo*A gene sequences from type I methanotrophs (Holmes et al., 1995a; Bodrossy et al., 1997).

C_1 carbon assimilation Type II methanotrophs are specialized to utilize C_1 compounds, including methane, methanol, and formaldehyde. C_{2+} (acetate, D-glucose, etc.) and other C_1 compounds (formate, methylamine, etc.) are not utilized as energy sources, but they may be used as supplementary carbon sources when cells are grown in the presence of methane or methanol (Hanson et al., 1992). Formaldehyde is toxic to methanotrophic cells at relatively low concentrations and so is often not tested as a carbon source. In addition, freshly isolated methanotrophs often prove sensitive to methanol (due to accumulation of formaldehyde); consequently, methanol should be tested only at low concentrations (10–30 mM) or provided as a vapor in a sealed container. Methanotrophs can be "trained" to tolerate higher concentrations of methanol (Lidstrom, 1988). Type II methanotrophs use the serine pathway to incorporate formaldehyde into synthetic pathways (Large and Quayle, 1963), in contrast to type I methanotrophs, which utilize the ribulose monophosphate (RuMP) pathway to fix carbon (Strom et al., 1974). The serine pathway has been described in detail by Hou (1984). The enzyme α-hydroxypyruvate reductase is often used to detect the serine pathway and thus can be used as a direct way to distinguish type I and II methanotrophs; however, some type I methanotrophs may possess a low level of activity for α-hydroxypyruvate reductase. Type II methanotrophs may also be distinguished by their lack of key enzymes (i.e., hexose phosphate synthase) for the RuMP pathway (Colby et al., 1979).

Intracytoplasmic membranes When methanotrophs are grown in the presence of methane and methanol, characteristic intracytoplasmic membranes (ICMs) are formed from convolutions of the cytoplasmic membrane. ICMs are about 80–90 nm thick, appear as typical lipid bilayers, and in type II methanotrophs are arranged in pairs parallel to the cytoplasmic membrane (type II ICM) (Best and Higgins, 1981) (Fig. BXII.α.153). The relative ICM content in cells is enhanced under reduced methane tensions, at elevated copper ion concentrations, and when a stable and rapid rate of methane transfer is available (Best and Higgins, 1981; Scott et al., 1981).

Ecology Methane is an important greenhouse gas and the most abundant organic gas in the atmosphere (Crutzen, 1991). Methanotrophs are the largest global methane sink and as a result are ubiquitous in nature. They produce the highest and most active populations in environments with a stable gas exchange in which both oxygen and methane are readily available (Reeburgh et al., 1993). Recent evidence suggests methanotrophs make up a high proportion of the total bacterial biomass (up to 40%) in many aquatic environments and surface sediments (Ross et al., 1997; P.I. Boon, personal communication). Stable isotopic analyses (methane is highly ^{13}C-depleted) indicate that a considerable proportion of carbon found in aquatic life at different trophic levels has its origin from methanotrophic bacteria (Boschker et al., 1998; Boon et al., unpublished).

Many studies have used indirect, culture-independent means to study the ecology of type II methanotrophs. These include indirect immunofluorescence (Reed and Dugan, 1978; Smirnova and Archipova, 1981), lipid signatures (Nichols et al., 1985, 1987; Bowman et al., 1991a) and probes or PCR to detect pMMO and sMMO (Tsien and Hanson, 1992; Hanson et al., 1993; Brusseau et al., 1994; McDonald et al., 1995, 1996; McDonald and Murrell, 1997b; Ross et al., 1997; Dedysh et al., 1998b), methanol dehydrogenase (McDonald and Murrell, 1997a), and 16S rRNA genes (Brusseau et al., 1994; Holmes et al., 1995a, 1996; McDonald et al., 1996). This use of culture-independent means is perhaps due to the effort and time necessary to obtain pure cultures. In only a few instances have studies coupled culture-independent and -dependent investigations, thereby permitting a definitive identification of the type II methanotrophs present in environmental samples. In any case, type II methanotrophs are ubiquitous in

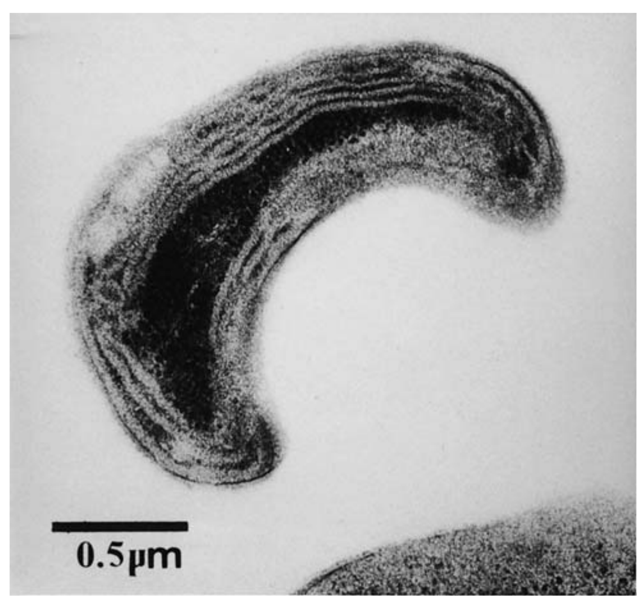

FIGURE BXII.α.153. Electron micrograph of a thin section of *Methylocystis parvus* showing the typical ultrastructure of type II intracytoplasmic membranes.

aquatic and terrestrial ecosystems and have been successfully isolated or enriched from marshes and swamps; roots of aquatic macrophytes; sediments of rivers and streams; rice paddies; ponds, lakes; soils of meadows, forests, peat bogs, and tundra; groundwater; and sewage sludge (Whittenbury et al., 1970b; Gal'chenko, 1977, 1994; Haubold, 1978; Heyer et al., 1984; Nichols et al., 1985; Bowman et al., 1993a, c; Hanson et al., 1993; Vecherskaya et al., 1993; Boon et al., 1996; Calhoun and King, 1998; Dedysh et al., 1998b). In general, type II methanotrophs appear to have a narrower distribution than do type I methanotrophs because they have not been isolated from marine habitats or low and high temperature ecosystems and have not been found to form endosymbioses.

Type II methanotrophs outcompete type I methanotrophs in copper- and nitrogen-limiting oligotrophic environments such as groundwater and soil (Bowman et al., 1993a; Graham et al., 1993) and in environments with low oxygen tensions where methane is not limiting for growth (Amaral et al., 1995a, b). Though as common as type I methanotrophs in various freshwater environments (Saralov et al., 1984; Gal'chenko, 1994; Ross et al., 1997), type II methanotrophs preferentially concentrate in surface layers of sediment (Reed and Dugan, 1978; Hanson et al., 1993) that have high methane fluxes. When present together, type I and II methanotrophs can produce either mutually beneficial or antagonistic effects depending on the strains compared (Starostina et al., 1995; Pashkova et al., 1997).

Cells **are small, rod-like to reniform** in shape, 0.3–0.5 × 0.5–1.5 µm, usually arranged singly. **Reproduce by binary division.** Nonmotile. Cells contain **type II intracytoplasmic membranes,** which are arranged as multiple layers along the periphery of the cell wall. May form **cylindrical spinae**. Cells may contain a **desiccation-resistant lipoidal cyst resting stage**. Form inclusions of poly-β-hydroxybutyrate. **Aerobic**, possessing a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Obligately methanotrophic**, utilizing only methane and methanol as sole carbon and energy sources. C_{2+} and other C_1 compounds are not utilized. Fixes formaldehyde for cell carbon via the serine pathway. Enzymes for the Benson-Calvin cycle pathway are absent and the tricarboxylic acid pathway is complete. **Fixes atmospheric nitrogen.** Mesophilic, neutrophilic, and nonhalophilic ecophysiology with optimal growth at about 25–30°C and pH 7.0. Major habitats include rice paddy soils, sewage, and freshwater sediments. Primary fatty acids are $C_{18:1\ \omega8c}$ and $C_{18:1\ \omega7c}$. Primary quinone is ubiquinone-8 (Q-8). Member of the family *Methylocystaceae* in the *Alphaproteobacteria.*

The mol% G + C of the DNA is: 61–67 (T_m).

Type species: **Methylocystis parvus** (ex Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993c, 751.

Further descriptive information

Methylocystis strains grow well in nitrate mineral salts (NMS) medium[1] under a methane/air headspace (usually provided in a 1:1 ratio). Crimped sealed serum vials, anaerobic jars, or desiccators with an inlet tap provide useful vessels for cultivating strains. Colonies on NMS agar or silica gels appear initially white but become pale pink following extended incubation, probably due to accumulated cytochromes. Colonies have a convex and circular shape with an entire edge and butyrous consistency. *Methylocystis echinoides* colonies are pinpoint on standard agar nitrate mineral salts media but develop larger colonies on silica gel solidified media. Over extended incubation times, many *Methylocystis* strains form a diffusible tan pigment, the intensity of which varies from strain to strain but is thought to be linked to cyst formation (Whittenbury et al., 1970a).

Fatty acid profiles *Methylocystis* species possess a fatty acid profile consisting of mainly $C_{18:1\ \omega8c}$, $C_{18:1\ \omega7c}$, and $C_{18:0}$ with smaller amounts of cyclopropane fatty acids (Table BXII.α.135). The profile is very similar to that of *Methylosinus*, differing only in a greater abundance of $C_{18:0}$ and a lower level of $C_{16:1\ \omega7c}$ (Bowman et al., 1991a). The fatty acid $C_{18:1\ \omega8c}$ is an unusual feature that is almost unique to the Family *Methylocystaceae* and is very rarely encountered in other procaryotes (Nichols et al., 1985; Bowman et al., 1991a). In ecological studies $C_{18:1\ \omega8c}$ has become a very useful signature for the detection and quantification of type II methanotroph populations in environmental samples (Nichols et al., 1985, 1987; Guckert et al., 1991; Boon et al., 1996; Guezennec and Fiala-Medioni, 1996; Sundh et al., 1997). The major lipopolysaccharide-derived hydroxy fatty acids

1. Nitrate mineral salts (NMS) medium consists of the following: 100 ml of a 10× NMS salt stock solution (10 g KNO_3, 10 g $MgSO_4 \cdot 7H_2O$, and 2 g anhydrous $CaCl_2$, dissolved in 700 ml distilled water) is diluted in distilled water to approximately 1 liter. To this is added 0.1 ml of iron EDTA solution (3.8 g FeEDTA in 100 ml distilled water), 1 ml molybdate solution (0.26 g $Na_2MoO_4 \cdot 2H_2O$ per liter distilled water), 1 ml of a trace element solution (1 g $CuSO_4 \cdot 5H_2O$, 2.5 g $FeSO_4 \cdot 7H_2O$, 2 g $ZnSO_4 \cdot .H_2O$, 0.075 g H_3BO_4, 0.25 g $CoCl_2 \cdot 6H_2O$, 1.25 g EDTA disodium salt, 0.1 g $MnCl_2 \cdot 4H_2O$ and 0.05 g $NiCl_2 \cdot 6H_2O$, per liter distilled water), and (optional) 1.5% agar. The solution is sterilized by autoclaving. After cooling to approximately 50°C, 10 ml of phosphate buffer (71.6 g $Na_2HPO_4 \cdot 12H_2O$ and 26 g KH_2PO_4 per liter distilled water) is added.

include $C_{14:0\ 3OH}$ and $C_{18:0\ 3OH}$. In addition, *Methylocystis* species also possess unusual ω-1 hydroxy fatty acids with carbon chain lengths of 26 and 28 (Skerratt et al., 1992) that make up about 15% of the total hydroxy fatty acids. These hydroxy acids have been previously detected in freshwater sediments (Mendoza et al., 1987) and *Methylocystis* and *Methylosinus* represent the first recognized biological source of these particular lipids. *Methylocystis* species contain a suite of polar lipids that vary slightly between strains, possibly due to cultivation conditions (Andreev and Galchenko, 1983). Polar lipids present include phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylmethylethanolamine, phosphatidyl-*N,N*-dimethylethanolamine, and lysophosphatidylglycerol. The major quinone in *Methylocystis* is Q-8 (Collins and Green, 1985).

Enrichment and Isolation Procedures

Methylocystis species can be enriched and isolated from the microaerobic and aerobic sediments of freshwater lakes and rivers, soil, and sewage samples. A small amount of sample is added to a liquid NMS medium in serum vials or in cotton wool-stoppered flasks placed within airtight containers. Methane is added directly to the vials and containers, usually by first removing a portion of the headspace. The best methane/air ratio to use is equivocal but should be in a range of 1:10–1:1. The methane should be of high purity. Natural gas may contain acetylene, which is a suicide substrate of pMMO and sMMO and will hinder or prevent growth even at low concentrations. Static incubation should then proceed at 25–30°C. Growth from the enrichments can then be plated onto mineral salts agar plates which are then incubated under 1:1 methane/air at 25°C.

One of the most problematic areas of methanotroph study lies in obtaining pure cultures. In practically all situations, methanotroph enrichments are severely contaminated by nonmethanotrophic (often methylotrophic) bacteria, which can easily overgrow and/or predate the cultures. Due to the relatively slow growth of type II methanotrophs such as *Methylocystis* and the humid conditions in which plates are incubated, fungal contamination is frequent unless containers are thoroughly cleaned with ethanol before each use. Addition of fungicides such as cycloheximide or nystatin to the medium is usually effective in reducing this problem.

A straightforward method for the isolation of *Methylocystis* and other methanotrophs uses NMS agar media containing a small amount of yeast extract (0.05% w/v) and methanol (0.05% v/v) (Malashenko et al., 1975), with incubation still occurring under a methane/air atmosphere. The enrichment culture is then serially diluted onto the media to the point of extinction. Single colonies on spread plates are then transferred to liquid media. A number of passages from liquid media to spread plates and back to liquid media are often required. The purity of the culture can be assessed by assuring that strains show no growth on nutrient media in the presence or absence of methane and that cells possess a reasonably consistent morphology. More details on enrichment, isolation, and the potential problems have been detailed by Whittenbury et al. (1970b) and Hanson et al. (1992).

Some *Methylocystis* strains, especially those of *M. echinoides*, grow poorly on agar-solidified media. Highly purified agars at lower concentrations may lead to improved growth. Alternatively, silica gel can be employed (Gal'chenko et al., 1975, 1977); however, silica gel is often difficult and time-consuming to prepare. For direct purification of these strains, an alternative approach involves serially diluting enrichments in NMS liquid media to extinction in 96-well plastic titer trays (Bowman et al., 1997b). Several strains can be purified simultaneously in the same tray. After sufficient incubation, the wells of the highest dilutions showing growth are examined by microscopy. A number of separate transfers may be required to obtain morphologically homogeneous cultures.

Maintenance Procedures

Plate or slant cultures can be stored for several months at 4°C when stored under an atmosphere of 1:1 methane/air. Takeda (1988) found that the shelf life could be increased to over 12 months if cultures were kept under a 100% nitrogen atmosphere. *Methylocystis* strains are also amenable to cryopreservation (with 20% dimethylsulfoxide as a cryoprotectant) and freeze drying (with 20% skim milk or 10% horse serum as the cryoprotectant).

Procedures for Testing Special Characters

The acetylene reduction assay traditionally used for detecting nitrogenase activity cannot be used for methanotrophs growing on methane because of co-oxidation of ethylene by MMO and because of the toxicity of the acetylene. Nitrogenase can be detected in methanotrophs grown at low oxygen partial pressures (in semi-solid agar) on methanol or in pre-grown cells supplied with a suitable source of reducing power such as formate, hydrogen, or ethanol (Murrell and Dalton, 1983b; Toukdarian and Lidstrom, 1984a, b; Takeda, 1988).

Putative soluble methane monooxygenase activity in methanotrophs can be rapidly assessed using the naphthalene oxidation technique (Brusseau et al., 1990). The methanotroph to be tested is cultured in copper-free NMS liquid media. Glassware used for cultivation should be washed with 1% (v/v) nitric acid to remove contaminating copper ions. An equal volume of a saturated naphthalene solution (approximately 30 mg/l at 25°C) is added to a suspension of methanotrophic cells that have been degassed briefly with nitrogen to remove residual methane. The mixture is then incubated at room temperature for approximately 1 h. 20 μl of a freshly prepared solution of 1% (w/v) tetraotized *o*-dianisidine (Fast Blue salt B) is then added and mixed. The presumptive presence of soluble methane monooxygenase is indicated by the immediate formation of a reddish semi-soluble diazo compound formed from α-naphthol, which can be measured by spectrophotometry at 540 nm. An adaptation of this procedure to test colonies on agar plates is also available (Graham et al., 1992).

Differentiation of the genus *Methylocystis* from other genera

Characteristics differentiating *Methylosinus* from *Methylocystis* are given in Table BXII.α.136.

Taxonomic Comments

Phylogenetic analysis based on 16S rRNA sequencing indicates that *Methylocystis* strains should be classified in the *Alphaproteobacteria* (Bratina et al., 1992; Brusseau et al., 1994) and that they are closely related to strains of the genus *Methylosinus*. Due to the poor quality of some sequences, it is difficult to make a clear delineation of *Methylocystis* species from *Methylosinus* species. The close phylogenetic relationship of the genera is supported by the similarity of nucleotide distribution width and asymmetry of DNA melting curves across the genera (De Ley, 1969; Gebers et al., 1985; Bowman et al., 1991b). However, *Methylocystis* strains have

TABLE BXII.α.136. Differential characteristics of the genera *Methylocystis* and *Methylosinus*[a]

Characteristics	*Methylocystis*	*Methylosinus*

[a]For symbols see standard definitions.

genomes 30–50% larger than those of *Methylosinus* strains; *Methylocystis* genomes range from 4.4–5.6 Mb in size (Bowman et al., 1991b). The DNA base composition of *Methylocystis parvus* is 63–67 mol% G + C (T_m), while the values for *Methylocystis echinoides* are slightly lower (61–62 mol% G + C [T_m]) (Meyer et al., 1986; Lysenko et al., 1988; Bowman et al., 1991a, b). DNA–DNA hybridization studies indicate *M. parvus* and *M. echinoides* are genetically distinct, sharing only low levels of DNA hybridization, and that no significant levels of hybridization occur between *Methylocystis* and *Methylosinus* strains (Lysenko et al., 1988; Bowman et al., 1991a, b).

Although *Methylocystis* was originally described by Romanovskaya et al. (1978) based on the phenotypic groupings created by Whittenbury et al. (1970b), the genus was not included in the Approved List of Bacterial Names (Skerman et al., 1980). Only *M. parvus* was included in the genus at the time, and several other species including *"Methylocystis methanolicus"* (Gal'chenko et al., 1977), *"Methylocystis pyreformis"*, *"Methylocystis fuscus"* (Gal'chenko, 1977), and *"Methylocystis fistulosa"* (Meyer, 1977) were ignored owing to lack of data, lack of a type strain, and/or the possibility that some were still mixed cultures (D. Prauser, personal communication). The genus was subsequently revived and described in 1993 (Bowman et al., 1993c). Studies using protein electrophoresis (Gal'chenko and Nesterov, 1981) and serotyping (Bezrukova et al., 1983) still suggest that the diversity in *Methylocystis* is greater than what is currently recognized.

Strains designated *M. echinoides* by Gal'chenko et al. (1977) were very similar to the strain IC 493S/5 (IMET 10491) of Haubold (1978) according to protein electrophoretic patterns (Gal'chenko and Nesterov, 1981), and strain IMET 10491 subsequently became the type strain of *M. echinoides*. *"Methylocystis minimus"* IMET 10519 (Whittenbury et al., 1970b; Romanovskaya et al., 1978) is a subjective synonym of *M. parvus* (Bowman et al., 1993c), as it shares about 68% similarity by DNA hybridization with *M. parvus* strain OBBP. Strain A of *"Methylovibrio soehngenii"* (Hazeu and Steenis, 1970) probably should be described as a strain of *M. parvus* (Anthony, 1982).

Differentiation of the species of the genus *Methylocystis*

Phenotypic characteristics differentiating the species *M. parvus* and *M. echinoides* are presented in Table BXII.α.137. Additional phenotypic characteristics for these species are presented in Table BXII.α.138.

List of species of the genus Methylocystis

1. **Methylocystis parvus** (ex Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993c, 751[VP]

par'vus. L. adj. *parvus* small.

Phenotypic characteristics are presented in the genus description, in the text, and in Tables BXII.α.137 and BXII.α.138.

Isolated from soil and fresh water sediments.

The mol% G + C of the DNA is: 63–67 (T_m).

Type strain: OBBP, ACM 3309, ATCC 35066, IMET 10483, NCIMB 11129.

GenBank accession number (16S rRNA): M29026, Y18945.

2. **Methylocystis echinoides** (ex Gal'chenko, Shishkina, Suzina and Trotsenko 1977) Bowman, Sly, Nichols and Hayward 1993c, 751[VP]

ech.i.noi'des. Gr. adj. *echino* spiny, hedgehog-like; Gr. suff. *ides* similar to; M.L. neut. adj. *echinoides* spiny like a hedgehog.

Phenotypic characteristics are presented in the genus description, in the text, and in Tables BXII.α.137 and BXII.α.138.

Isolated from sewage and fresh water sediments.

The mol% G + C of the DNA is: 61–62 (T_m).

Type strain: IMET 10491, NCIMB 13100.

GenBank accession number (16S rRNA): L20848.

Additional Remarks: This sequence is not from the type strain.

Species Incertae Sedis

1. **"Methylocystis fistulosa"** Meyer 1977, 19.
2. **"Methylocystis fuscus"** Gal' chenko 1977, 15.
3. **"Methylocystis methanolicus"** Gal' chenko, Shishkina, Suzina and Trotsenko 1977, 726.
   Deposited strain: 36, NCIMB 13101, IMET 10597.
4. **"Methylocystis pyreformis"** Gal' chenko 1977, 15.
   Deposited strain: NCIMB 13102.
   GenBank accession number (16S rRNA): L20803.

Genus II. **Albibacter** *Doronina, Trotsenko, Tourova, Kuznetsov and Leisinger 2001, 1056*[VP]

Nina V. Doronina and Yuri A. Trotsenko

Al.bi.bac' ter. L. adj. *albus* white; M.L. masc. n. *bacter* equivalent of Gr. neut. n. *baktron* a small rod; M.L. masc. n. *Albibacter* small, white rod.

Rods 0.9–1.0 × 1.2–1.8 µm, singly, in pairs, or in clusters. **Nonmotile**. Gram negative. Multiplication is by binary fission. Endospores and prosthecae are not formed. Colonies are white. Obligately **aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nitrate is reduced to nitrite. Growth occurs on nutrient agar and peptone–yeast extract–glucose (PYG) agar. **Facultatively methylotrophic and chemolithotrophic**. **Assimilate C_1 compounds via the ribulose bisphosphate pathway**. Able to grow on a wide spectrum of polycarbon substrates. Sugars are utilized aerobically but not fermented. Ammonium salts, nitrate, urea, peptone, some amino acids, and methylated amines are utilized as nitrogen sources. Growth factors are not required. Methyl red and Voges–Proskauer negative. Catalase and urease positive. **Oxidase activity is very low**. Indole is formed from L-tryptophan in the mineral medium with methanol as a sole carbon and energy source and with KNO_3 as the nitrogen source. The major ubiquinone is Q-10. The predominant cellular fatty acids are *cis*-vaccenic ($C_{18:1\ \omega7}$) and palmitic ($C_{16:0}$). The dominant phospholipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylcholine, and phosphoserine. Belongs to the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 66.7.

Type species: **Albibacter methylovorans** Doronina, Trotsenko, Tourova, Kuznetsov and Leisinger 2001, 1056.

Further descriptive information

Albibacter species are facultatively autotrophic and methylotrophic. Good growth occurs on mineral salt medium with gas mixture of $CO_2/H_2/O_2$, dichloromethane (0.05–0.1%, v/v), methanol (0.5%, v/v), methylamine (0.3%, w/v), or formate (0.05%, w/v) as the carbon and energy sources. Dichloromethane-grown cells contain an inducible, reduced glutathione (GSH)-dependent dichloromethane dehalogenase, whereas methylamine- or methanol-grown cells possess the appropriate pyrroloquinoline quinone-linked dehydrogenases. Formaldehyde is further oxidized by a GSH-dependent formaldehyde dehydrogenase to formate. The latter is finally oxidized to CO_2 by formate dehydrogenase. The cells assimilate CO_2 via the ribulose bisphosphate (RuBP) pathway and show phosphoribulokinase and ribulosebisphosphate carboxylase activity. Neither the serine nor the ribulose monophosphate pathway of C_1 assimilation is operative, due to the absence of the appropriate specific enzymes, namely hydroxypyruvate reductase (NADH), serine-glyoxylate aminotransferase, ATP malate lyase, and hexulosephosphate synthase, respectively.

The cells have no 2-keto-3-deoxy-6-phosphogluconate aldolase; therefore, the Entner–Doudoroff pathway is not functioning. In addition, the enzymes of the pentose phosphate pathway (glucose-6-phosphate and 6-phosphogluconate dehydrogenases) possess low activities. Hence, fructose-1,6-bisphosphate aldolase plays an important role in metabolic conversions of phosphotrioses. The cells contain pyruvate dehydrogenase as well as a complete set of the citric acid cycle and glyoxylate shunt enzymes.

The primary assimilation of ammonia occurs by both reductive amination of α-ketoglutarate and by the glutamate cycle.

Enrichment and Isolation Procedures

Albibacter methylovorans was isolated on dichloromethane agar from enrichment culture that had been inoculated with a groundwater sample (Doronina et al., 2001).

Maintenance Procedures

The bacteria can be stored in liquid mineral medium K, which has the following composition (g/l): KH_2PO_4, 2.0; $(NH_4)_2SO_4$, 2.0; NaCl, 0.5; $MgSO_4 \cdot 7H_2O$, 0.125; $FeSO_4 \cdot 7H_2O$, 0.002; pH 7.2. The cultures can be stored in the liquid medium at 4°C for at least one month and on agar slants at 4°C for 2–3 months. Cells can also be frozen in medium K containing 40% glycerol and stored at −70°C or lyophilized with a cryoprotectant (skim milk).

Differentiation of the genus *Albibacter* from other genera

Albibacter methylovorans differs from the facultatively chemolithotrophic and methylotrophic members of the genera *Xanthobacter*, *Blastobacter*, *Angulomicrobium*, *Ancylobacter*, and *Ralstonia* by morphological features. The representatives of *Xanthobacter* form pleomorphic cells, and their colonies are slimy and are yellow due to the water-insoluble carotenoid pigment, zeaxanthin dirhamnozide. Species of the genera *Blastobacter* (irregular, ovoid, pleomorphic rods) and *Angulomicrobium* (tetrahedron-shaped cells) multiply by budding. The vibrioid cells of the genus *Ancylobacter* have a characteristic morphology and rings are formed occasionally prior to cell division. *Ralstonia* (formerly *Alcaligenes*) species are motile by one to eight peritrichous flagella.

Taxonomic Comments

The levels of DNA similarity with representatives of *Xanthobacter*, *Blastobacter*, *Angulomicrobium*, *Ancylobacter*, and *Ralstonia* are less than 7%. Phylogenetic analysis by 16S rDNA sequencing (Doronina et al., 2001) confirmed the absence of close relatedness between *A. methylovorans* and the species of the genera *Xanthobacter* and *Blastobacter*. Although *A. methylovorans* resembles *Paracoccus* species in morphology, ubiquinone system, C_1-assimilation pathway, and range of mol% G + C content, it has very low DNA–DNA similarities (5–7%) with the type species of this genus

and thus belongs to another subgroup of the *Alphaproteobacteria*. Despite rather high 16S rDNA sequence similarity to *Methylopila capsulata*, *A. methylovorans* is clearly distinct from this serine pathway methylotroph by morphology, cellular phospholipids and fatty acids, autotrophic growth, and RuBP pathway operation, as well as by a very low DNA–DNA similarity. In the phylogenetic tree derived from 16S rDNA sequences, the genus *Albibacter* forms a distinct branch within the *Alphaproteobacteria* (Doronina et al., 2001).

List of species of the genus Albibacter

1. **Albibacter methylovorans** Doronina, Trotsenko, Tourova, Kuznetsov and Leisinger 2001, 1056^{VP}
me.thy.lo.vor′ ans. Fr. *méthyle* the methyl group; L. part. adj. *vorans* devouring, digesting; *methylovorans* digesting methyl groups.

The characteristics are as described for the genus, with the following additional features.

Fig. BXII.α.154 illustrates the morphological features.

Colonies on methanol or peptone agar are circular and 1–2 mm in diameter, white, convex, translucent to opaque, and mucoid. Growth occurs at 10–35°C and pH 6.0–9.0. Optimal conditions for growth are 28–30°C, pH 7.5–8.0. No growth occurs in the presence of 3% NaCl. Starch is hydrolyzed but not gelatin or cellulose.

Utilizable carbon sources are dichloromethane, methanol, methylamine, formate, CO_2/H_2, D-glucose, D-fructose, D-mannose, L-arabinose, D-xylose, sorbose, ribose, maltose, sucrose, D-sorbitol, D-mannitol, inositol, glycerol, dulcitol, adonitol, ethanol, acetate, α-ketoglutarate, fumarate, pyruvate, succinate, malate, citrate, oxaloacetate, propionate, *cis*-aconitate, L-glutamate, L-alanine, and acetamide. Not utilizable are methane, chloromethane, formaldehyde, di- and trimethylamines, thiocyanate, thiosulfate, dimethylsulfoxide, and dimethylacetamide. Yeast extract (0.01%), or a mixture of biotin and thiamin (both at 20 μg/l), stimulates growth.

Resistant to penicillin and rifampicin, but sensitive to gentamicin, kanamycin, ampicillin, neomycin, novobiocin, nalidixic acid, tetracycline, and lincomycin.

The type (and only) strain was isolated from groundwater in Switzerland.

The mol% G + C of the DNA is: 66.7 (T_m).

Type strain: DM10, DSM 13819, VKM B-2236.

GenBank accession number (16S rRNA): AF273213.

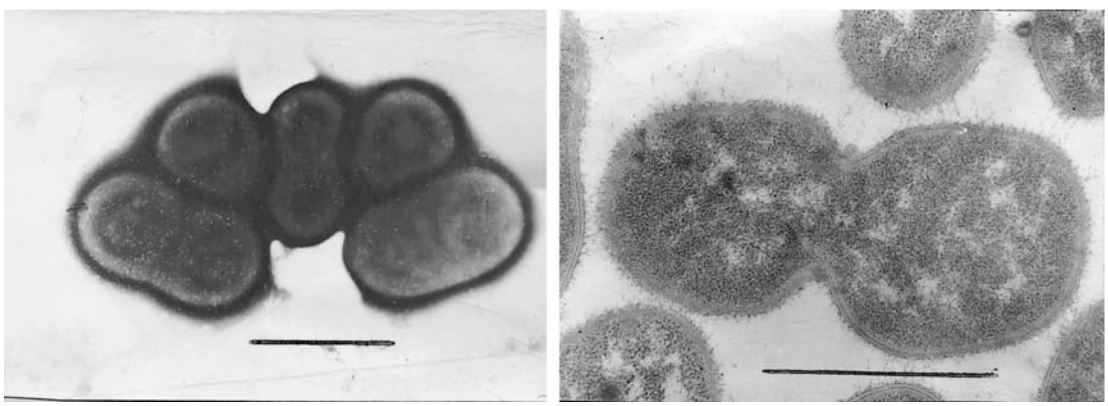

FIGURE BXII.α.154. *Albibacter methylovorans* (*a*) Negatively stained cells. (*b*) Ultrathin sections showing cell wall structure. Bars = 1 μm.

Genus III. **Methylosinus** *(ex Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993c, 751*^{VP}

JOHN P. BOWMAN

Me.thyl.o.si′ nus. Fr. *methyle* the methyl radical; *sinus* bend; M.L. n. *Methylosinus* methyl bender.

Cells are **pyriform or vibrioid** in shape, 0.5–1.5 × 1.5–3.0 μm, usually arranged in rosettes of 4–6 cells. Reproduce by **binary and budding division**. In budding division, the bud contains a **heat and desiccation-resistant exospore**, which germinates into a vegetative daughter cell; this **daughter cell is motile**, propelled by a tuft of 3–10 polar and/or subpolar flagella. Cells contain **type II intracytoplasmic membranes** that are arranged as multiple layers along the periphery of the cell wall. Strongly accumulate inclusions of poly-β-hydroxybutyrate. Aerobic, possessing a **strictly respiratory type of metabolism with oxygen as the terminal electron acceptor**. **Obligately methanotrophic**, utilizing only methane and methanol as sole carbon and energy sources. C_{2+} and other C_1 compounds are not utilized. Fix formaldehyde for cell carbon via the serine pathway. Enzymes for the Benson–Calvin cycle pathway are absent. The tricarboxylic acid pathway is complete. **Fix atmospheric nitrogen by means of an oxygen-sensitive nitrogenase.** Mesophilic. Nonhalophilic. Optimal temperature, 25–30°C; optimal pH, 6.5–7.0. Major habitats include soil, freshwater sediments and groundwater. **Primary fatty acids are $C_{18:1\ \omega8c}$ and $C_{18:1\ \omega7c}$. Primary quinone is ubiquinone-8 (Q-8).** Member of the Family *Methylocystaceae* found in the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 62–67 (T_m).

Type species: **Methylosinus trichosporium** (ex Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993c, 751.

Further descriptive information

Morphology and exospore formation Cells of *Methylosinus trichosporium* have a pear-shaped (pyriform) morphology with a width of 0.5–1.5 µm and a length of 1.5–3 µm. *Methylosinus sporium* cells have a similar size but are vibrioid. When grown in liquid media, both species form rosettes consisting of 4–6 cells. Photomicrographs of the morphology of *Methylosinus* species have been published by Whittenbury et al. (1970a, b). In logarithmic phase, the cells divide by standard binary division. As cultures enter the stationary growth phase, an increasing proportion of cells begin to sporulate and reproduce by budding, either when the cells are arranged in rosettes or singly. The bud that is formed consists of an exospore surrounded by a part of the cell wall. A sporulating cell ceases to divide or bud, becomes granulated, and eventually lyses. It will often produce an extensive fibrillar capsule, which is not formed by vegetative cells (Whittenbury et al., 1970a). Exospore formation by *M. trichosporium* is stimulated by oxygen limitation (Reed and Dugan, 1978). When spores appear, they are initially non-refractile, Gram-negative, coccoid bodies at the end of sporulating cells. As the spores mature, they become increasing refractile and acid-fast. The malachite green spore stain (Doetsch, 1981) can be used to visualize mature spores. Thin sections show that the exospore consists of an electron-dense outer coat (exosporium) surrounded by a cell wall derived from the parent cell. The *M. trichosporium* exospores possess a capsular coat that is attached to the exosporium but is distinct from the parent cell's capsular layer (Reed et al., 1980). Within the exospore, there is a laminated inner coat and a poorly defined cortex (Reed et al., 1980; Titus et al., 1982). Dipicolinic acid and respiratory activity are not detectable in the mature exospores. The exospores are resistant to desiccation and can survive 18 months of drying. Exospores can also withstand heating at 85°C for 10 min and 10 min of ultrasonication. The exospores are structurally similar to those formed by *Rhodomicrobium vannielii* (Titus et al., 1982). When freshly formed, exospores take ~2–3 d to germinate, whereas heat- or desiccation-treated exospores may take weeks to recover. During the germination process, which lasts 5–7 h, the exospores lose their refractility and shed the capsular coats (if any). The exosporium then opens to release a short rod-like daughter cell, which rapidly becomes motile by forming a tuft of 3–10 unsheathed flagella. This cell usually undergoes a few generations of binary division before settling into a rosette to commence exospore production.

Cell walls *Methylosinus* strains produce poly-β-hydroxybutyrate as an internal carbon reserve (Weaver et al., 1975b; Best and Higgins, 1981). The cell walls are of the usual Gram-negative type; however, unlike most other Gram-negative bacteria, *Methylosinus* strains are very resistant to lysis by detergents (such as sodium dodecyl sulfate) and to lytic bacteria (Bowman et al., 1993c; Starostina and Pashkova, 1993). Cell lysis can be caused by a lysozyme pretreatment (1 mg/ml lysozyme at 37°C, for 30–60 min), followed by addition of 2% sodium dodecyl sulfate.

Cultural characteristics *Methylosinus* strains grow abundantly in nitrate mineral salts broth and on media solidified by all brands of agar (see *Methylocystis* for medium formula). The colonies of *M. trichosporium* and *M. sporium* are similar: circular, convex, with an entire edge and creamy consistency. Colonies typically reach 1–2 mm in diameter on NMS agar after 7 d incubation. One strain (IMV B-3037), identified as a strain of *M. sporium*, forms brilliant red nondiffusible pigments that have a slight green metallic sheen. Spectral analysis suggests they are similar to the prodigiosin pigments of *Serratia marcescens*. Two different pigment types were detected and are referred to as methylosin A and B (Strauss and Berger, 1983).

Methylosinus strains are mesophilic and neutrophilic with growth occurring from 10 to 40°C and pH 5.5–9.0. Optimal growth occurs at approximately 30°C and at pH 6.5–7.0. Most strains will either not grow or grow only poorly in the presence of NaCl concentrations greater than 0.3 M. No strains have been found to possess growth factor requirements.

Nutrition and metabolism *Methylosinus* strains are strictly aerobic and obligately methanotrophic. The only carbon and energy sources supporting growth are methane and methanol (Meyers, 1982; Bowman et al., 1993c). Formaldehyde is assimilated by cells for cell carbon via the serine pathway (Wolfe and Higgins, 1979). All strains possess a complete tricarboxylic acid cycle containing a NADP-dependent isocitrate dehydrogenase (Colby et al., 1979). Strains can grow over a wide range of oxygen concentrations (<0.5–60%, v/v) and are not microaerophilic as has been suggested in some previous studies. Only when oxygen levels drop below 0.5% does growth become limiting (Ren et al., 1997). Interestingly, *M. trichosporium* OB3b can survive anoxia for several months (presumably due to exospore formation) and can rapidly respond when methane and oxygen once again become available (Roslev and King, 1994, 1995). Oxygen limitation results in a reduction in the amount of intracytoplasmic membrane (ICM) formation (Scott et al., 1981). When grown under either methane or nitrogen limitation, cells also appear to lack the typical paired type II ICMs, instead having membrane vesicles (Best and Higgins, 1981; Scott et al., 1981). All strains produce catalase and cytochrome *c* oxidase. Nitrate and ammonia salts, amino acids, yeast extract and Casamino acids (Difco) can be used as sources of nitrogen (Warner et al., 1983; Toukdarian and Lidstrom, 1984b; Bowman et al., 1993c). Ammonia and nitrate are metabolized by the glutamine synthetase-glutamine 2-oxoglutarate aminotransferase system (Shishkina and Trotsenko, 1979; Murrell and Dalton, 1983a; Toukdarian and Lidstrom, 1984b). In addition, *Methylosinus* species are capable of fixing atmospheric nitrogen by means of an oxygen-sensitive nitrogenase (Murrell and Dalton, 1983b), which in some *Methylosinus* strains shows homology with the nifH genes of *Klebsiella pneumoniae* (Toukdarian and Lidstrom, 1984a; Oakley and Murrell, 1993).

To date, all strains tested form soluble methane monooxygenase (sMMO), which can be detected using the naphthalene oxidation assay (Brusseau et al., 1990), by a gene probe (Stainthorpe et al., 1991), or by PCR detection of sMMO genes by means of specific primers (Holmes et al., 1995b; McDonald et al., 1995). Many studies have focused on the capability of *M. trichosporium* OB3b to co-oxidize a wide range of carbon substrates by its production of sMMO. The compounds oxidized are too many to list but include a wide range of aliphatic, heterocyclic, and aromatic compounds (Burrows et al., 1984). Several studies have focused on the industrial applications of this biocatalytic ability, particularly in the production of epoxides for plastics manufacture (Hou, 1984). Another focus of research has been in the bioremediation field. *M. trichosporium* OB3b and other similar strains can co-metabolize a wide range of chlorinated

aliphatic compounds, including major groundwater pollutants such as trichloroethylene, chloroform, and tetrachloroethylene (Oldenhuis et al., 1989; Tsien et al., 1989; Castro et al., 1996; Hamamura et al., 1997; Moran and Hickey, 1997; Tartakovsky et al., 1998). However, the industrial application of methanotrophs has been hampered by their relatively slow growth and their requirement for methane, which is a potentially explosive substrate that also competitively inhibits cometabolic reactions. Another problem is that trace copper levels can suppress sMMO activity, thereby eliminating or reducing transformation rates (Oldenhuis et al., 1989; Lontoh and Semrau, 1998). To overcome this, constitutive mutants lacking sMMO activity have been created by chemical mutagenesis and by marker exchange (Phelps et al., 1992; Fitch et al., 1993; Martin and Murrell, 1995; Tellez et al., 1998). These mutants can cometabolize trichloroethylene in the presence of high levels of copper. Some of these copper-tolerant mutants have been used for the development of treatment strategies for chlorinated aliphatic pollutants (Tschantz et al., 1995). In addition the sMMO gene cluster has been successfully cloned into *Pseudomonas putida* strain F1, which is not only able to degrade trichloroethylene but also possesses the ability to grow rapidly; moreover, it lacks the problem associated with methane competitive inhibition (Jahng and Wood, 1994; Jahng et al., 1996).

Plasmids Strains of *M. trichosporium* possess three large plasmids of cryptic function, which are 147 kb, 150 kb, and 160 kb in size, respectively. *M. sporium* ATCC 35069 has two cryptic plasmids, each around 100 kb in size. Restriction endonuclease analysis has indicated that different *M. trichosporium* strains possess identical plasmids; however, Southern blot hybridization analysis indicated that these plasmids share negligible homology with the plasmids of *M. sporium* (Lidstrom and Stirling, 1990).

DNA composition *Methylosinus* strains possess DNA base composition values of 62–67 mol% G + C (T_m). *M. trichosporium* strains possess values of 62–63 (T_m), while the values for *M. sporium* are slightly higher, at 65–67 (T_m) (Table BXII.α.139). The characteristics of the DNA melting curves support a close relationship between *Methylosinus* and *Methylocystis*, as they possess similar nucleotide distribution widths and curve asymmetries (De Ley, 1969; Gebers et al., 1985; Bowman et al., 1991b). The genome size of various *Methylosinus* strains, as calculated by renaturation kinetics, is in the range of 3.0–3.5 Mb, somewhat smaller than that of *Methylocystis* species (Bowman et al., 1991b).

Protein analysis Analysis of protein banding patterns has shown *M. sporium* and *M. trichosporium* to be similar, sharing about 60% of the bands (Gal'chenko and Nesterov, 1981). Only low levels of serological cross reactivity have been detected between antisera raised from *M. trichosporium* and *M. sporium* (Bezrukova et al., 1983).

TABLE BXII.α.139. Differentiation of the species of the genus *Methylosinus*[a]

[a]For symbols see standard definitions.

Lipids *Methylosinus* species possess phospholipid fatty acids that consist mainly of $C_{18:1\ \omega 8c}$, $C_{18:1\ \omega 7c}$, and $C_{16:1\ \omega 7c}$, with smaller amounts of $C_{18:0}$ and cyclopropane fatty acids (Weaver et al., 1975b; Makula, 1978; Nichols et al., 1985; Bowman et al., 1991b; Guckert et al., 1991) (Table BXII.α.136). The profile is very similar to that of *Methylocystis* and differs only in possessing a greater abundance of $C_{16:1\ \omega 7c}$ and a lower level of $C_{18:0}$. The fatty acid $C_{18:1\ \omega 8c}$ is an unusual feature that is practically unique to the family *Methylocystaceae* (Nichols et al., 1985; Bowman et al., 1991b). In ecological studies, $C_{18:1\ \omega 8c}$ has become a very useful signature for the detection and quantification of type II methanotroph populations in environmental samples (Nichols et al., 1985, 1987; Bowman et al., 1991a, b; Guckert et al., 1991; Ross et al., 1997; Sundh et al., 1997). In addition, major lipopolysaccharide-derived hydroxy fatty acids include $C_{14:0\ 3OH}$, $C_{16:0\ 3OH}$, and $C_{18:0\ 3OH}$ (Bowman et al., 1991a; Skerratt et al., 1992). In addition, *Methylosinus sporium* possesses unusual ω-1 hydroxy fatty acids with carbon chain lengths of 26 and 28 (Skerratt et al., 1992) that make up about 15% of the total hydroxy fatty acids. These hydroxy acids have been previously detected in freshwater sediments (Mendoza et al., 1987), and *Methylocystis* and *Methylosinus* represent the first recognized biological source of these particular lipids.

The neutral sugar components of the LPS oligosaccharide core in *M. trichosporium* OB3b include mostly rhamnose, glucose, and heptose (Sutherland and Kennedy, 1986). *Methylosinus* species contain a suite of phospholipids (Makula, 1978; Andreev and Galchenko, 1983), including (with relative % levels): phosphatidyldimethylethanolamine (50%), phosphatidylglycerol (13%), phosphatidylmethylethanolamine (20%), phosphatidylcholine (10%), and lysophosphatidylglycerol (5%). The major quinone in *Methylosinus* is Q-8 (Collins and Green, 1985). Neunlist and Rohmer (1985) found that *M. trichosporium* OB3b contained two free triterpenoids of the hopane family, including an aminotriol (35-aminobacteriohopane-32,33,34-triol) and a novel tetrol (35-aminobacteriohopane-31,32,33,34-tetrol). The aminotriol has been observed previously in *Rhodomicrobium vannielii* (Neunlist and Rohmer, 1985).

Ecology *Methylosinus* strains have been isolated from a variety of soil and freshwater sediment habitats with *M. sporium* being more frequently isolated than is *M. trichosporium* (Bowman, 1992). *Methylosinus* dominates the culturable methanotroph population from groundwater (Bowman et al., 1993a) and has been isolated from the root systems of various aquatic macrophytes (Calhoun and King, 1998). Indirect immunofluorescence studies give a rough indication of the presence of *Methylosinus* species and indicate that *Methylosinus* species congregate at high populations in surface sediments of various freshwater and brackish water bodies (Reed and Dugan, 1978; Abramochkina et al., 1987; Malashenko et al., 1987; Gal'chenko et al., 1988; Gal'chenko, 1994). *Methylosinus* also occurs in rice paddy soils (Saralov and Babnazarov, 1982) and has been detected by gene probe in blanket peat bogs (McDonald et al., 1996).

Enrichment and Isolation Procedures

Procedures for enrichment and isolation are the same as described for the genus *Methylocystis*.

Maintenance Procedures

Methods for preservation and storage of strains are the same as described for the genus *Methylocystis*.

Differentiation of the genus *Methylosinus* from other genera

Characteristics differentiating *Methylosinus* from *Methylocystis* are given in Table BXII.α.136.

Taxonomic Comments

Phylogenetic studies place *Methylosinus* within the *Alphaproteobacteria*. The genus is very closely related to *Methylocystis* and is more distantly related to an assemblage of facultatively methylotrophic, nitrogen-fixing, and phototrophic bacteria, including *Azorhizobium*, *Xanthobacter*, *Ancylobacter*, *Blastochloris*, *Rhodoplanes*, *Rhodopseudomonas viridis*, *Rhodopseudomonas rosea*, *Rhodopseudomonas acidophila*, and *Beijerinckia*. Owing to the relatively poor quality of some of the 16S rRNA sequences, the distinction between *Methylosinus* and *Methylocystis* based on phylogeny alone is ambiguous.

No significant DNA–DNA hybridization (<25%) exists between *Methylosinus trichosporium* and *Methylosinus sporium* strains and with various strains of *Methylocystis* (Lysenko et al., 1988; Bowman et al., 1993c).

Differentiation of the species of the genus *Methylosinus*

Characteristics differentiating *M. trichosporium* and *M. sporium* are shown in Table BXII.α.139. Additional phenotypic characteristics for these species are presented in Table BXII.α.140.

List of species of the genus Methylosinus

Genus Incertae Sedis IV. Methylopila *Doronina, Trotsenko, Krausova, Boulygina and Tourova 1998a, 1319*[VP]

Nina V. Doronina and Yuri A. Trotsenko

Me.thy.lo.pi′la. Fr. *méthyle* the methyl radical; Gr. adj. *pila* ball or sphere; M.L. *Methylopila* methyl-using sphere.

Rods, 0.5–0.7 × 1.0–1.3 µm, occurring singly or in pairs. **Motile or nonmotile.** If motile, the cells have a single lateral flagellum. Gram negative. **Poly-β-hydroxybutyrate granules are formed.** Prosthecae are not formed. Colonies are white. Do not produce pyocyanine and fluorescein. Methyl red and Voges–Proskauer negative. **Oxidase and urease positive.** Indole is formed from L-tryptophan on the mineral medium with methanol as the sole carbon and energy source and KNO_3 as the sole nitrogen source. Produce acid from sugars oxidatively. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Chemoorganotrophic. **Facultatively methylotrophic. Assimilate C_1 compounds by the serine pathway (isocitrate lyase$^-$ variant).** Growth factors are not required. Optimal pH 6.5–7.5; no growth above pH 9 or below pH 5. Optimal temperature, 28–35°C; no growth at 42°C. No growth with 7% NaCl. NaCl is not required for growth. Cellular fatty acid profile is characterized by the presence of 45–70% *cis*-vaccenic acid ($C_{18:1\ \omega7}$); main quinone is Q-10. Dominant cell phospholipids

are phosphatidylethanolamine and phosphatidylcholine. The genus belongs to the order *Rhizobiales* in the class *Alphaproteobacteria*.

The mol% G + C of the DNA is: 66–70.

Type species: **Methylopila capsulata** Doronina, Trotsenko, Krausova, Boulygina and Tourova 1998a, 1320.

Further descriptive information

After division, the cells remain connected by a constriction that appears to be formed by the outer membrane.

The serine-pathway-specific enzymes (hydroxypyruvate reductase, serine–glyoxylate aminotransferase, malate lyase) are present. Isocitrate lyase is absent.

Primary assimilation of ammonia occurs both by reductive amination of α-ketoglutarate and via the glutamate cycle.

Enrichment and Isolation Procedures

Methylopila capsulata strains can be isolated from soil samples as colonies on the mineral base medium K[1] with 2% (w/v) of Difco agar and 1% methanol (Doronina et al., 1998a). *Methylopila helvetica* strains can be isolated from groundwater and active sludge as dichloromethane-utilizing bacteria on the medium DM[2]. Water and sludge samples (0.5 g) (Gälli and Leisinger, 1985) are used for direct inoculation of 10 ml DM medium in closed 50 ml flasks containing 100 μmol CH_2Cl_2. Enrichment cultures are grown at 30°C for 5 d on a rotary shaker and those acidifying the medium are then transferred to fresh medium. After three transfers, the enrichment cultures are then plated into Petri dishes with solidified medium containing 2% (w/v) of Difco agar and 0.01% (w/v) of bromothymol blue, and incubated in a desiccator with 0.05% (v/v) CH_2Cl_2 in the gas phase; pure cultures can then be isolated from individual colonies that change the medium color.

Maintenance Procedures

Strains may be maintained on agar slants at 4°C for at least 2 months. Lyophilization may be used for long-term preservation, with skim milk as a cryoprotectant.

Differentiation of the genus *Methylopila* from other genera

The major characteristics differentiating the genus *Methylopila* from other facultative serine pathway methylobacteria are summarized in Table BXII.α.63 in Genus *Methylarcula*.

Taxonomic Comments

In the phylogenetic tree derived from 16S rRNA sequences, the genus *Methylopila* forms a distinct branch within the order *Rhizobiales* of the class *Alphaproteobacteria*.

Methylopila species share less than 10% DNA–DNA similarity with members of *Methylorhabdus*, *Methylobacterium*, *Aminobacter*, *Hyphomicrobium*, *Methylarcula*, and *Pseudomonas*.

1. K medium contains (g/l of distilled water): $(NH_4)_2SO_4$, 2.0; KH_2PO_4, 2.0; NaCl, 0.5; $MgSO_4 \cdot 7H_2O$, 0.125; $FeSO_4 \cdot 7H_2O$, 0.002. The pH of the medium is adjusted to 7.2 prior to autoclaving. Methanol is added to a final concentration of 1% (v/v).

2. DM medium contains (g/l of distilled water): KH_2PO_4, 1.36; Na_2HPO_4, 2.13; $(NH_4)_2SO_4$, 2.0; $MgSO_4 \cdot 7H_2O$, 0.2. Prior to autoclaving, the pH of the medium is adjusted to 7.2. After sterilization, 1 liter of the medium is supplemented with 1 ml of a trace element solution containing (g/l): $MnSO_4 \cdot 5H_2O$, 1.0; H_3BO_3, 1.0; $CaCl_2$, 0.25; $ZnCl_2$, 0.25; NH_4VO_3, 0.1; $CoCl_2 \cdot 6H_2O$, 0.25 and $Ca(NO_3)_2$, 25.

List of species of the genus Methylopila

1. **Methylopila capsulata** Doronina, Trotsenko, Krausova, Boulygina and Tourova 1998a, 1320[VP]
cap.su.la'ta. L. n. *capsule* a small chest, capsule; M.L. adj. *capsulata* having a capsule.

Pleomorphic rods or cocci, occurring singly or in pairs, having capsules covered in spikes. Motile by means of a single lateral flagellum. Fig. BXII.α.155a and b illustrate the morphological features. Colonies on nutrient agar or glucose–potato agar are round, viscous, semitransparent, convex, with even edges, 2 mm in diameter. Nitrates are reduced to nitrites slowly. Catalase activity is weak. H_2S is produced during growth in nutrient broth. The following carbon sources are used: methanol, mono-, di-, and trimethylamine, butanol, ethanol, glycerol, maltose, sucrose, L-arabinose, D-fructose, D-glucose, succinate, fumarate, and pyruvate. Weak hydrolysis of gelatin and starch occurs. The following nitrogen sources are used: ammonium salts, nitrate, urea, peptone, some amino acids, and methylated amines. Methylamine is oxidized to formaldehyde by amine dehydrogenase.

The type strain was isolated from soil of Tashkent City, Uzbekistan.

The mol% G + C of the DNA is: 67.2 (T_m).
Type strain: IM1, ATCC 700716, VKM B-1606.
GenBank accession number (16S rRNA): AF004844.

2. **Methylopila helvetica** Doronina, Trotsenko, Tourova, Kuznetsov and Leisinger 2000c, 1953[VP] (Effective publication: Doronina, Trotsenko, Tourova, Kuznetsov and Leisinger 2000b, 216.)
hel.ve'ti.ca. M.L. neut. adj. *helvetica* from Helvetia, an old name of Switzerland.

Short rods or cocci, occurring singly or rarely in pairs. Motile by means of a single lateral flagellum. Fig. BXII.α.155c and d illustrate the morphological features. No growth occurs on nutrient agar or peptone–yeast extract–glucose agar. Colonies on methanol–salt agar are white, round, viscous, semitransparent, convex, 1–3 mm in diameter. Nitrate is reduced to nitrite. H_2S and NH_3 are not formed. Catalase positive. The following carbon sources are used: dichloromethane, methanol, formate, mono- and trimethylamine, ethanol, glycerol, pyruvate, fumarate, and succinate. Gelatin and starch are not hydrolyzed. Ammo-

nium salts, nitrate, methylated amines, and some amino acids are utilized as nitrogen sources. Methylamine is oxidized to formaldehyde by the *N*-methylglutamate pathway enzymes γ-glutamylmethylamide synthetase and *N*-methylglutamate synthase/lyase.

The type strain was isolated from groundwater in Switzerland.

The mol% G + C of the DNA is: 68.5 (T_m).

Type strain: DM9, CIP 106788, VKM B-2189.

GenBank accession number (16S rRNA): AF227126.

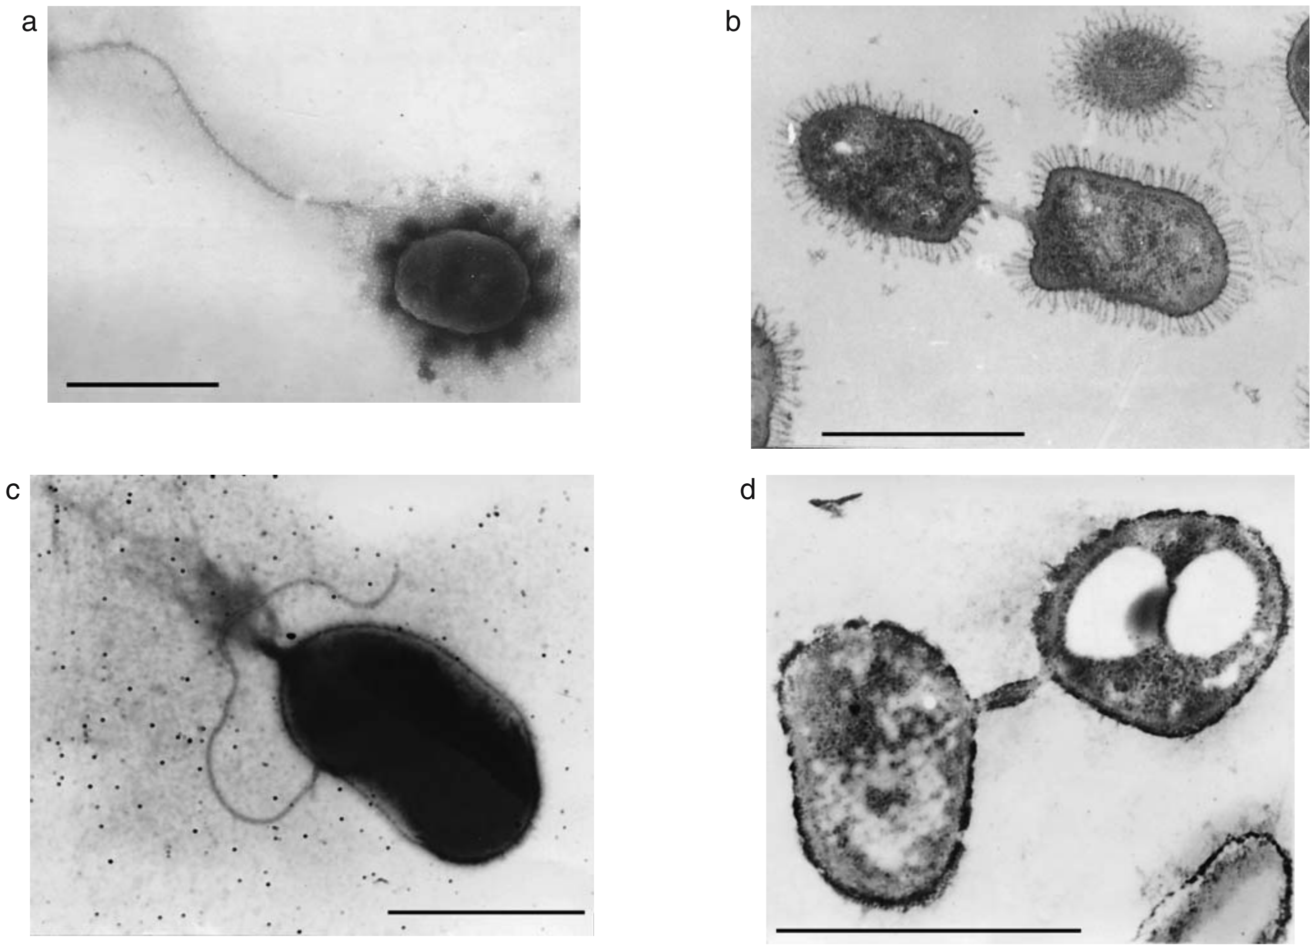

FIGURE BXII.α.155. *Methylopila capsulata* (*a*, *b*) and *Methylopila helvetica* (*c*, *d*). *a* and *c*, negatively stained cells, note the subpolar location of the single flagellum; *a*, the large amount of capsular material is evident. *b* and *d*, ultrathin sections; constriction in the final stage of cell division and granules of PHB. Bars = 1 μm.

Family VI. **Beijerinckiaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Beij.e.rinck.i.a′ ce.ae. M.L. fem. n. *Beijerinckia* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Beijerinckiaceae* the *Beijerinckia* family.

The family *Beijerinckiaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Beijerinckia* (type genus), *Chelatococcus*, *Methylocapsa*, and *Methylocella*. *Methylocapsa* was proposed after the cut-off date for inclusion in this volume (June 30, 2001) and is not described here (see Dedysh et al. (2002)).

Aerobic. Form poly-β-hydroxybutyrate granules. Family is metabolically diverse. *Beijerinckia* and *Methylocella* fix nitrogen.

Type genus: **Beijerinckia** Derx 1950a, 145.

Genus I. **Beijerinckia** *Derx 1950a, 145*[AL]

CHRISTINA KENNEDY

Beij.e.rinck' i.a. M.L. fem. n. *Beijerinckia* named after M.W. Beijerinck, the Dutch microbiologist (1851–1931).

Straight or slightly curved rods, ~0.5–1.5 × 7–4.5 μm, with rounded ends. Cells occur singly or appear as dividing pairs. Sometimes large, misshapen cells 3.0 × 5.0–6.0 μm occur; these are occasionally branched or forked. Intracellular granules of **poly-β-hydroxybutyrate (PHB)** are formed, generally one at each pole. Cysts (enclosing one cell) and capsules (enclosing several cells) may occur in some species. Gram negative. Motile by peritrichous flagella or nonmotile. **Aerobic**, having a strictly respiratory type of metabolism. **N_2 is fixed under aerobic or microaerobic conditions**. Optimal temperature for growth, 20–30°C; no growth occurs at 37°C. **Growth occurs between pH 3.0 and pH 9.5–10.0**. **Liquid cultures can become a highly viscous, semitransparent mass**; in some species the whole medium becomes opalescent and turbid, and adhering slime is not produced. **On agar media, especially under N_2-fixing conditions, copious slime is produced** and giant colonies with a smooth, folded, or plicate surface develop; some strains form slime having a more granular consistency. **Catalase positive**. **Glucose, fructose, and sucrose are utilized** by all strains and oxidized to CO_2. No growth occurs on peptone medium. Glutamate is utilized poorly or not at all. Species are found in soils, particularly **tropical regions**.

The mol% G + C of the DNA is: 54.7–60.7.

Type species: **Beijerinckia indica** (Starkey and De 1939) Derx 1950a, 146 (*Azotobacter indicum* (sic) Starkey and De 1939, 337.)

FURTHER DESCRIPTIVE INFORMATION

Cell morphology The typical microscopic appearance of *Beijerinckia* cells is shown in Figs. BXII.α.156 and BXII.α.157. Cells may be bicellular due to crosswall formation in the middle of the longitudinal direction of the cell (Figs. BXII.α.158 and

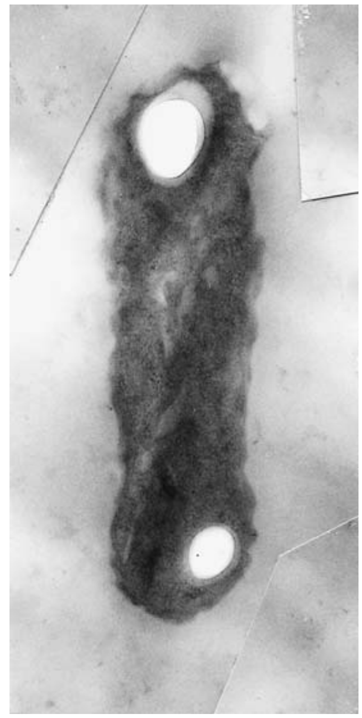

FIGURE BXII.α.157. *Beijerinckia indica* electron micrograph of a thin section showing the two polar lipoid bodies, which are surrounded by a membrane (× 33,300).

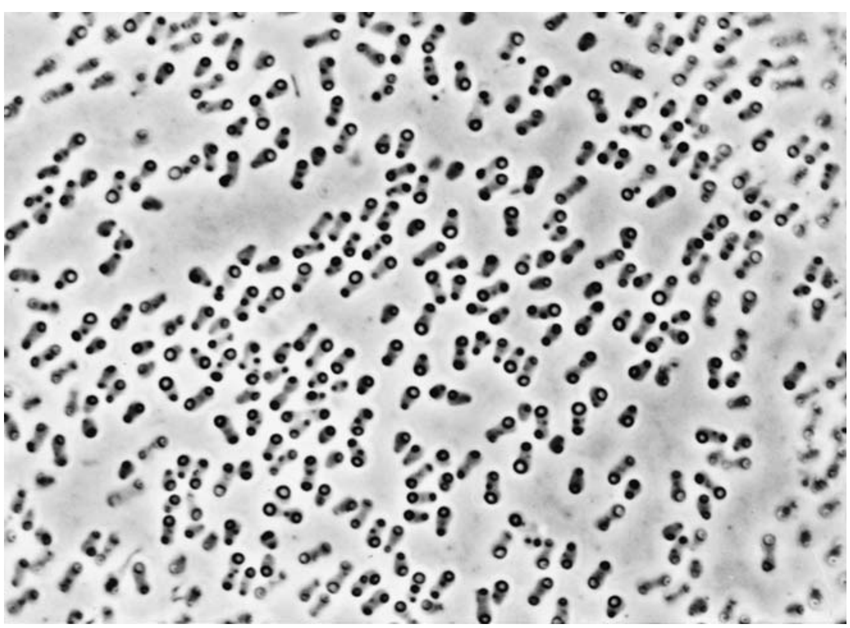

FIGURE BXII.α.156. *Beijerinckia indica* cells cultured on nitrogen-free glucose mineral agar (pH 5.0). The typical appearance of the cells and their intracellular polar lipid bodies is illustrated. Living preparation, phase-contrast microscopy (× 1500).

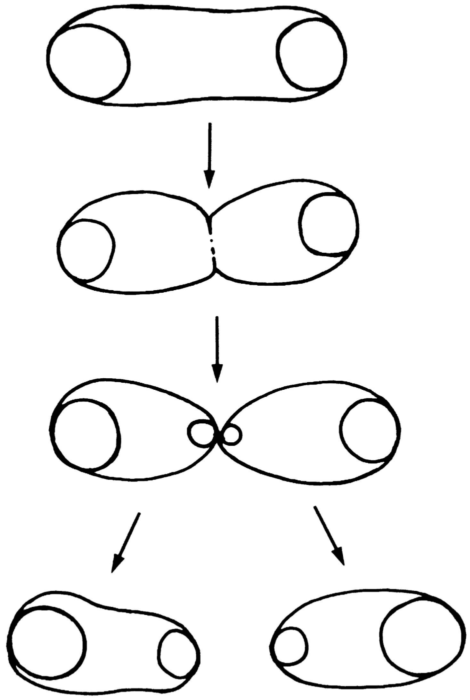

FIGURE BXII.α.158. Diagram of the life cycle of a *Beijerinckia* cell. A cell in division forms a crosswall in the middle of the longitudinal axis of the cell. In actively dividing cells, intermediate stages can often be seen.

BXII.α.159). Under certain cultural conditions, some *Beijerinckia* strains show coccoid cells without terminal lipoid globules (Fig. BXII.α.160). Sometimes, especially in *B. mobilis* strains, more than two lipoid globules per cell occur (Fig. BXII.α.162). The lipoid material is poly-β-hydroxybutyrate (PHB) (Becking, 1974, 1984b). Cyst and capsule formation occur in some species (*B. fluminensis*, *B. mobilis*, and *B. indica*) (Figs. BXII.α.161, BXII.α.162, and BXII.α.163).

The flagella of motile cells are peritrichous in those strains studied (Thompson and Skerman, 1979). Flagella appear to originate from one-half of the often dumbbell-shaped cells. The wave pattern is normal or curly, the wavelength has an average value of ~1.1–1.3 μm, and the amplitude is 0.26–0.35 μm. The amplitude of the waves in *B. fluminensis* and *B. derxii* strains is usually somewhat larger (0.26–0.35 μm) than in strains of *B. indica* (0.26 μm) (Thompson and Skerman, 1979).

Colonial and cultural characteristics On agar media, especially under N_2-fixing conditions, *Beijerinckia* strains may produce giant colonies containing copious amounts of exopolysaccharide. This slime is often extremely tough, tenacious, or elastic, which makes it difficult to remove part of a colony with a loop. In *B. mobilis* and *B. fluminensis* the exopolysaccharide has a more granular consistency (Becking, 1984a).

On nitrogen-free mineral agar medium[1], *Beijerinckia* species exhibit various kinds of colonial characteristics and pigmentation, and in liquid cultures they show differences in viscosity and pellicle formation; see the individual species descriptions for details.

1. N-free mineral medium, g/l: glucose, 20.0; K_2HPO_4, 0.8; KH_2PO_4, 0.2; $MgSO_4 \cdot 7H_2O$, 0.5; $FeCl_3 \cdot 6H_2O$, 0.025 or 0.05; $Na_2MoO_4 \cdot 2H_2O$, 0.005; $CaCl_2$, 0.05; and agar, 15.0. The pH is adjusted to 6.9. The $CaCl_2$ may be omitted to obtain a calcium-free medium.

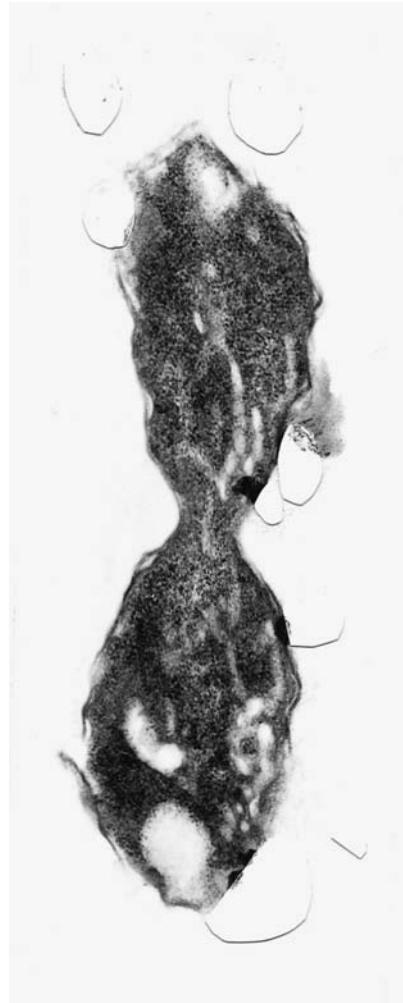

FIGURE BXII.α.159. Electron micrograph of a *Beijerinckia* cell in the process of division. The constriction in the middle of the cell is clearly visible and the two terminal lipoid bodies of the original cell can be seen (× 33,000).

The temperature range for growth of *Beijerinckia* species is from 10 to 35°C. Cells are resistant to freezing: no reduction of viability occurs when stored for 3–4 months at −4°C (Becking, 1961).

Metabolism and metabolic pathways Carbon sources utilized include many sugars, organic alcohols, and organic acids (see Table BXII.α.141 and Table BXII.α.142). Since the compilation of strain characteristics by Thompson and Skerman (1979) and Becking (1984a), few reports of new features have appeared. One report describes the ability of *B. mobilis* to utilize several aromatic compounds as carbon sources and as energy sources for nitrogen fixation (Chen et al., 1993); these include benzoate, catechol, 4-hydroxybenzoate, naphthalene, protocatechuate, and 4-toluate. Most *Beijerinckia* species hydrolyze starch.

In alkaline, nitrogen-free, glucose minimal medium, *Beijerinckia* strains decrease the pH to 4.0–5.0. The acids produced are mainly acetic and a small amount of lactic (Kauffmann and Toussaint, 1951; Becking, 1961).

As with other N_2 fixers, *Beijerinckia* species require molybdenum for optimal growth and N_2 fixation. The molybdenum requirement—4.0–35.0 mg/l (Becking, 1962)—is notably higher

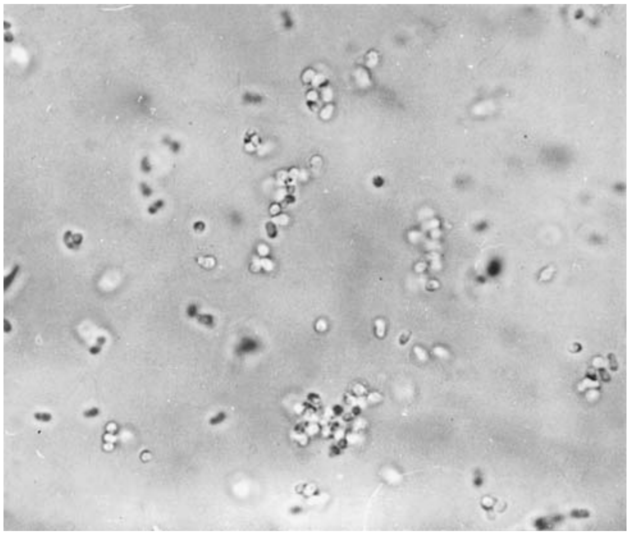

FIGURE BXII.α.160. *Beijerinckia mobilis* from an aged culture. The individual cells often lack the characteristic polar lipoid bodies and are more rounded in form, resembling certain *Azotobacter* species (× 1000).

than that of *Azotobacter* and *Azomonas*. Moreover, unlike *Azotobacter*, the molybdenum cannot be replaced by vanadium (Becking, 1962). This finding suggests that alternative nitrogenases are not present in *Beijerinckia*, at least not the nitrogenase that contains vanadium (nitrogenase-2) (for further explanation, see the genus *Azotobacter*, this volume). Growth of *Beijerinckia* species under N_2-fixing conditions does not require calcium, in contrast to most (but not all) *Azotobacter* species; indeed, $CaCO_3$ is even slightly inhibitory because it tends to prolong the lag phase of growth. The efficiency of N_2 fixation in *Beijerinckia* strains varies from 6 to 17 mg N_2 per g glucose consumed and is inversely proportional to growth (Becking, 1984a); the efficiency is greater at lower carbohydrate and/or oxygen supply levels (Spiff and Odu, 1973; Becking, 1978). The exocellular polysaccharide produced in copious amounts by species of *Beijerinckia* may protect nitrogenase from oxygen damage, as was shown for *B. derxii* subsp. *venezuelae* (Barbosa and Altherthum, 1992). Removal of the exopolysaccharide resulted in a drastic loss of nitrogenase activity.

Strains of *Beijerinckia indica* and *Beijerinckia mobilis* have been reported to contain large amounts of triterpenoids of the hopane series. In the former species, both bacteriohopanetetrol and aminobacteriohopanetriol were present, whereas in the latter, amino-bacteriohopanetriol was the only C35 hopanoid (Vilcheze et al., 1994). Whether this difference represents a distinguishing feature for all, or several, members of each species was not indicated.

Occurrence and transfer of plasmids No studies involving isolation of mutants or genetic analysis of metabolism have been reported. The broad-host-range IncP plasmid RP4 could be mobilized into *B. indica* by conjugation and stably maintained (Naik et al., 1994). A tributyltin-sensitive strain, *Beijerinckia* sp. MC-27, isolated from freshwater sediment became resistant to this compound after transfer of a plasmid associated with chromium resistance from *Pseudomonas aeruginosa* PAO1 (Miller et al., 1995). The presence of indigenous plasmids in species of *Beijerinckia* was reported (Murai et al., 1990) but no function could be assigned.

Ecology *Beijerinckia* strains were originally isolated from a quartzite soil (pH 4.5) of Malaysia (Altson, 1936) and later from acid soils of Dacca, Bangladesh (pH 4.9), and Insein in Burma (pH 5.2) by Starkey and De (1939). They were later observed to be widely distributed in acidic tropical soils of Africa, Southeast Asia, and South America (Kluyver and Becking, 1955; Becking, 1961). *B. indica* is the most commonly encountered species and has been isolated from tropical soils of all continents and sometimes from nontropical regions. *Beijerinckia* strains can also be recovered from waterlogged soils of wet rice fields (Becking 1961, 1978). In a survey of 392 soils of worldwide distribution, *Beijerinckia* strains were found infrequently in some temperate and subtropical soils (Becking, 1959, 1961; see also the review by Becking, 1981). Nevertheless, their occurrence in temperate habitats might be more widespread than originally thought, based on reports of *Beijerinckia* spp. being isolated from European white fir (Streichan and Schink, 1986). Moreover, acidophilic, methanotrophic organisms with a soluble methane monooxygenase were isolated from three boreal forests in acidic northern wetlands of West Siberia and European north Russia (Dedysh et al., 1998a), and analysis of 16S rDNA sequence from these organisms placed them close to *Beijerinckia indica*. However, more recent studies show that these organisms—unlike *Beijerinckia* species—are unable to grow on sugars and other multicarbon compounds. In addition, *Beijerinckia* cannot grow on methane, and genes coding for methane monooxygenase have not been detected in *B. indica* (Dedysh, personal communication). These bacteria are now named *Methylocella palustris* (Dedysh et al., 2000).

B. mobilis occurs mainly in very acid soils (pH 4.0–4.5) of tropical Southeast Asia, Africa, and South America, and this is in accordance with its ability to fix nitrogen optimally at pH 3.9 (Becking, 1961). This high degree of acid tolerance might be useful for the specific enrichment and isolation of this species. *B. fluminensis* was originally isolated from a "Baixada Fluminensis" (pH 4.2–5.2) of Rio de Janeiro and from some other Brazilian soils (Döbereiner and Ruschel, 1958). It was also isolated from several African and Asian soils (Becking, 1961). *B. derxii* was originally isolated from an Australian soil (Tchan, 1957) and then found in several South American and Asian locations, as well as in further locations in Australia (Thompson and Skerman, 1979).

In addition to soil or water habitats, *Beijerinckia* species are also found in plant rhizosphere and phyllosphere habitats. Associations with roots of sugarcane in Brazil and with a salt-tolerant grass *Leptochloa fusca* in Pakistan have been reported (Zafar et al., 1987; Baldani et al., 1997). *Beijerinckia* species have also been isolated from the leaves of plants such as coffee, cocoa, and cotton (Ruinen, 1956, 1961; Murty, 1984). There is no evidence that nitrogen fixation by *Beijerinckia* species provides an amount of fixed nitrogen sufficient to benefit plant growth.

Enrichment and Isolation Procedures

An acidic, nitrogen-free medium[2] can be used for selective isolation of *Beijerinckia* from soil. The low pH of this medium favors development of beijerinckias, which are acid tolerant, and inhibits growth of other organisms, especially *Azotobacter* species. The requirement for trace elements (iron, molybdenum) in this medium is provided by the soil used as the inoculum. The medium is poured as thin layers (2–3 mm deep) into Petri dishes to allow good aeration. This partially inhibits the development

2. Enrichment medium (g/l of distilled water): glucose, 20.0; KH_2PO_4, 1.0; and $MgSO_4 \cdot 7H_2O$, 0.5. The pH is adjusted to 5.0.

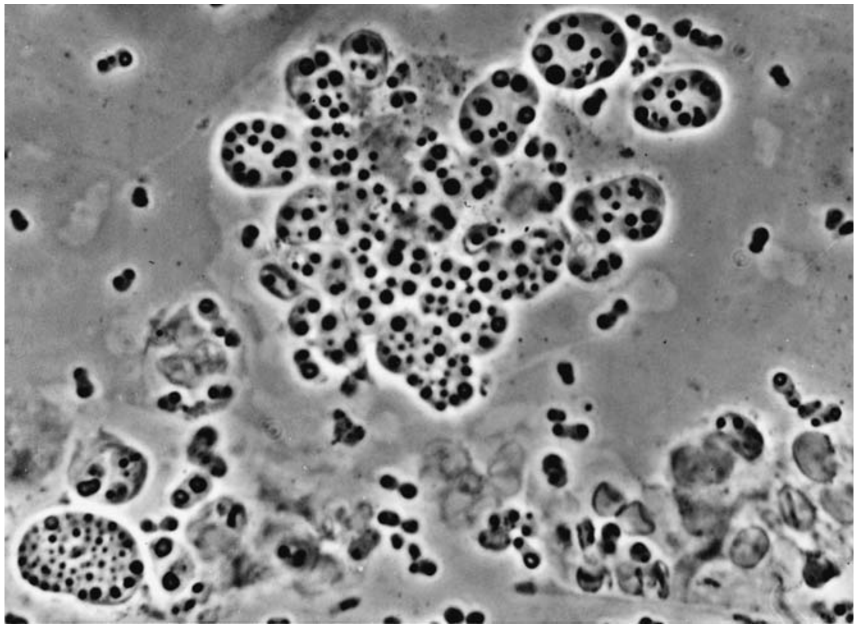

FIGURE BXII.α.161. *Beijerinckia fluminensis* cultured in nitrogen-free glucose mineral agar (pH 5.0), showing distinct capsule formation. The capsules enclose a large number of individual cells. Living preparation, phase-contrast microscopy (× 1500).

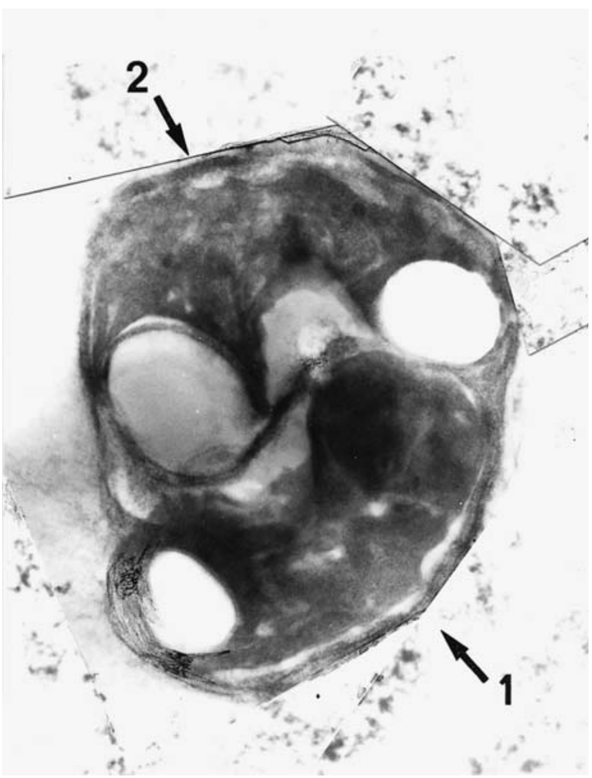

FIGURE BXII.α.162. Electron micrograph of a capsule of *Beijerinckia mobilis* containing two cells (see *arrows 1* and *2*). The terminal lipoid bodies of each cell are visible and also the distinct capsular wall (see *arrow 1*) (× 33,000).

of anaerobic or facultative N_2 fixers. Approximately 0.5 g of soil, 10 ml of water sample, or detached leaves can be used as the inoculum. The enrichment cultures are incubated at 30°C for 2 or more weeks (*Beijerinckia* strains grow slowly). The entire culture may eventually change into a viscous mass due to slime production. The cultures are examined microscopically at various times for the presence of characteristic *Beijerinckia*-like cells. When such cells occur, the enrichment culture is plated onto a nitrogen-free, mineral agar medium (see Further Descriptive Information). Although an acidic agar medium can be used for isolation, it is not recommended because the agar may be hydrolyzed.

The sieved-soil plate method of Winogradsky (1932), using nitrogen-free mineral agar (pH 4.5–5.0) with glucose or sucrose (10 or 20 g/l), can also be applied. *Beijerinckia* colonies develop after 2–3 weeks around the soil particles on the plates. The type strain of *B. indica* was obtained by this method. In general, however, it is less satisfactory than the use of liquid enrichment media because purification is more difficult (the slime is more tenacious) when one starts with solid media. If the plating method is chosen, a drop inoculation is recommended rather than spreading, because of the higher number of colonies obtained with the former approach (Barbosa et al., 1995).

On agar media, *Beijerinckia* species form characteristic, highly raised, glistening colonies containing a tough, elastic slime. For further purification, a similar medium is used, but it is made neutral or alkaline by the addition of $CaCO_3$[3]. This is because the slime is more soluble under alkaline conditions, and it is easier to suspend the cells in sterile tap water or liquid medium for further streaking. On the alkaline agar medium, *B. indica* strains usually form highly raised colonies, whereas *B. mobilis* colonies are flatter and produce a uniform reddish brown or amber-brown color on aging.

3. N-free mineral agar medium with $CaCO_3$: composition is similar to that given in Further Descriptive Information, but the $CaCl_2$ is replaced by $CaCO_3$ (10–20 g/l).

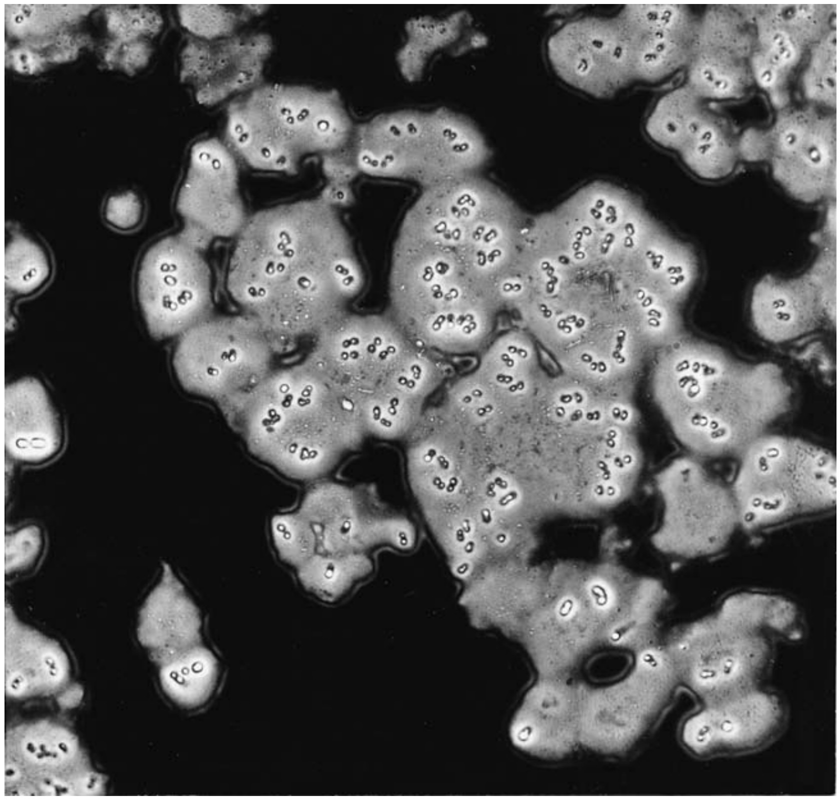

FIGURE BXII.α.163. Cells of *Beijerinckia indica* suspended in India ink, showing the polysaccharide formation around the cells. Living preparation, phase-contrast microscopy. (× 1350)

TABLE BXII.α.141. Differential characteristics of the species of the genus *Beijerinckia* and the genus *Derxia*[a]

Characteristics	*B. indica*	*B. derxii*	*B. fluminensis*	*B. mobilis*	*Derxia gummosa*
Water-soluble, green fluorescent pigment	−	+	−	−	−
Colony color after aging	P	B	P	AB	Br
Motility	[−][b]	−	[−][b]	+	+
Resistant to 1% peptone	d	−	−	d	+
Starch hydrolyzed	−	d	−	−	−
Growth on asparagine as C and N source	−	−	−	d	+
Urea hydrolyzed	+	+	−	+	+
H_2S production from cysteine	−	−	+	−	−
Tween 20 hydrolyzed	−	−	−	−	+
Indole produced	−	−	−	−	+
Antagonism to Gram positive organisms	−	d	−	−	+

[a]For symbols, see standard definitions; P, pink; B, buff; AB, amber-brown; Br, brown. For additional distinguishing characteristics, see Table BXII.α.142, utilization of carbon compounds.

[b]If positive, motility occurs mostly in young stages and the cells are usually only weakly motile.

Specific enrichment procedures No specific procedure is known to select for a particular *Beijerinckia* species, and all existing strains are random isolates obtained from soil using one of the general procedures outlined above. In general, carbon source utilization is not distinctive for particular species, although certain substrates might be useful for enrichment of one or two particular species because of their preferential use: e.g., benzoate for enrichment of *B. mobilis* and mannose for *B. indica* or *B. fluminensis* (see Table BXII.α.142). Thompson and Skerman (1979) suggested that certain substrates or inhibitors might be useful for enrichment of various species, although this has not yet been experimentally tested. From the properties of the strains studied, the following compounds have potential value for enrichment or selection:

1. *B. indica*: L-arabinose, D-mannose, glycerol, caprylate, and *trans*-aconitate. Glycerol might be useful for *B. indica*, and for *Derxia gummosa* and some *B. fluminensis* strains. Nitrilotriacetate might also be useful for *B. indica*.
2. *B. mobilis*: pentan-2-ol, 1,3-butylene glycol, asparagine, and *n*-valerate might be useful. Phenol (0.05%) might be used to inhibit the growth of other *Beijerinckia* species.
3. *B. indica* and *B. mobilis*: propan-1-ol, butan-1-ol, or 1,3-propylene glycol for enrichment.

4. *B. indica* subsp. *lacticogenes* and *B. mobilis*: caproate, *p*-hydroxybenzoate, or phenol for enrichment.
5. *B. derxii* and *B. fluminensis*: α-methyl-D-glucoside, maltose, melibiose, or melezitose for enrichment. Where both species are present, *B. derxii* would likely outgrow the extremely slow-growing *B. fluminensis*.
6. *B. derxii* subsp. *venezuelae*: L-arabitol for enrichment.

Because the colony morphology and chromogenesis of growth on solid media differs among the various *Beijerinckia* species, primary selection of colonies from the enrichment cultures is done mainly on the basis of these colonial characteristics. A more precise identification is performed later using additional differential characteristics.

Maintenance Procedures

Beijerinckia strains can be lyophilized in skim milk or dextran-sodium glutaminate solution on filter paper and stored in the dark at room temperature (Becking, 1984a).

Storage has also been achieved on the usual agar media in tubes plugged with sterile rubber seals, with storage in the dark at room temperature (Antheunisse, 1972, 1973); after 10 years, 33% of the cultures retained viability. *Beijerinckia* cultures stored under a seal of sterile liquid paraffin or mineral oil generally survive for at least 3–5 years (Becking, 1984a).

Strains may also be preserved indefinitely in liquid nitrogen. At the type culture collection in Delft, The Netherlands, DMSO (10%, v/v) is added to cultures in the log phase or end of log phase, and the cultures are frozen as rapidly as possible in liquid nitrogen. For recovery, the vials are thawed rapidly in a waterbath at 37°C (Becking, 1984a).

Cryopreservation in 10% glycerol was also successful (Thompson, 1987). See the genus *Azotobacter* for details.

Differentiation of the genus *Beijerinckia* from other genera

Beijerinckia strains can be distinguished from other aerobic N_2 fixers by their great acid tolerance (which allows them to grow well at pH 4.0 or 5.0), by their failure to form a pellicle on the surface of liquid media, and by their ability to make a liquid medium viscous by slime production (Fig. BXII.α.164). Moreover, on solid media they produce characteristic large, slimy colonies having a tough, tenacious, and sometimes elastic slime. Because of this exopolysaccharide production, it is often difficult to subculture portions of a colony for purification. For other features distinguishing *Beijerinckia* strains from *Derxia**, the most closely related genus, see Tables BXII.α.141 and BXII.α.142.

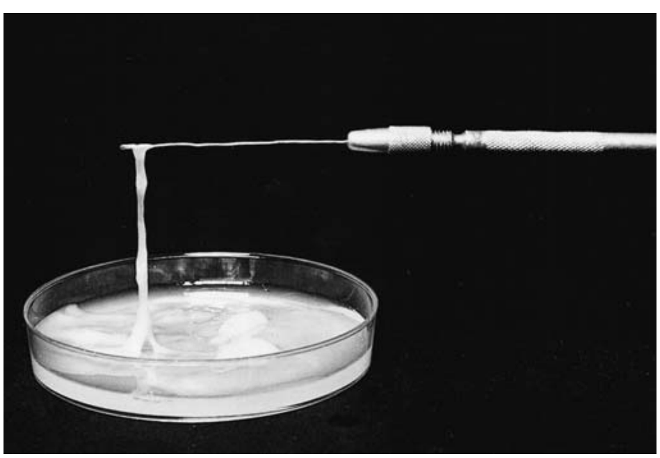

FIGURE BXII.α.164. Enrichment culture of *Beijerinckia* inoculated with tropical soil, demonstrating the highly viscous consistency of the medium after 3 weeks (× 0.8).

Beijerinckia cells can be distinguished from those of *Azotobacter* and *Azomonas* by their generally smaller size, by their more rod-shaped or sometimes pear- or dumbbell-shaped appearance, and by the characteristic presence of a lipoid body at each pole (Fig. BXII.α.156). Many strains of *Beijerinckia* utilize nitrate poorly or not at all and, in this respect, differ from strains of *Azotobacter*.

Although both *Beijerinckia* and *Derxia* produce slimy colonies on agar and viscosity in broth, *Beijerinckia* strains can be distinguished by (a) failure to produce dark mahogany-brown colonies with aging, (b) cells that contain bipolar lipoid bodies rather than numerous lipoid bodies throughout the whole cell, (c) failure to form a pellicle at the surface of liquid media, and (d) a positive catalase reaction. In addition, a number of C sources should distinguish the two genera; for instance, *Beijerinckia* species, but not *Derxia*, can utilize sorbose and raffinose, and *Derxia*, but not *Beijerinckia*, utilizes aspartate, glutamate, or ethylamine (Table BXII.α.142).

Taxonomic Comments

When numerical analysis methods are applied to species of *Beijerinckia*, *Azotobacter*, and *Azomonas*, the *Beijerinckia* species fuse into a single, apparently coherent group (Thompson and Skerman, 1979). Using a wide range of attributes, and considering all strains of named and unnamed *Beijerinckia* species, numerical analysis supports the concept of a separate genus for these bacteria. In addition, the experiments reported by De Smedt et al. (1980), in which ^{14}C-labeled rRNA from *Beijerinckia indica* was hybridized with filter-fixed DNA from a wide variety of Gram-negative bacteria, indicated the genus *Beijerinckia* to be a heterogeneous but coherent group. From rRNA cistron similarities, it was concluded that *Beijerinckia* and *Azotobacter/Azomonas* belong to different classes. Analysis of the 16S rDNA sequence of *Beijerinckia indica* places this genus within the phylum *Proteobacteria*. The family *Beijerinckiaceae*, including the genera *Beijerinckia*, *Derxia*, and *Chelatococcus*, is in the class *Alphaproteobacteria* and the order *Rhizobiales*. This family is most closely related to the families *Methylocystaceae* and *Bradyrhizobiaceae*.

Thompson and Skerman (1979) used many phenotypic characters of *Beijerinckia* strains for numerical analysis, yielding a hierarchical classification. These authors confirmed the presence of four species, in two main groups within the genus. Group 1294 (*B. fluminensis* + *B. derxii*) fuses with group 1289 (*B. indica* subsp. *indica* + *B. indica* subsp. *lacticogenes* + *B. mobilis*) to produce the group 1297. Group 1289 strains generally differed from group 1294 strains in having thinner cells and using caprylate, propan-1-ol, 1,3-propylene glycol, *trans*-aconitate, nitrilotriacetate, and L-arabinose, but not maltose and α-methyl-D-glycoside, as sole carbon sources. Moreover, strains of group 1289 produced acid from L-arabinose and glycerol and were resistant to 0.5% NaCl, 0.05% phenol, and 1.0% sodium benzoate. One widely studied member of the genus, *Beijerinckia* sp. strain B1, was reclassified as a strain of *Sphingomonas yanoikuyae* on the basis of 16S rDNA analysis (Khan et al., 1996a).

**Editorial Note:* Because of the 16S rDNA placement, the genus *Derxia* has been moved to the family *Alcaligenaceae* and is no longer listed in *Beijerinckiaceae*.

TABLE BXII.α.142. Utilization of carbon compounds by *Beijerinckia* and *Derxia* species[a]

Carbon compounds utilized[b,c]	*B. indica* (14)[d]	*B. derxii* (21)	*B. fluminensis* (10)	*B. mobilis* (2)	*Derxia gummosa* (6)

[a]For symbols, see standard definitions.

[b]Data represent a merger of information in Thompson and Skerman (1979) and Becking (1984a) in the 1st edition of *Bergey's Manual of Systematic Bacteriology*. Not all compounds tested by Thompson and Skerman (1979) are included.

[c]All species can utilize glucose, sucrose, lactate, pyruvate, succinate, gluconate, and fumarate. All species fail to utilize ribose, fucose, cellobiose, lactose, trehalose, glutarate, and oxoglutarate.

[d]Numbers in parentheses represent the number of strains tested.

Acknowledgments

The description of the genus as given by J.-H. Becking in the 1st edition of the *Manual* remains largely unchanged; information has been reorganized, reevaluated, and updated.

Further Reading

Becking, J.H. 1992. The Genus *Beijerinckia*. *In* Balows (Editor), The Prokaryotes. A Handbook on the Biology Of Bacteria: Ecophysiology, Isolation, Identification, Applications, 2nd Ed., Vol. 3, Springer-Verlag, New York. pp. 2254–2267.

List of species of the genus Beijerinckia

1. **Beijerinckia indica** (Starkey and De 1939) Derx 1950a, 146[AL] (*Azotobacter indicum* (sic) Starkey and De 1939, 337.) *in' di.ca.* L. fem. adj. *indica* of India.

The characteristics are as described for the genus and as given in Tables BXII.α.141 and BXII.α.142, with the following additional information. Straight or slightly curved rods 0.5–1.2 × 1.6–3.0 μm. PHB granules persist in aged cultures. No resting stages occur; neither cyst nor spore formation is observed.

Agar colonies are raised. At first, they are semitransparent but soon become uniformly turbid or opaque white. On aging, the colonies develop a light reddish pink, cinnamon, or fawn color on neutral or alkaline media; on acid media, they remain colorless. On acid media, the slime is more tenacious, tough, and elastic than on alkaline media. Giant colonies may develop, first with a smooth surface (Fig. BXII.α.165), but later with a folded or wrinkled surface (Fig. BXII.α.166).

Liquid media become viscous as cell density increases. Color may be produced, but is less prominent than on agar.

Grows between pH 3.0 and 10.0 (optimum is 4.0–10.0). Temperature range for growth, 10–35°C; no growth at 37°C.

Growth on, and utilization of, nitrate is poor, and N_2 is fixed in preference to utilization of nitrate in the medium (Becking, 1962). Weak growth occurs on malt agar, no growth in plain broth or peptone agar.

Widely distributed in acid tropical soils.

The mol% G + C of the DNA is: 54.7–58.5 (T_m) (De Ley and Park, 1966; De Smedt et al., 1980).

Type strain: Delft E.II.12.1.1, ATCC 9039, DSM 1715, NCIB 8712, WR-119.

GenBank accession number (16S rRNA): M59060.

Derx (1950a) described "*B. indica* biovar alba", which was distinguished by its lack of pigmentation on aging; however, under extreme (alkaline) conditions it produced a pink pigment. In the hierarchical classification of Thompson and Skerman (1979), one co-type (strain WR-236) of *B. indica* biovar alba was placed in *B. indica* subsp. *lacti-*

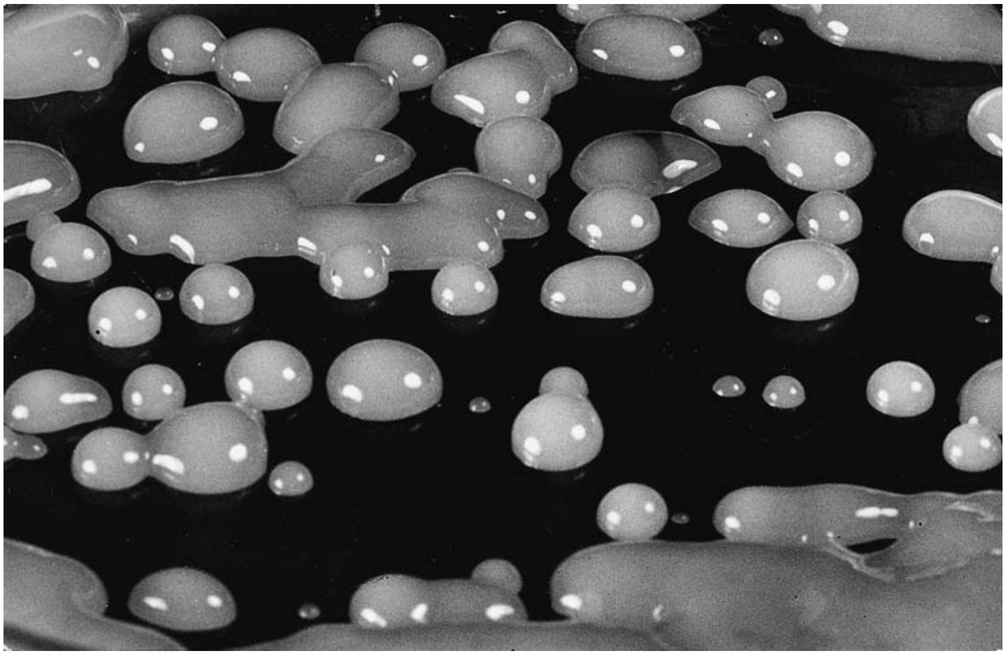

FIGURE BXII.α.165. Typical colony type of *Beijerinckia indica* on nitrogen-free glucose mineral agar. The colonies are highly raised and have a very tough, elastic slime. In young cultures these colonies are colorless and transparent (× 2).

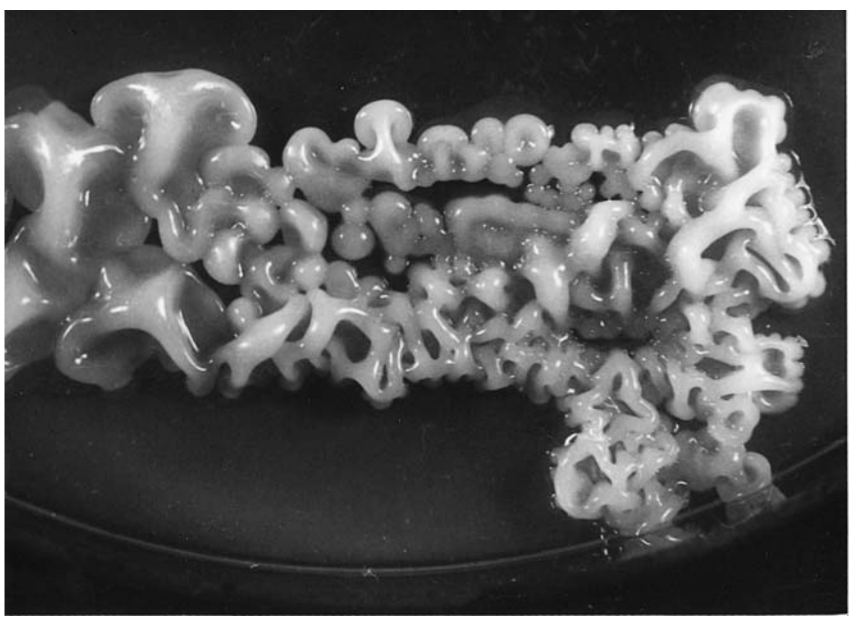

FIGURE BXII.α.166. Typical colony of an aged culture of *Beijerinckia indica* on nitrogen-free glucose mineral agar. The colonies increase greatly in size due to copious slime production. The colonies become massive and opaque, with a plicate surface. In this stage they often attain a light reddish, pink, or cinnamon color, especially on neutral or alkaline media (× 2).

cogenes (group 1270) and the other (strain WR-235) was placed in *B. derxii* subsp. *venezuelae* (group 1271).

a. **Beijerinckia indica** *subsp.* **indica** (Starkey and De 1939) Derx 1950a, 146^{AL} (*Azotobacter indicum* (sic) Starkey and De 1939, 337.)

Thompson and Skerman (1979) distinguished *B. indica* subsp. *indica* from subsp. *lacticogenes* by differences in organic carbon utilization, nitrate reduction, and resistance to peptone-nitrogen. Based on their study of nine strains of subsp. *indica* and four or five strains of

subsp. *lacticogenes*, the only absolute character that differentiated the two subspecies was the failure of subsp. *indica* to utilize *p*-hydroxybenzoate as a sole carbon source. Nitrate was reduced to nitrite by eight of nine strains of subsp. *indica* but not by four of four strains of subsp. *lacticogenes*. The differences in utilization of sole carbon sources by subsp. *indica* vs. subsp. *lacticogenes* were as follows: propan-2-ol, 7/9 vs. 5/5; butan-2-ol, 0/9 vs. 3/5; D-arabitol, 4/9 vs. 1/5; phenol, 0/9 vs. 4/5; caproate, 0/9 vs. 4/5; adipate, pimelate, suberate, azelate, and sebacate, 0/9 vs. 1/5 or 1/4; α-oxybutyrate, 0/9 vs. 1/5; fumarate, DL-malate, tartrate (D, L, and *meso*), oxaloacetate, mucate, and *trans*-aconitate, 9/9 vs. 3–4/5. None of the strains of subsp. *indica* lacked flagella, whereas half the strains of subsp. *lacticogenes* did lack flagella.

The mol% G + C of the DNA is: 54.7–58.5 (T_m) (De Ley and Park, 1966; De Smedt et al., 1980).

Type strain: Delft E.II.12.1.1, ATCC 9039, DSM 1715, NCIB 8712, WR-119.

GenBank accession number (16S rRNA): M59060.

b. **Beijerinckia indica** *subsp.* **lacticogenes** (Kauffmann and Toussaint 1951) Thompson and Skerman 1981, 215[VP] (Effective publication: Thompson and Skerman 1979, 332) (*Azotobacter lacticogenes* Kauffmann and Toussaint 1951, 710)
lac.ti.co′ge.nes. M.L. n. *acidum lacticum* lactic acid; Gr. v. *gennaio* to produce; M.L. adj. *lacticogenes* lactic acid producing (which is an error: acetic acid is produced).

This subspecies is distinguished from *B. indica* subsp. *indica* by the characteristics described above, and by the consistency of the colonies (less elastic and rubbery (cartilaginous) and more butyrous and brittle than those of subsp. *indica*). Moreover, subsp. *lacticogenes* is somewhat less resistant to diamond fuchsin, brilliant green, sodium fluoride, and streptomycin. In contrast to subsp. *indica*, four of five strains of subsp. *lacticogenes* grown on agar containing *p*-hydroxybenzoate could metabolize protocatechuate via the *ortho*-cleavage pathway (Thompson and Skerman, 1979).

The mol% G + C of the DNA is: unknown.

Type strain: WR-119, ATCC 19361.

2. **Beijerinckia derxii** Tchan 1957, 315[AL]
derx′i.i. M.L. gen. n. *derxii* of Derx; named after H.G. Derx, the Dutch microbiologist (1894–1953).

The characteristics are as described for the genus and as given in Tables BXII.α.141 and BXII.α.142, with the following additional information. Single straight or curved rods, or rods with clavate extremities, 1.5–2.0 × 3.5–4.5 µm. Polar lipoid bodies are very large and conspicuous. No cyst or capsule formation occurs. Nonmotile.

Colonies are highly raised, slimy, and smooth. The chemical composition of the slime has not yet been examined. Colonies are at first semitransparent or opaque white, but after 2–3 weeks, a yellow-green, water-soluble, fluorescent pigment is produced, particularly on iron-deficient media. When the pigment first appears it remains within the colony, but later it diffuses into the agar medium. Under certain conditions, pigment production on agar media may be very poor or absent.

Liquid cultures become uniformly turbid and pigment production is usually less than on solid media.

Growth occurs between pH 4.0 and 9.0 (optimum, 6.0–7.0). There is no growth at pH 3.0 or 11.0. Temperature range for growth, 10–35°C; no growth at 37°C.

Isolated from soils from Queensland, Northern Australia, and neutral and alkaline soils of South Africa.

The mol% G + C of the DNA is: 59.1 ± 1.6 (T_m) (De Ley and Park, 1966).

Type strain: Q13 of Tchan, ATCC 49361, DSM 2328, UQM 1968.

a. **Beijerinckia derxii** *subsp.* **derxii** Tchan 1957, 315[AL]

In the hierarchical classification of Thompson and Skerman (1979), the strains within the species *B. derxii* can be divided into two main groups: group 1263 and group 1271. Group 1263 contains a co-type of *B. derxii* Tchan 1957 and three co-type strains of *"Beijerinckia congensis"* Hilger 1965, as well as three Australian isolates. This group was named by Thompson and Skerman (1979) as *B. derxii* subsp. *derxii*. Differences between this subspecies and *B. derxii* subsp. *venezuelae* (group 1271) are not markedly consistent, apart from utilization of nitrate, as outlined below in the description of the subsp. *venezuelae*.

The mol% G + C of the DNA is: not available.

Type strain: Q13 of Tchan, ATCC 49361, DSM 2328, UQM 1968.

b. **Beijerinckia derxii** *subsp.* **venezuelae** (Materassi, Florenzano, Balloni and Favilli 1966) Thompson and Skerman 1981, 215[VP] (Effective publication: Thompson and Skerman 1979, 343) (*Beijerinckia venezuelae* Materassi, Florenzano, Balloni and Favilli 1966, 210.)
ven.e.zue′lae. M.L. gen. n. *venezuelae* of Venezuela, South America.

In the hierarchical classification of Thompson and Skerman (1979), group 1271 is classified as *B. derxii* subsp. *venezuelae*. This group consists of six co-type strains of *"B. venezuelae"* Materassi et al. 1966, one co-type of "*B. indica* biovar alba" Derx 1950a, and three Australian isolates.

Differences between group 1263 (subsp. *derxii*) and group 1271 (subsp. *venezuelae*) are not markedly consistent. In general, strains of group 1271 are distinguished by not utilizing nitrate as a sole source of nitrogen, being nonmotile, not hydrolyzing glycogen, growing over a slightly wider pH range (not more than 0.5 pH unit at each end of the range), and by differences in utilization of several organic compounds as sole sources of carbon. Of 14 strains of subsp. *venezuelae* and 7 strains of subsp. *derxii* tested by Thompson and Skerman (1979), the utilization of these substrates was as follows: melibiose, 5/14 vs. 7/7; propan-2-ol, 6/14 vs. 0/7; L-arabitol, 6/14 vs. 0/7; propionate, 7/14 vs. 0/7; fumarate, 8/14 vs. 1/7; and L-ascorbate, 6/14 vs. 5/7. Eleven of 14 strains of subsp. *venezuelae* used nitrate as a nitrogen source, whereas only 1 of 7 strains of subsp. *derxii* could do so.

The mol% G + C of the DNA is: not available.

Type strain: 2 of Materassi, DSM 2329, WR-222.

Of the six strains of subsp. *venezuelae* provided by G. Florenzano (i.e., strains WR-221 to WR-226), it is not

clear how many independent isolates are represented (Becking, 1984a).

3. **Beijerinckia fluminensis** Döbereiner and Ruschel 1958, 269[AL]
flu.mi.nen' sis. M.L. adj. *fluminensis* named after the locality "Baixada Fluminense", State Rio de Janeiro, Brazil, from which soil it was first isolated.

The characteristics are as described for the genus and as given in Tables BXII.α.141 and BXII.α.142, with the following additional information. Straight or slightly curved rods, 1.0–1.5 × 3.0–3.5 μm. Older cultures show characteristic large capsules enclosing 2–10 or more individual cells. Division of cells within the capsules has been observed. Motility is slow or absent, especially in older cells.

Colonies are typically small and granular, moderately raised, with an irregular rough surface (Fig. BXII.α.167). The slime is not liquid, tenacious, or elastic, but more granular and stiff; its chemical composition has not yet been examined. Colonies are at first opaque white, becoming pink, reddish brown, or fulvous (like *B. indica*) after 1–2 weeks on neutral or alkaline media.

Slime production in liquid media is reduced. No pellicle or viscosity occurs, but a bluish white turbidity develops.

Grows between pH 3.5 and 9.2. Temperature range for growth, 10–35°C (optimum, 26–33°C); no growth at 37°C.

Found in acidic soils of South America, Africa, and Asia (China, Indonesia).

The mol% G + C of the DNA is: 56.2 ± 1.8 (T_m) (type strain) (De Ley and Park, 1966; De Smedt et al., 1980).

Type strain: CD10 of Döbereiner and Ruschel, DSM 2327, UQM 1685.

4. **Beijerinckia mobilis** Derx 1950b, 10[AL] (*Beijerinckia mobile* (sic) Derx 1950b, 10.)
mo' bi.lis. L. fem. adj. *mobilis* movable, motile.

The characteristics are as described for the genus and as given in Tables BXII.α.141 and BXII.α.142, with the following additional information. Straight, curved, or pear-shaped rods, 0.6–1.0 × 1.6–3.0 μm. Misshaped or forked cells sometimes occur. *"Ascococcus"*-like clusters of cells are often visible in older cultures. The typical polar lipoid bodies may disappear in aging cells, and the cells are then more rounded and resemble *Azotobacter* cells (Fig. BXII.α.160). Motility is conspicuous.

Agar colonies are not as raised as those of *B. indica*, and slime production is less (Fig. BXII.α.168). The slime is neither elastic nor sticky; its chemical composition has not yet been examined. Older cultures on neutral or alkaline agar media show a typical dark amber or deep reddish brown color.

Broth cultures do not become viscous. There is a tendency to form a pellicle at the surface.

Grows between pH 3.0 and 10.0. Optimal growth and N_2 fixation occur at pH 4.0–5.0 and decrease sharply at the more alkaline values (Becking, 1961). Temperature range for growth, 10–35°C; no growth at 37°C.

All strains tested have grown well on nitrate or ammonium salts as the nitrogen source (in contrast to *B. indica*). Weak growth or no growth occurs on urea, glycine, glutamate, or tyrosine. All strains grow on leucine and casein agar. Moderate growth occurs on malt agar. The differences in levan production from sucrose observed by Derx (1950b) are variable and cannot be used for differentiation of this species.

Common in Indonesian (Java) soils; also isolated from soils of South America (Surinam) and tropical Africa.

The mol% G + C of the DNA is: 57.3 (T_m) (De Smedt et al., 1980).

Type strain: Delft E.III.12.2, ATCC 35011, DSM 2326, UQM 1969.

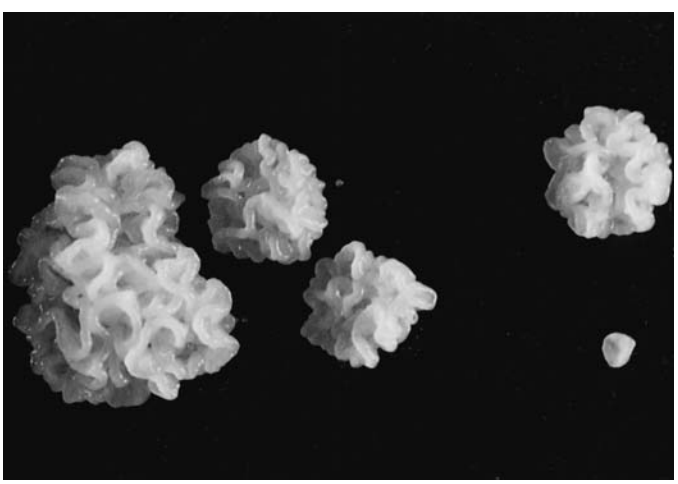

FIGURE BXII.α.167. Typical colonies of *Beijerinckia fluminensis* on nitrogen-free glucose mineral agar. This species forms rather small, raised colonies with a highly plicate surface. In this species the slime has a granular consistency (× 4).

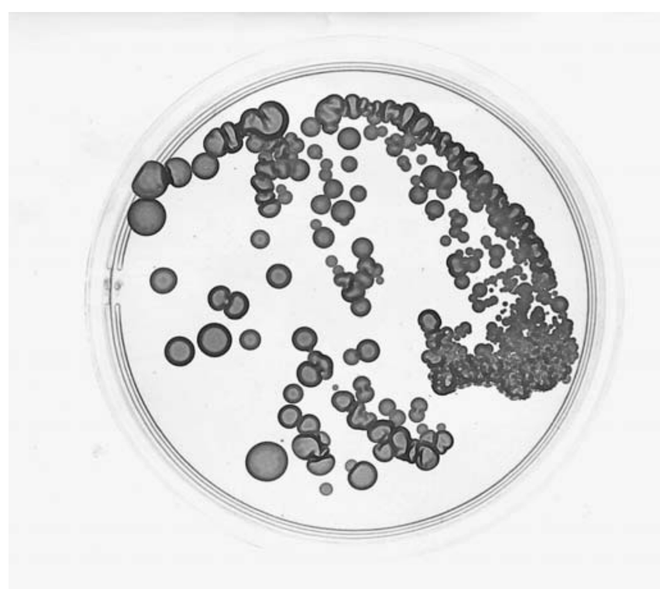

FIGURE BXII.α.168. Colonies of *Beijerinckia mobilis* on a nitrogen-free glucose mineral agar containing $CaCl_2$. On this transparent medium, the species forms only small raised colonies having a typical amber-brown color on aging (× 0.7).

Genus II. **Chelatococcus** Auling, Busse, Egli, El-Banna and Stackebrandt 1993b, 624^{VP} (Effective publication: Auling, Busse, Egli, El-Banna and Stackebrandt 1993a, 109)

THOMAS W. EGLI AND GEORG AULING

Che.la' to.coc.cus. Gr. n. *chele* claw; M.L. v. *chelato* to form claw-like complexes with divalent cations, i.e., to chelate; Gr. n. *coccus* berry, used for a bacterium of roughly spherical shape; M.L. masc. n. *Chelatococcus* chelating coccus.

Short, stout, almost coccoid rods, 0.5–1 × 1–2 μm; resemble diplococci during exponential growth. Gram negative. **Nonmotile. Obligately aerobic.** Optimal growth temperature, 35–37°C; temperature range for growth, 4–41°C. Slow growth with all substrates tested so far (μ_{max} <0.2 h^{-1}). Poly-β-hydroxybutyrate is accumulated within the cells. **Utilize the metal-chelating aminopolycarboxylic acids nitrilotriacetic acid (NTA) and *S,S*-ethylenediaminedisuccinic acid as sole sources of carbon, energy, and nitrogen.** Generally, sugars are not utilized (except for glycerol). **Require one or more vitamins.** All strains are sensitive to β-lactam antibiotics but resistant to nalidixic acid. Ubiquinone Q-10 is present. The main polyamine present is *sym*-homospermidine; putrescine and spermidine occur as major polyamines, and spermine as a minor polyamine.

The mol% G + C of the DNA is: 63.

Type species: **Chelatococcus asaccharovorans** Auling, Busse, Egli, El-Banna and Stackebrandt 1993b, 624 (Effective publication: Auling, Busse, Egli, El-Banna and Stackebrandt 1993a, 110.)

FURTHER DESCRIPTIVE INFORMATION

Morphological features The typical morphology of *Chelatococcus asaccharovorans* is shown in Fig. BXII.α.169a and b. Ultrathin sections reveal a Gram-negative cell envelope with a cytoplasmic membrane, a murein layer 6–8 nm wide, an outer membrane, and an additional proteinaceous surface layer (Fig. BXII.α.169c, d). The murein layer is always in close contact with the outer membrane. The outer proteinaceous crystalline surface layer (S-layer) is approximately 15 nm wide. Its outer side appears smooth, whereas, depending on the plane of sectioning, the inward-facing side of the S-layer exhibits a regular arrangement of protrusions (Fig. BXII.α.169d). This S-layer is a rather brittle structure. Easy detachment of the S-layer may explain the patchy surface structure of deep-etched cells (Fig. BXII.α.169c). It is not yet known whether this is an intrinsic property of the S-layer or an artifact resulting from excessive mechanical stress during preparation of the cells for electron microscopy. Detached patches with a hexagonal arrangement are usually found in the culture medium (Wehrli and Egli, 1988). The repeating units are most probably hexamers, with a central hole and a center-to-center spacing of approximately 16 nm. Since smooth cell surfaces were occasionally observed in deep-etched samples of both strains, the possibility that the S-layer is covered by a further outer protein layer remains. Although such S-layers are common in both prokaryotic domains (*Bacteria* and *Archaea*), their value for taxonomic purposes has not yet been shown (Messner and Sleytr, 1992).

Colony morphology Colonies of *Chelatococcus* are similar in appearance to those of *Chelatobacter* (see Fig. BXII.α.132 in the genus *Chelatobacter*). After 4–5 d incubation at 30°C on complex medium (PCA, Plate Count Agar, Difco), *Chelatococcus asaccharovorans* strain TE1 develops round and smooth colonies with a diameter of 3–4 mm, which appear white-to-beige and mucoid. On selective NTA mineral medium (see below), a different colony morphology is observed with a stereo-microscope, 25-fold magnification. Even well-developed colonies never exceed 0.5 mm in diameter. The smaller colony size on NTA agar (compared to growth on PCA) is probably due to a rise in pH resulting from the excretion of ammonia during growth with NTA as the only source of carbon, energy, and nitrogen. Colonies appear white (incident light) and translucent (transmitted light) when young (1–2 d). With prolonged incubation, the colonies are still white (incident light), but under the stereo-microscope (transmitted light) they appear brown and finally black, and their shape becomes "polygonal" (3–5 d) as shown in Fig. BXII.α.132. *Chelatococcus asaccharovorans* strain TE2 may be a nonmucoid mutant of strain TE1. Colonies are smaller (1 mm after 4–5 d) on both complex and mineral agar. They appear firm and raised on NTA agar.

Cultural characteristics The chemically-defined medium used for isolation, maintenance, and growth of *Chelatococcus asaccharovorans* strains in both batch and chemostat culture contains (g/l distilled water): $MgSO_4 \cdot 7H_2O$, 1.0; $CaCl_2 \cdot 2H_2O$, 0.2; $Na_2HPO_4 \cdot 2H_2O$, 0.41; KH_2PO_4, 0.26; 1 ml of the trace element stock solution described by Pfennig et al. (1981) with NTA as the chelating agent (5.2 g/l), and 1 ml of a vitamin stock solution. The vitamin solution contains (per liter): pyridoxine-HCl, 100 mg; thiamine-HCl, riboflavin, nicotinic acid, D-calcium pantothenate, *p*-aminobenzoic acid, lipoic acid, nicotinamide and vitamin B_{12}, 50 mg each; biotin, 20 mg; and folic acid, 20 mg. This medium is supplemented with either NTA or other carbon and/or nitrogen sources (up to a maximum of 5 g/l carbon). For growth with carbon sources containing no nitrogen, the medium is supplemented with NH_4Cl (0.54 g/l). For isolation and growth on agar plates, this medium was supplemented with 1.5% agar plus NTA (0.5 g/l). Growth is dependent on addition of the above vitamin mixture (Egli et al., 1988) or yeast extract (0.1 g/l).

Growth characteristics Growth in batch culture with NTA as the only carbon/energy and nitrogen source results in the excretion of ammonia, which causes an increase in pH of the culture medium. Under such conditions, growth ceases at approximately pH 9 and after transfer into new medium, the cells exhibit extended lag times (often 5–10 d) until growth resumes. Growth with mixtures of utilizable carbon sources plus NTA results in simultaneous utilization of the two substrates, and in faster growth than with NTA alone. For example, during simultaneous utilization of acetate plus NTA a maximum specific growth rate of 0.13 h^{-1} was reported, compared to 0.07 h^{-1} during growth with NTA alone (see Table BXII.α.115 in the genus *Chelatobacter*).

Nutritional and physiological characteristics For the nutritional and physiological characteristics of *Chelatococcus asaccharovorans* strains and NTA-utilizing *Chelatobacter heintzii* strains, the reader is referred to Table BXII.α.116 in the chapter on the genus *Chelatobacter*. Additional properties of *Chelatococcus asaccharovorans* are as follows. Substrates utilized for growth include acetate, alanine, aspartate, *n*-butanol, citrate, ethanol, *S,S*-ethylenediaminedisuccinate, glutamate, glycerol, glycine, lactate, malate, phenylalanine, propionate, proline, *n*-propanol, isopro-

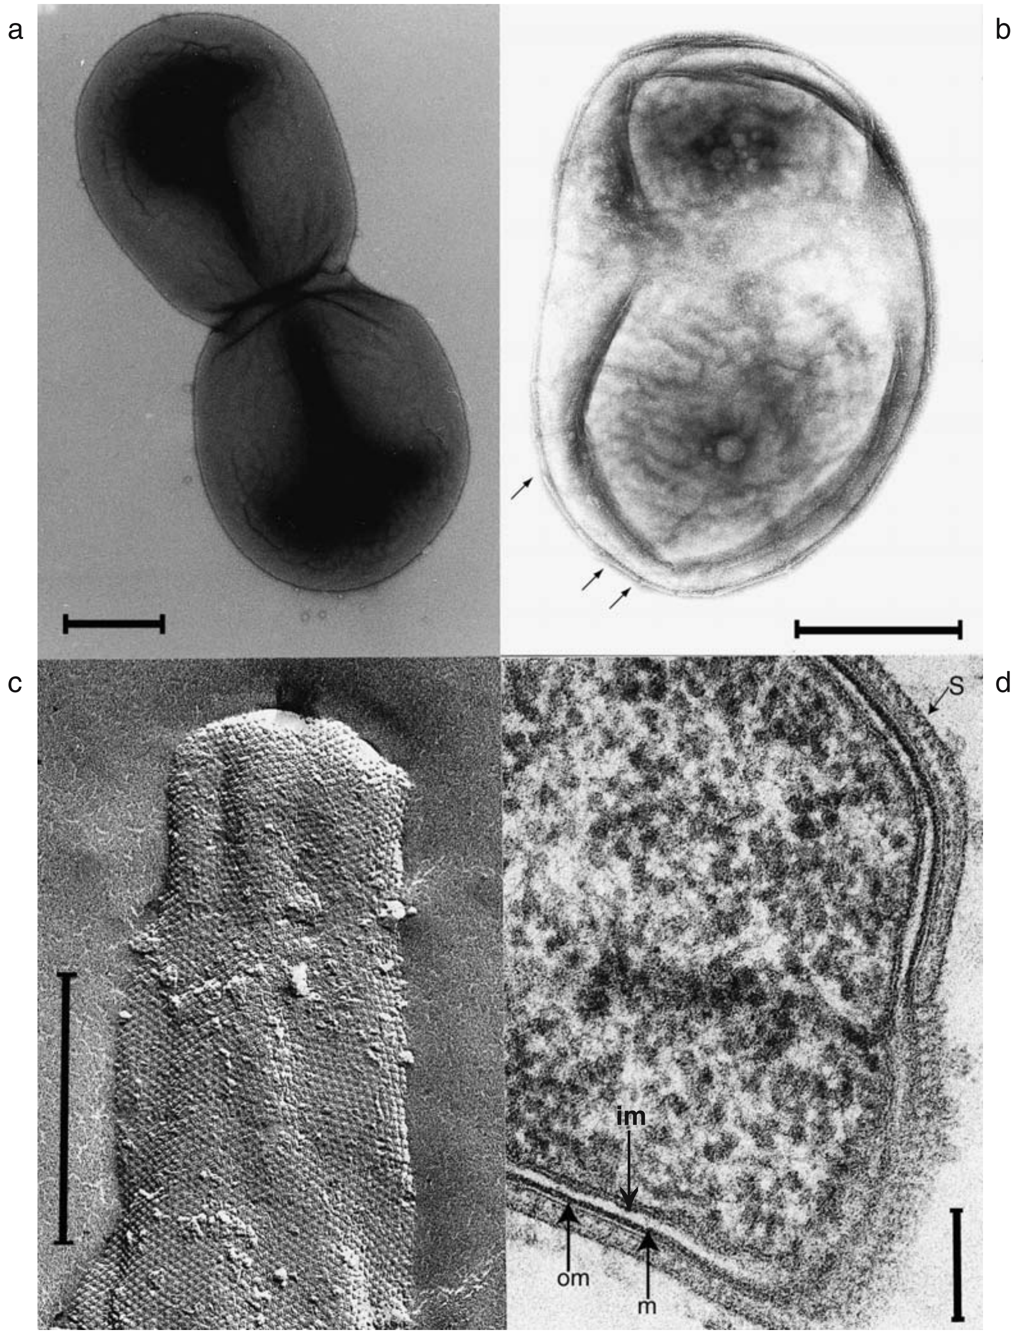

FIGURE BXII.α.169. Morphology of *Chelatococcus asaccharovorans* strains. (*a*), negatively stained cell of isolate TE 1 from the exponential growth phase, bar = 0.5 μm; (*b*), negatively stained cell of isolate TE 2 demonstrating the proteinaceous surface layer; the cracks in the S-layer suggest that it is brittle in nature (*arrows*), bar = 0.5 μm; (*c*), surface layer of strain TE 2 as revealed by deep-etching, note the paracrystalline arrangement of subunits, with a center-to-center distance of 16 nm, and the patchy appearance of the surface layer, bar = 0.5 μm; (*d*), higher magnification of thin-sectioned cell of isolate TE 1 demonstrating the fine structure of the cell wall with inner membrane (*im*), murein layer (*m*), outer membrane (*om*), and proteinaceous surface layer (*s*), bar = 0.1 μm.

panol, pyruvate, succinate, and serine. Substrates not utilized for growth include acetamide, adonitol, aniline, arabinose, L-arabitol, arginine, benzoate, *n*-decane, butyrate, D-(+)-cellobiose, cellulose, erythritol, dimethylformamide, dimethylsulfoxide, esculin, formate, fucose, D-(−)-fructose, galactose, gentiobiose, D-(+)-glucose, glycollate, glycyl-glycine, H_2/CO_2, inositol, lactose, lysine, mannitol, D-(+)-mannose, malate, D-(+)-maltose, methane, methanol, methylacetamide, methyldiethylamine, *N*-(2-acetamido)iminodiacetate, *N*-acetylglucosamine, oxalate, phenol, D-(+)-raffinose, rhamnose, D-(+)-ribose, D-(−)-sorbitol, sucrose, tetraethylammoniumchloride, triethanolamine, tris(hydroxymethyl)aminomethane, urea, xylitol, xylene, and D-(+)-xylose.

Other properties of *Chelatococcus asaccharovorans* strains include the following: no production of indole, H_2S, or acetoin (VP negative); no fermentation of glucose; no hydrolysis of starch or DNA and only weak hydrolysis of protein (skim milk); no dinitrogen fixation; no denitrification with NTA, glucose, or acetate; no acid production from glucose or ethanol; not acid fast; no growth on tellurite agar plates; no growth on mannitol (*Rhizobium*) agar; no gas from glucose; weak growth on gluconate. Growth occurs in the presence of 1% NaCl but not with 10% NaCl.

Metabolism and metabolic pathways A key nutritional feature of members of *Chelatococcus* is their ability to grow with the chelating agent NTA as the only source of carbon, energy, and nitrogen. (For a short overview on the use and importance of aminopolycarboxylates as metal-chelating agents, readers are referred to the chapter on *Chelatobacter*.) The current knowledge is summarized in Fig. BXII.α.133 in the chapter on the genus *Chelatobacter*. The data strongly support an identical catabolic route in both genera, i.e., initially, transport of NTA into the cell, a step which is most probably energy-dependent, and subsequently two enzymatic steps, catalyzed by a soluble NTA-monooxygenase complex and a membrane-bound dehydrogenase. These enzymes are sufficient to degrade NTA to the central metabolites glycine and glyoxylate.

NTA monooxygenase The first intracellular step is catalyzed by a monooxygenase (NTA-Mo). NTA-Mo was originally isolated from *Chelatobacter heintzii* ATCC 29600 as a two-component system consisting of component A (cA) and a FMN-containing protein component B (cB), with both components being present as dimers (Uetz et al., 1992). Using antibodies raised against cA isolated from *Chelatobacter heintzii* ATCC 29600, the presence of cA was confirmed in *Chelatococcus asaccharovorans* strains, whereas no cross reaction was observed in cell-free extracts of *Chelatococcus* strains with antibodies raised against the flavin-containing cB (Uetz et al., 1992). Later, cA purified from *Chelatococcus asaccharovorans* TE 2 was found to be virtually identical to the protein present in *Chelatobacter heintzii* ATCC 29600 (Uetz, 1992), i.e., only 1 out of the first 17 amino acids of cA was different (in position 3 Asn instead of Asp was present in cA purified from *Chelatococcus*). A hybrid enzyme composed of cA purified from *Chelatococcus* and cB from *Chelatobacter heintzii* ATCC 29600 exhibits the typical NTA-Mo activity known from strain ATCC 29600. According to Witschel et al. (1997), cA of *Chelatococcus* acts as a monooxygenase supplied with $FMNH_2$ by an independent FMN oxidoreductase. Recent data suggest that any FMN oxidoreductase can supply reduced FMN to the NTA-Mo (Witschel et al., 1997; Xu et al., 1997). Although not yet investigated in detail, the substrate specificity of NTA-Mo from *Chelatococcus* is probably as narrow as that found for NTA-Mo isolated from *Chelatobacter*, with NTA being the only substrate presently known (Uetz, 1992).

Iminodiacetate dehydrogenase A membrane-bound iminodiacetate dehydrogenase (IDA-DH) catalyses the second enzymatic step during biodegradation of NTA in *Chelatococcus asaccharovorans* strain TE 2, as also occurs in members of *Chelatobacter* (Uetz and Egli, 1993).

Regulation of NTA-degrading enzymes The enzyme system for NTA utilization is inducible (Uetz, 1992) but no detailed information is presently available. Nevertheless, other carbon sources do not seem to repress the synthesis of NTA-utilizing enzymes, as growth in batch culture with mixtures of NTA plus acetate results in the simultaneous utilization of the two substrates concomitant with an enhanced growth rate (Egli et al., 1988; see also Table BXII.α.115 in the chapter describing the genus *Chelatobacter*.).

Genetics Hybridization experiments with different gene probes from *Chelatobacter heintzii* ATCC 29600 strongly indicate that both the genes encoding *ntaA* and the ORF1—which probably encodes a regulatory protein—are present in *Chelatococcus asaccharovorans* strain TE 2 in a similar arrangement as that reported for the *Chelatobacter* strain (Knobel, 1997). This supports the data reported by Uetz (1992) on the N-terminal sequence of NTA-Mo purified from *Chelatococcus* strain TE 2. In contrast, only weak hybridization was found with probes directed towards *ntaB*, confirming the conclusion drawn by Uetz (1992), based on immunological evidence, that quite a different FMN oxidoreductase is supplying $FMNH_2$ to NTA-Mo in this strain.

Antigenic structure Polyclonal antibodies have been raised against whole cells (Wilberg et al., 1993) or isolated cell walls (Bally, 1994) of NTA-utilizing *Chelatobacter* and *Chelatococcus* strains. In Ouchterlony double diffusion or indirect immunofluorescence tests, the antisera raised against the two central NTA-utilizing *Chelatobacter* strains, i.e., *Chelatobacter heintzii* strains TE 6 and ATCC 29600, did not crossreact with cell homogenates from either *Chelatococcus asaccharovorans* strain. Similarly, the antiserum raised against *Chelatococcus asaccharovorans* strain TE 2 did not crossreact with homogenates of the two central strains of *Chelatobacter heintzii* (Wilberg et al., 1993). Crossreaction of *Chelatococcus* antibodies was also tested with a variety of bacteria that were expected to co-exist with *Chelatococcus* in the same habitat, and no crossreaction was found with any of the strains tested (for the strains tested, see the section on antigenic structure in the chapter on the genus *Chelatobacter*).

Antibiotics and drug resistance The susceptibility of *Chelatococcus asaccharovorans* strains TE 1 and TE 2 to a range of antibiotics was tested (Auling et al., 1993a; see Table BXII.α.117 in the chapter on the genus *Chelatobacter*. Both *Chelatococcus asaccharovorans* strains were resistant to cephaloridine, cephalexin, nalidixic acid, vancomycin, and trimethoprim-sulfamethoxazole, but sensitive to penicillin G, carbenicillin, most of the aminoglycosides tested (neomycin, kanamycin, gentamicin, tobramycine, except for streptomycin), and to tetracycline, doxycycline, erythromycin, rifampicin, polymyxin B, and novobiocin. The resistance of *Chelatococcus* strains to nalidixic acid, in combination with their resistance to vancomycin, might be used to isolate such strains with a medium containing NTA as the sole source of carbon and energy, as these two antibiotics would suppress growth of the faster-growing *Chelatobacter* strains.

Ecology Data reported so far indicate that cells of *Chelatococcus* are ubiquitously distributed in the aquatic environment, and that their number increases with both increasing eutrophication and temperature. Cells crossreacting with antibodies raised against *Chelatococcus asaccharovorans* TE 1 (*α-Cc*) have been detected in surface waters and wastewater (Wilberg et al., 1993; Bally, 1994). In surface waters, their numbers were in the order of 1×10^3 to 5×10^5 cells/l (0.03–3‰ of the total bacterial population). Cells of *Chelatococcus* have even been detected in mountain streams with no detectable NTA present and little chance of having been ever exposed to NTA; only in a cold pristine alpine stream were cells crossreacting with *α-Cc* not ob-

served (Bally, 1994). Generally, the number of crossreacting cells increased by several orders of magnitude in nutrient-rich environments such as polluted rivers or wastewater treatment plants. For example, in aerated reactors of two Swiss wastewater treatment plants (with NTA concentrations between 10 and 100 μg/l) numbers of *α-Cc*-crossreacting cells up to 2×10^{11} per liter were observed (in the range of one to a few percent of the total bacterial counts); many of the cells exhibited the typical diplococcoid shape (Bally, 1994). In this environment, members of *Chelatococcus* seem as numerous as strains of *Chelatobacter* or even more so (although these numbers have to be treated with caution considering possible crossreactivity of the antibodies used).

Polyamines and ubiquinones The two *Chelatococcus asaccharovorans* strains studied contained *sym*-homospermidine as the main polyamine compound, putrescine and spermidine as major components, and spermine as a minor component (Auling et al., 1993a). Ubiquinone Q-10 was present in both strains of *Chelatococcus asaccharovorans*.

Soluble protein patterns The soluble protein patterns of *Chelatococcus asaccharovorans* strains have been compared to those of *Chelatobacter heintzii* strains (Auling et al., 1993a). *Chelatobacter* and *Chelatococcus* strains exhibited clearly different patterns, whereas the soluble protein pattern of the two *Chelatococcus* strains tested were virtually identical.

Enrichment and Isolation Procedures

Only two strains of *Chelatococcus* have been isolated to date. Both were isolated with a batch enrichment procedure using NTA as the only source of carbon, energy, and nitrogen (Egli, 1988). However, they were not as easily enriched as members of the genus *Chelatobacter*. The fact that the optimal growth temperature of *Chelatococcus* strains (35–37°C) is considerably higher than that of *Chelatobacter* strains, together with their resistance to vancomycin, might be a way to preferentially enrich members of this genus when using NTA as the only source of carbon and nitrogen for growth.

Maintenance Procedures

Strains can be maintained indefinitely in a freeze-dried condition. Alternatively, cultures grown in SM with NTA and amended with either glycerol (15%, v/v) or DMSO (50%, v/v) can be stored in liquid nitrogen. With either method, revival of cultures may take a while. Best results have been obtained by streaking cultures from liquid nitrogen directly onto SM agar plates containing NTA as the only carbon and nitrogen source. When maintaining cultures on selective NTA agar plates, it is recommended to transfer them to new plates at least every week, because growth leads to an increased pH in and around the colonies. Cells stored under such conditions exhibit long lag phases (up to several weeks) before they restart growing. Cultures grown in liquid media behave similarly. To avoid long lag times and erratic growth responses, it is best to transfer the cells to fresh medium when they are still growing exponentially. Excessive concentrations of NTA, combined with the low buffering capacity of the medium or lack of pH control, might lead to an early cessation of growth.

Procedures for Testing Special Characters

Growth with NTA as the only source of carbon, energy, and nitrogen is a key property of *Chelatococcus*. Consumption of NTA can be measured either by the disappearance of dissolved organic carbon (DOC) paralleled by the excretion of ammonia, or via the consumption of NTA. A HPLC method specially developed for the analysis of NTA in culture media and cell extracts has been described by Schneider et al. (1988).

Differentiation of the genus *Chelatococcus* from other genera

Differentiation of *Chelatococcus* from the closely related genospecies *Methylobacterium organophilum* and *Bradyrhizobium japonicum* (see taxonomic comments) can be easily done, based on the ability to grow with NTA as the sole carbon, nitrogen, and energy source, and the coccobacillary shape of the cells, their nonmotility, and the inability to grow on sugars (Green, 1992; Auling et al., 1993a, or see *Methylobacterium* in this *Manual*).

Taxonomic Comments

The presence of ubiquinone Q-10 (Egli et al., 1988) and the characteristic polyamine pattern, with *sym*-homospermidine as the main polyamine and putrescine plus spermidine as major polyamines (Auling et al., 1993a), clearly allocate the members of the genus *Chelatococcus* to the *Alphaproteobacteria*. Sequencing of a 150-nucleotide 16S rRNA gene fragment (position 1220–1377) revealed nucleotides characteristic of the *Alphaproteobacteria* at specific positions, but a difference of 13 nucleotides between *Chelatococcus* and *Chelatobacter* indicated only a low degree of relationship between these genera (Auling et al., 1993a). This conclusion is supported by the absence of serological crossreaction between both genera of NTA-utilizing bacteria (Wilberg et al., 1993). Recently, analysis of complete 16S rRNA gene sequences revealed that *Methylobacterium organophilum* and *Bradyrhizobium japonicum* are more closely related to *Chelatococcus asaccharovorans* than to *Rhodopseudomonas acidophila* (C. Strömpl, personal communication). The next relative in this group for which 16S rRNA gene sequence data are available is *Beijerinckia indica*, with 94.5% sequence homology (C. Strömpl, personal communication).

A comparison of the complete 16S rDNA sequence of the type strain *Chelatococcus asaccharovorans* strain TE 2 with a partial sequence of strain TE 1 has so far shown identity of the two 16S rRNA genes (C. Strömpl, personal communication).

Acknowledgments

We are indebted to Ernst Wehrli for supplying us with excellent electron micrographs. Also we thank C. Strömpl for supplying us with unpublished information on the phylogenetic position of *Chelatococcus asaccharovorans*. T.E. would like to thank H.U. Weilenmann and the students that have contributed to the study of NTA-utilizing microorganisms. Furthermore, the generous financial support of research on NTA in the laboratory of T.E. by grants from the Swiss National Science Foundation, Lever AG Switzerland and Unilever Port Sunlight, the Research Commission of ETH Zürich, and by EAWAG is gratefully acknowledged.

List of species of the genus Chelatococcus

1. **Chelatococcus asaccharovorans** Auling, Busse, Egli, El-Banna and Stackebrandt 1993b, 624[VP] (Effective publication: Auling, Busse, Egli, El-Banna and Stackebrandt 1993a, 110.)

a.sac.cha.ro.vo′rans. Gr. pref. *a* not; Gr. n. *sacchar* sugar; L. v. *voro* to devour; M.L. part. adj. *asaccharovorans* not devouring sugars.

The characteristics are as described for the genus. To date, only two strains (TE1, DSMZ 6461; TE2, DSMZ 6462) represent the species.

The mol% G + C of the DNA is: 63 (T_m).

Type strain: TE 2, DSM 6462.

GenBank accession number (16S rRNA): AJ294349.

Genus III. **Methylocella** *Dedysh, Liesack, Khmelenina, Suzina, Trotsenko, Semrau, Bares, Panikov and Tiedje 2000, 967*[VP]

THE EDITORIAL BOARD

Me.thyl.o.cel′ la. M.L. n. *methyl* the methyl group; L. n. *cella* a cell; M.L. n. *Methylocella* methyl-using cell.

Encapsulated, nonmotile straight or curved Gram-negative rods (0.6–1.0 × 1.0–2.5 μm). One large **poly-β-hydroxybutyrate granule** at each pole. **Form exospores.** Contain **intracytoplasmic membranes**. **Grow only on C_1 compounds using serine pathway.** Complete TCA cycle. **Fixes N_2.** Major fatty acids are $C_{18:1}$ forms.

The mol% G + C of the DNA is: 61.2.

Type species: **Methylocella palustris** Dedysh, Liesack, Khmelenina, Suzina, Trotsenko, Semrau, Bares, Panikov and Tiedje 2000, 967.

FURTHER DESCRIPTIVE INFORMATION

A single species, *Methylocella palustris*, has been described; three independent isolates have been examined in detail. *Methylocella palustris* inhabits acidic peat bogs in northern Russia and Siberia (Dedysh et al., 1998a, b). Both the temperature range (10–20°C) and the pH range (4.5–7.0) for growth, as well as a requirement for dilute environments, reflect adaptation to this habitat (Dedysh et al., 2000).

Methylocella palustris is able to grow on methane and methanol as sole source of energy and carbon; the serine pathway is the route of carbon fixation. The organisms are able to fix N_2 in microaerobic environments and are able to use nitrate, ammonium ion, and organic nitrogen (Dedysh et al., 2000).

Intracytoplasmic membranes consist of spherical vesicles formed from the cytoplasmic membrane and located next to it. These membranes do not resemble either the vesicular discs found in type I methanotrophs or the laminar membranes found in type II methanotrophs (Dedysh et al., 2000).

Analysis of 16S rDNA sequences showed that *Methylocella palustris* is most closely related to *Beijerinckia indica* and *Rhodopseudomonas acidophila*; it is related to but clearly different from other type II methylotrophs (*Methylocystis* and *Methylosinus* spp.) in the *Alphaproteobacteria* (Dedysh et al., 1998a, 2000). Attempts to PCR-amplify portions of the *pmoA* gene from *Methylocella palustris* isolates using two sets of primers that yielded specific products from *Methylococcus capsulatus* (type X methylotroph), *Methylosinus trichosporium* (type II methylotroph), and *Methylomicrobium album* (type I methylotroph) were unsuccessful. Southern hybridization of *Methylocella palustris* genomic DNA digests with a probe specific for the *Methylococcus capsulatus pmoA* gene produced only weak hybridization at low stringency, further indicating substantial genetic distance between *Methylocella palustris* and other methylotrophs in the *Alphaproteobacteria* (Dedysh et al., 1998a, 2000). An analysis of the fatty acid profiles of methylotrophs of all known metabolic types of methylotrophs (I, II, and X) also showed that *Methylocella palustris* was distinct from all other strains examined (Fang et al., 2000).

ENRICHMENT AND ISOLATION PROCEDURES

Enrichment and isolation procedures have been described by Dedysh et al. (1998a, b). Enrichment required multiple passages and was achieved in dilute liquid mineral medium under a 50% methane:air atmosphere with or without KNO_3 as a nitrogen source.

MAINTENANCE PROCEDURES

Strains can be maintained by subculturing monthly (Dedysh et al., 1998a, b).

DIFFERENTIATION OF THE GENUS *METHYLOCELLA* FROM OTHER GENERA

Dedysh et al. (2001) have developed FISH (fluorescence *in situ* hybridization) probes based on 16S rDNA sequences that can be used to distinguish *Methylocella palustris* from other methylotrophs in enrichment cultures and environmental samples.

List of species of the genus Methylocella

1. **Methylocella palustris** Dedysh, Liesack, Khmelenina, Suzina, Trotsenko, Semrau, Bares, Panikov and Tiedje 2000, 967[VP]

   pa.lus′ tris. L. n. *palus* a bog; M.L. adj. *palustris* bog-inhabiting.

   Description as for the genus with the following additional characteristics. Utilize methane and methanol. Growth optima at pH 5.5 and 20°C. Inhibited by 0.5% NaCl.

   The mol% G + C of the DNA is: 61.2 (T_m).

   Type strain: K, ATCC 700799.

   GenBank accession number (16S rRNA): Y17144.

Family VII. **Bradyrhizobiaceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Bra.dy.rhi.zo.bi.a' ce.ae. M.L. neut. n. *Bradyrhizobium* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Bradyrhizobiaceae* the *Bradyrhizobium* family.

The family *Bradyrhizobiaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Bradyrhizobium* (type genus), *Afipia*, *Agromonas*, *Blastobacter*, *Bosea*, *Nitrobacter*, *Oligotropha*, *Rhodoblastus*, and *Rhodopseudomonas*.

The family is phenotypically, metabolically, and ecologically diverse. It includes organisms that fix N_2, photosynthetic organisms, organisms capable of aerobic and/or anaerobic respiration, and human pathogens.

Type genus: **Bradyrhizobium** Jordan 1982, 137.

Genus I. **Bradyrhizobium** *Jordan 1982, 137*[VP]

L. DAVID KUYKENDALL

Bra.dy.rhi.zo' bi.um. Gr. adj. *bradus* slow; M.L. neut. n. *Rhizobium* a bacterial generic name; M.L. neut. n. *Bradyrhizobium* the slow (growing) rhizobium.

Rods 0.5–0.9 × 1.2–3.0 µm. **Commonly pleomorphic under adverse growth conditions.** Usually contain granules of poly-β-hydroxybutyrate that are refractile by phase-contrast microscopy. **Nonsporeforming. Gram negative. Motile by one polar or subpolar flagellum.** Fimbriae have not been described. **Aerobic, possessing a respiratory type of metabolism with oxygen as the terminal electron acceptor. Optimal temperature 25–30°C.** Optimal pH, 6–7, although lower optima may be exhibited by strains from acid soils. Colonies are circular, opaque, rarely translucent, white, and convex, and tend to be granular in texture; they do not exceed 1.0 mm in diameter in less than 5–6 days incubation on A1EG medium. **Turbidity develops only after 3–4 days in agitated broth. Generation times are 9–18 h.** Chemoorganotrophic, utilizing a range of carbohydrates and salts of organic acids as carbon sources, without gas formation; arabinose and other pentoses are preferred carbon sources. Cellulose and starch are not utilized. Produce an alkaline reaction in mineral salts medium containing mannitol and/or many other carbohydrates. **Growth on carbohydrate media is usually accompanied by extracellular polysaccharide slime production particularly with glycerol, gluconate, or mannitol.** Some strains can grow chemolithotrophically in the presence of H_2, CO_2, and low levels of O_2. Ammonium salts, usually nitrates, and some amino acids, can serve as nitrogen sources. Peptone is poorly utilized (except for strains isolated from *Lotononis*). Casein and agar are not hydrolyzed. There is usually no requirement for vitamins with the rare exception of biotin, which also may be inhibitory to some strains. 3-Ketoglycosides are not produced (Bernaerts and De Ley, 1963). **The organisms are characteristically able to enter the root hairs of tropical-zone and some temperate-zone leguminous plants (family Leguminosae) and incite the production of root nodules, in which the bacteria occur as intracellular nitrogen-fixing symbionts.** Some strains, especially *B. elkanii*, fix nitrogen in the free-living state when examined under special conditions.

The mol% G + C of the DNA is: 61–65.

Type species: **Bradyrhizobium japonicum** (Kirchner 1896) Jordan 1982, 137 (*"Rhizobacterium japonicum"* Kirchner 1896, 221; *Rhizobium japonicum* (Kirchner 1896) Buchanan 1926, 90.)

FURTHER DESCRIPTIVE INFORMATION

In young cultures, cells are short rods but in older cultures or under adverse growth conditions, such as low concentrations of calcium or magnesium, cells are commonly pleomorphic (swollen and elongated). Older cells stain to give a banded appearance because of large accumulations of poly-β-hydroxybutyrate. Within the root nodules the bacteroids are rod shaped and slightly swollen but not branched or highly distorted, and they contain polyphosphate inclusions as well as poly-β-hydroxybutyrate accumulations.

All strains produce large amounts of water-soluble extracellular polysaccharide. The main constituent is acidic heteropolysaccharide (80–90%); the remainder is neutral β-1,2-, β-1-3-, and α-1,2-glucans (Breedveld and Miller, 1994). About six different types of acidic heteropolysaccharides have been noted in an examination of 30 or more strains of *Bradyrhizobium* and possess three distinctive features: (a) heterogeneity in composition and structure, (b) the frequent presence of methylated sugars (Dudman, 1976, 1978; Kennedy and Bailey, 1976), and (c) the presence of D-galacturonic acid (Dudman, 1976) in some strains.

Young cells are motile with one polar or subpolar flagellum. Growth on carbohydrate-containing solid media is clear, translucent, or opaque white with a tendency to become tan on prolonged incubation. Colonies of bacteria from *Lotononis bainesii* are pink to deep red but those from *Lotononis angolensis* are colorless.

Most strains grow on a chemically defined minimal medium with arabinose as a carbon source and NH_4Cl as the sole source of nitrogen (Kuykendall, 1987). All strains grow on a buffered mineral salts medium containing yeast extract and either glucose, galactose, gluconate, glycerol, fructose, or arabinose. Disaccharides such as lactose and sucrose are usually not used. Colony-type derivatives differing in symbiotic nitrogen fixation ability and carbon source utilization occur (Kuykendall and Elkan, 1976) (Fig. BXII.α.170).

As with *Rhizobium*, *Bradyrhizobium* strains lack the ability to absorb Congo red from a yeast extract–mannitol–mineral salts medium containing this dye (0.0025% final concentration). The colonies are colorless white or very faintly pink colonies, whereas most other soil bacteria produce colonies that are red on this differential medium.

The optimal temperature for most strains is 25–30°C. The maximum growth temperature ranges from 33–35°C, with many strains failing to grow above 34°C. Usually acid-tolerant with most strains growing at pH 4.5. Over 30% of the strains will grow at pH 4.0 and a few as low as pH 3.5. Growth usually does not occur above pH 9.0.

An alkaline reaction is produced in litmus milk without the production of a clear, upper serum zone.

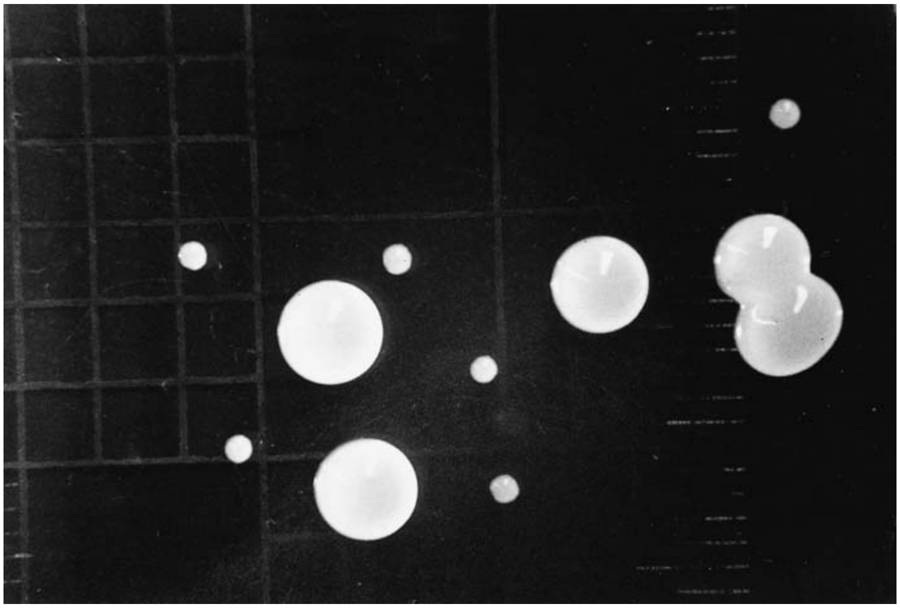

FIGURE BXII.α.170. *Bradyrhizobium japonicum* strain USDA 110 derivatives I-110 (smaller colonies) and L1-110 (larger colonies) after 14 d incubation at 30°C grown on HM salts agar (Cole and Elkan, 1973) with yeast extract (0.25 g/l), L-arabinose (0.5 g/l), and D-mannitol (5.0 g/l).

Bradyrhizobium strains fail to grow in media containing 2% NaCl, do not produce H_2S, and do not form a precipitate in calcium glycerophosphate medium (Hofer, 1941). Penicillinase production is common.

The Entner–Doudoroff pathway is employed in carbohydrate degradation (Martínez-De Drets and Arias, 1972; Mulongoy and Elkan, 1977) with the simultaneous operation of the Embden–Meyerhof–Parnas pathway (Mulongoy and Elkan, 1977). Low levels of fructose-1,6-bisphosphate aldolase are present, however. $NADP^+$-dependent 6-phosphogluconate dehydrogenase is not present but an NAD-linked 6-phosphogluconate dehydrogenase occurs, suggesting operation of a new pathway. The tricarboxylic acid cycle operates in both free-living cells (Keele et al., 1969; Mulongoy and Elkan, 1977) and in symbiotic bacteroids from root nodules (Stovall and Cole, 1978). A pathway for the direct oxidation of gluconate by the tricarboxylic acid cycle, via 2-keto- and 2,5-diketogluconate and α-ketoglutarate, has been described by Keele et al. (1970). Many differences in carbon metabolism between fast-growing *Rhizobium* and slow-growing *Bradyrhizobium* were described by Elkan and Kuykendall (1982); they seem especially significant since these genera are now in separate families.

The ability to take up H_2 was shown by the laboratory of Dr. Harold J. Evans to be a key determining factor in the efficiency of symbiotic nitrogen fixation, because without this capability the nodules evolve large quantities of H_2 as a byproduct of the nitrogenase enzyme action. Some strains do not evolve any H_2; such strains possess an active uptake hydrogenase, which also enables them to grow chemolithotrophically in an atmosphere of $H_2/CO_2/O_2$ (10:15:1) (the balance being N_2). Under such conditions, ribulose bisphosphate carboxylase is primarily responsible for the fixation of CO_2 (Hanus et al., 1979; Lepo et al., 1980). Mutants unable to grow chemolithotrophically fall into several classes, including those impaired in H_2 uptake and those deficient in CO_2 uptake (Maier, 1981).

Nitrogenase activity by free living cells occurs in certain strains but only in media containing selected carbon sources and under a low level of oxygen (Keister, 1975; Kurtz and LaRue, 1975; McComb et al., 1975; Pagan et al., 1975).

Auxotrophic mutants (Kuykendall, 1981) were characterized by Wells and Kuykendall (1983) and Kummer and Kuykendall (1989). Most tryptophan-requiring mutants do not nodulate soybeans but those that specifically lack only tryptophan synthetase do form nodules. An indole glycerol phosphate-requiring mutant, strain TA-11, was discovered to produce phenotypic revertants having the capacity to quantitatively form more nodules (Hunter and Kuykendall, 1990; Kuykendall and Hunter, 1991).

Host specificity, nitrogen fixation (*nif*) and nodulation (*nod*) genes have been analyzed (Kaluza and Hennecke, 1984; Lamb and Hennecke, 1986; Nieuwkoop et al., 1987; Banfalvi et al., 1988; Gottfert et al., 1990a, b, 1992; Sadowsky et al., 1991; Wang and Stacey, 1991; Barbour et al., 1992; Dockendorff et al., 1994; and Stacey et al., 1994). Unlike the fast-growing *Rhizobiaceae*, *Bradyrhizobium* strains have only one rRNA operon (Kundig et al., 1995). A correlated physical and genetic map is available and all *nif* and *nod* genes are contained in a large but discrete region of the 8700 kb chromosome (Kundig et al., 1993). Kaneko et al. (2002) recently reported the complete polynucleotide sequence of *B. japonicum* USDA 110. Much is known about the function, organization and sequence of symbiosis-controlling genes (see reviews by Schultze et al., 1994; Stacey et al., 1995; van Rhijn and Vanderleyden, 1995). Kaluza et al. (1985) demonstrated the presence of a repeated DNA sequence, RSα, clustered around the symbiosis-controlling region of the genome, and Minamisawa et al. (1998) recently described some new strains with an unusually high RSα copy number.

Bacteriophages active against *Bradyrhizobium* have been isolated from soil (Hashem et al., 1986). Bacteriocins have been reported (Roslycky, 1967).

Bradyrhizobium strains are often resistant to a number of anti-

biotics (tetracyclines, streptomycin, penicillin G, viomycin, vancomycin), but are said to be more sensitive to growth inhibitors such as D-alanine or ethidium bromide (Jordan, 1984c).

Bradyrhizobium strains cause nodule production on *Glycine* (soybean), *Vigna* (cowpea), *Macroptilium* (siratro), certain species of *Lotus*, and a wide variety of leguminous plants that are also nodulated by *Mesorhizobium loti*, such as *Acacia*. In fact there appear to be three distinct groups of *Acacia* species: one group nodulated by *M. loti*, one group nodulated by *Bradyrhizobium* sp. (*Acacia*) and one group nodulated by both of these species (Dreyfus and Dommergues, 1981). As with *Rhizobium*, *Bradyrhizobium* strains produce specific Nod Factors thought to control host specificity (Dénarié et al., 1992; Carlson et al., 1993; Stacey et al., 1995).

A highly specific nodulation of the nonleguminous plant *Parasponia* (*Trema*) is caused by a strain of *Bradyrhizobium* (Trinick, 1973, 1976). This is the only completely validated instance of plant nodulation that occurs outside of the Leguminosae.

Enrichment and Isolation Procedures

Isolation from root nodules and soil is by the techniques described for the genus *Rhizobium* of the *Rhizobiaceae*.

Maintenance Procedures

A suitable maintenance medium is A1EG (Kuykendall, 1987) or arabinose enriched (0.1% yeast extract) gluconate, as given by Kuykendall et al. (1988). Storage recommendations are the same as given for *Rhizobium*, except *Bradyrhizobium* persists on agar slants in tightly closed screw-capped tubes for more than five years at 4°C.

Procedures for Testing Special Characters

For antibiotic resistance determinations, Petri dishes containing about 25 ml of A1EG agar medium containing a specific concentration of antibiotic are streaked for isolation with about 10 μl of a fresh 3–5 day-old broth culture. Growth of isolated colonies is determined visually after 10 d incubation. Resistance to a particular concentration is defined as the ability of a strain to form colonies at that concentration.

Differentiation of the genus *Bradyrhizobium* from other genera

The ability to fix nitrogen symbiotically in association with legumes is the primary characteristic that distinguishes *Bradyrhizobium* from other closely related genera in the new family *Bradyrhizobiaceae*. It is easily differentiated from the not so closely-related, relatively fast-growing, legume-nodulating microsymbionts in *Mesorhizobium*, *Rhizobium*, and *Azorhizobium* (Table BXII.α.143).

Taxonomic Comments

In the first edition of *Bergey's Manual of Systematic Bacteriology*, *Bradyrhizobium* was still in the family *Rhizobiaceae*. The genus *Rhizobium* had previously been subdivided into two groups, distinguished by their growth rate in yeast extract–mannitol–mineral salts medium, flagellar arrangement, DNA base composition and the genera of host plants nodulated (Jordan and Allen, 1974). Jordan (1982) transferred the slow-growing root nodule bacteria into a new genus, *Bradyrhizobium*, separate from the fast growing, acid-producing, nodulating bacteria, which subsequently were placed in genera of their own. This revision resulted from numerous studies involving numerical taxonomy (Graham, 1964; Moffett and Colwell, 1968), DNA base ratios (Wagenbreth, 1961; De Ley and Rassel, 1965), nucleic acid hybridization (Heberlein et al., 1967; Gibbins and Gregory, 1972), cistron similarities (De Smedt and De Ley, 1977), serology (Graham, 1963; Vincent and Humphrey, 1970; Humphrey et al., 1973; Vincent, 1977), composition of extracellular gum (Dudman, 1976; Kennedy, 1976; Kennedy and Bailey, 1976; Dudman, 1978), carbohydrate metabolism (Martínez-De Drets and Arias, 1972), bacteriophage sensitivity (Napoli et al., 1980), antibiotic sensitivity (Strzelcowa, 1968), protein composition (Roberts et al., 1980), and type of bacteroid inclusion bodies (Craig et al., 1973). Based on 16S rRNA sequences analyses, *Bradyrhizobium* is now grouped with phylogenetically related organisms in a new separate family, the *Bradyrhizobiaceae*.

Three species of *Bradyrhizobium* are presently recognized; at least 16 genomospecies have also been isolated (Lafay and Burdon, 1998).

In the first edition of *Bergey's Manual of Systematic Bacteriology*, the genus *Bradyrhizobium* had only one recognized species, *B. japonicum*. However, DNA–DNA hybridization studies by Hollis et al. (1981) had earlier suggested that a subset of strains in *B. japonicum* could perhaps be separated into a distinct species, and that two DNA homology groups of bona fide *B. japonicum* existed as well. *B. elkanii* (Kuykendall et al., 1992, 1993b; Devine and Kuykendall, 1996) was named to recognize a species of *Bradyrhizobium* bacteria clearly distinct from *B. japonicum*. Extra-slow-growing strains from alkaline soils were then named *Bradyrhizobium liaoningense* Xu et al. (1995).

The taxonomic position of nodule bacteria from the pasture legume *Lotononis* is uncertain (Norris, 1958). Isolates from *L. bainesii* are red because of an intracellular red carotenoid pigment, although isolates from *L. angolensis* are nonpigmented. As with other strains of *Bradyrhizobium*, these strains are monotrichous, grow slowly, and produce an alkaline reaction and no serum zone in litmus milk; however, cultured cells appear as enlarged, banded ovoids. Resistance of these strains to ultraviolet light is greater than that exhibited by other strains of *Bradyrhizobium* or of *Rhizobium* (Law, 1979). They also utilize peptone, are not recognized by antisera that detect other slow growers or species of *Rhizobium*, and the mol% G + C of the DNA is 68–69 (T_m) (Godfrey, 1972). Nodulation by these strains is extremely specialized. Nodulation by *Lotononis* spp. and *Macroptilium atropurpureum* is effective, whereas by selected species of *Aeschynomene* and *Crotolaria* is ineffective.

Comments concerning *Sinorhizobium fredii* (Scholla and Elkan, 1984; Chen et al., 1988b) are presented under Taxonomic Com-

TABLE BXII.α.143. Phenotypic differentiation of *Bradyrhizobium* from other genera of nodule-forming, nitrogen-fixing legume microsymbionts

Characteristic	*Bradyrhizobium*	*Azorhizobium*	*Mesorhizobium*
Grows *in vitro* on fixed N	−	+	−
Fixes nitrogen *ex planta*	+	+	−
Slow doubling times, >8h	+	−	−

ments for the genus *Rhizobium*. These fast growing root-nodule bacteria are capable of producing effective nodules on *Glycine soja* and *G. max* cv Peking, but ineffective nodules on commercial lines of soybean.

Acknowledgments

The author appreciates Dr. Bob Davis, Research Leader of the Molecular Plant Pathology Laboratory, for support and encouragement, thanks Dr. Thomas E. Devine whose collaboration and friendship made a real difference, and was indebted to Professors Gerald Elkan and Hauke Hennecke who were mentors. Drs. Fawzy Hashem, Babita Saxena, Jim Hunter, Greg Upchurch, Mulongoy Kalemani, Gail Hollowell, Robin Kummer, Margaret Roy, Ketan Shah, Matthias Hahn, Bill Gillette, Susan Wells, and Tom Wacek all helped investigate the properties of *Bradyrhizobium*.

Differentiation of the species of the genus *Bradyrhizobium*

While *B. elkanii* and *B. japonicum* are readily distinguished by a variety of phenotypic analyses, there is a paucity of data available on qualitative differences between *Bradyrhizobium liaoningense* and the two previously named species (Table BXII.α.144). This highlights the need for phenotypic characterization of the third species.

List of species of the genus Bradyrhizobium

1. **Bradyrhizobium japonicum** (Kirchner 1896) Jordan 1982, 137[VP] (*"Rhizobacterium japonicum"* Kirchner 1896, 221; *Rhizobium japonicum* (Kirchner 1896) Buchanan 1926, 90.)
ja.po′ni.cum. M.L. adj. *japonicum* pertaining to Japan.

The characteristics are as described for the genus and as indicated in Table BXII.α.144. Whole cell fatty acid content is 1.3% $C_{16:1\ \omega7c}$, 3.6% $C_{16:1}$, 8.8% $C_{16:0}$, 1.2% $C_{19:0\ cyclo}$, and 81.2% $C_{18:1}$, when grown on A1EG agar medium at 30°C for 6 days. Resistant to trimethoprim at 50 mg/l and to vancomycin at 100 mg/l but sensitive to nalidixic acid (50 mg/l), tetracycline (100 mg/l), streptomycin (100 mg/l), erythromycin (250 mg/l), chloramphenicol (500 mg/l), rifampicin (500 mg/l), and carbenicillin (500 mg/l). Does not grow on Beringer's TY Medium that is used to grow *Rhizobium*. The exocellular polysaccharide contains glucose, mannose, galacturonic acid, and galactose. Denitrification positive. Bacteroids in root nodules are usually viable when plated onto media. Cells of *B. japonicum* have one polar or subpolar flagellum. The species normally causes the formation of root nodules on species of *Glycine* (soybean) (see Fig BXII.α.171) and on *Macroptilium atropurpureum* (siratro). Some strains express hydrogenase activity with the soybean host and thus are more efficient in symbiotic nitrogen fixation.

The mol% G + C of the DNA is: 61–65 (T_m).
Type strain: USDA 6, ATCC 10324, DSMZ 30131.
GenBank accession number (16S rRNA): U69638, X87272.

2. **Bradyrhizobium elkanii** Kuykendall, Saxena, Devine, and Udell 1993b, 398[VP] (Effective publication: Kuykendall, Saxena, Devine, and Udell 1992, 504.)
el.ka′ni.i. M.L. n. *elkanii* of G.H. Elkan.

Most characteristics are as described for the genus and as indicated in Table BXII.α.144. Unlike *B. japonicum*, *B. elkanii* readily fixes nitrogen *ex planta*, strains generally produce indole acetic acid in liquid or broth cultures, they produce at least some growth on TY medium, and they generally grow at 34°C or higher temperatures. Strains are better established in the southeastern United States than the rest of the country. Whole cell fatty acid content is 0.5% $C_{16:1}$, 11.1% $C_{16:0}$, 0.8% $C_{17:0\ cyclo}$, 24.7% $C_{19:0\ cyclo}$, and 62.3% $C_{18:1}$, when grown on A1EG agar medium at 30°C for 6 days. Like *B. japonicum*, it is resistant to trimethoprim at 50 mg/l and to vancomycin at 100 mg/l. Unlike *B. japonicum*, *B. elkanii* is resistant to nalidixic acid (50 mg/l), tetracycline (100 mg/l), streptomycin (100 mg/l), erythromycin (250 mg/l), chloramphenicol (500 mg/l), rifampicin (500 mg/l), and carbenicillin (500 mg/l). The exocellular polysaccharide contains rhamnose and 4-*o*-methyl-glucuronic acid. Cells lack nitrite reductase activity but can possess the ability to reduce nitrate to nitrite. The species normally causes the formation of root nodules on species of *Glycine* (soybean), non-nodulating *rj1rj1* soybean, black-eyed peas (*Vigna*), mungbean, and on *Macroptilium atropurpureum* (siratro). Unlike *B. japonicum*, *B. elkanii* often produces rhizobitoxine-induced chlorosis on sensitive soybean cultivars (Devine et al., 1988; 1990). Strains often are hydrogenase positive on *Vigna* but not *Glycine*, suggesting more symbiotic affinity or compatibility with the former than the latter. *B. elkanii* may have originated on a continent other than Asia, where *B. japonicum* originates. Bottomley et al. (1994) used

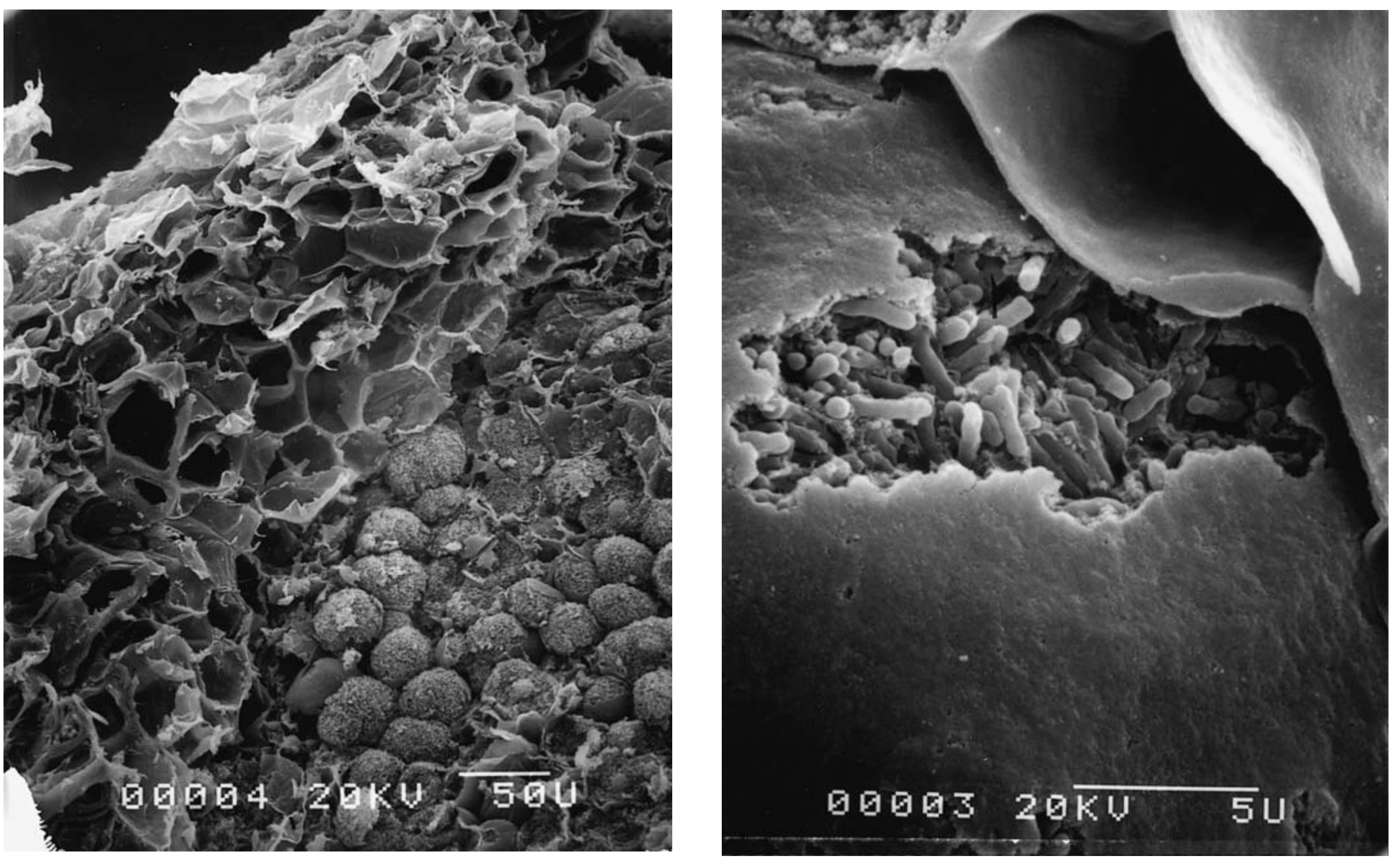
[a]For symbols, see standard definition; L, low; H, high; NR, not reported.

multilocus enzyme electrophoresis to confirm the genetically distinct lineages of *B. japonicum* and *B. elkanii*. The data of Barrera et al. (1997) indicate that many Mexican *Lupinus*-nodulating bacteria belong to *B. elkanii* but some are *B. japonicum*.

The mol% G + C of the DNA is: 61–65 (T_m).
Type strain: USDA 76, ATCC 49852, DSMZ 11554.
GenBank accession number (16S rRNA): U35000.

3. **Bradyrhizobium liaoningense** Xu, Ge, Cui, Li and Fan 1995, 706[VP]



li.a.o.ning.en' se. M.L. adj. *liaoningense* referring to a province in China where they originated.

This species consists of extra-slow-growing bradyrhizobia from alkaline soils. Colonies are only 0.2–1.0 mm on YMA medium (recipe given in *Rhizobium* chapter) after 7–14 days. Unlike *B. elkanii*, this species is more susceptible to antibiotics at low concentrations. Numerical taxonomy and serotyping were also used to establish an identity for this species apart from the two previously described species. A representative strain, 2062, had less than 25% DNA homology with strains of either *B. japonicum* or *B. elkanii*.

The mol% G + C of the DNA is: 61–65 (T_m).
Type strain: 2281.
GenBank accession number (16S rRNA): X86065.
Additional Remarks: This sequence is not from the type strain.

Other Organisms

Ladha and So (1994) used numerical taxonomy to show that *Bradyrhizobium* sp. (*Aeschynomene*) strains may constitute a separate taxon from *B. japonicum* and *B. elkanii* but FAME and 16S rRNA sequence data did not support this hypothesis (So et al., 1994). Wong et al. (1994) demonstrated that *Bradyrhizobium* spp. (*Aeschynomene*) are closely related to *B. japonicum*. Other *Bradyrhizobium* species are known to occur but have not yet been named. For example, the fatty acid data of Graham et al. (1995) clearly document distinct microorganisms. Dupuy et al. (1994) established that *Acacia*-nodulating *Bradyrhizobium* strains in Africa corresponded to either *B. japonicum*, *B. elkanii*, or one or more as yet unnamed *Bradyrhizobium* spp. Related organisms cause nodule production on certain species of *Lotus* (*L. uliginosus* and *L. pedunculatus*) and also on *Vigna* and species of *Lupinus*, *Ornithopus*, *Cicer*, *Sesbania*, *Leucaena*, *Mimosa*, *Lablab*, and *Acacia*, which are also nodulated by the relatively fast-growing species *Mesorhizobium loti*. Such strains also usually nodulate *Macroptilium* and, more rarely, *Glycine*. It is suggested that until such time as further species or biovars are created within the genus *Bradyrhizobium*, these organisms (other than the species described above) be desig-

(*A*) Plant cells filled with viable bacteria are in the center portion. (*B*) The cell wall of a bacteria-filled cell was partially torn away, showing the rod-shaped bacteria within. (EM micrographs were taken in the laboratory of Dr. Bill Wergin at Beltsville, MD.)

nated as *Bradyrhizobium* sp. with the name of the appropriate host plant given in parenthesis immediately following; e.g., *Bradyrhizobium* sp. (*Acacia*). A number of *Bradyrhizobium* sp. (*Arachis*) strains were found to be closely related to *B. japonicum* (Van Rossum et al., 1995).

Genus II. **Afipia** *Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger 1992, 327^VP (Effective publication: Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger, 1991, 2457.)*

Robbin S. Weyant and Anne M. Whitney

A.fip' i.a. L. fem. n. *Afipia* derived from the abbreviation AFIP, for the Armed Forces Institute of Pathology, where the type strain of the type species was isolated.

Gram-negative rods in the *Alphaproteobacteria*. **Motile** by means of one or two polar, subpolar, or lateral flagella. **Optimal growth is obtained at 30°C** and growth does not occur at or above 42°C. Grows well on buffered charcoal yeast extract (BCYE) agar and in nutrient broth with 0% added NaCl. Growth does not occur in nutrient broth with 6% added NaCl and is not enhanced by increased CO_2. Colonies are gray-white, glistening, convex and opaque, 0.5–1.5 mm in diameter at 72 hours of incubation at 30°C on BCYE agar. Nonfermentative metabolism; acid is not produced from D-glucose, lactose, maltose, or sucrose. **Positive for oxidase, urease, and litmus milk alkalinization**. Negative for hemolysis, gas production from nitrate, production of indole and H_2S (triple sugar iron agar method), and hydrolysis of gelatin and esculin. Isolated from potable water. Associated with human infection. Interrelatedness of species by DNA–DNA hybridization is 12–69%.

The mol% G + C of the DNA is: 61.5–69.

Type species: **Afipia felis** Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O' Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger 1992, 327 (Effective publication: Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger, 1991, 2458.)

Further descriptive information

Phylogenetic treatment On the basis of DNA hybridization and phenotypic characterization, the genus *Afipia* currently contains 3 named species, *Afipia felis*, *A. broomeae*, and *A. clevelandensis* as well as three unnamed genomospecies (Brenner et al., 1991a). When compared with other members of the *Alphaproteobacteria* by 16S rDNA sequence analysis, *Afipia* species are intermingled with species of *Rhodopseudomonas*, *Bradyrhizobium*, *Nitrobacter*, and *Blastobacter* as shown in the phylogenetic tree in Fig. BXII.α.172. The 16S rRNA genes of *A. felis*, *A. broomeae*, and *A. clevelandensis* share 97.6–98.5% similarity to each other, and 97.0–98.5% to *Afipia* genomospecies 3, *Rhodopseudomonas palustris*, *Nitrobacter winogradskyi*, *Nitrobacter hamburgensis*, *"Bradyrhizobium lupini"*, *Bradyrhizobium japonicum*, and *Blastobacter denitrificans*. The high degree of sequence similarity supports Willems and Collins' proposal that these species could be classified as members of a single genus (Willems and Collins, 1992). The 16S rRNA sequences for *Afipia* genomospecies 1 and 2, however, are 95–95.9% similar to those of the named *Afipia* species and *Afipia* genomospecies 3.

Eleven additional genomospecies have been tentatively included in the genus *Afipia* based on phenotypic characteristics, chemotaxonomy, and DNA relatedness (Weyant et al., unpublished data). These strains are described in the section Other Organisms.

Cell and flagella morphology *Afipia* cells can be visualized using the Gram stain and other common staining techniques. Gram-stained preparations of 48-hr BCYE cultures show short to medium-length (>1.0 μm) Gram-negative rods of medium width (>0.5 μm). Cells are randomly distributed and do not form chains or clusters. Motility is achieved by one or two polar or subpolar flagella. Flagella may be easily visualized using the Ryu method (Ryu, 1937; Kodaka et al., 1982). Characteristic Gram and flagella stains of *Afipia* species have been illustrated by English et al. (1988) and Weyant et al. (1995).

Cellular fatty acid (CFA) composition and ubiquinone content All *Afipia* species share a unique CFA profile of predominately branched fatty acids ($C_{16:1\ \omega7c}$, $C_{18:1\ \omega7c}$, and $C_{Br\text{-}19:1}$). The high amount of $C_{Br\text{-}19:1}$ (10–23%) is unique to *Afipia*. All *Afipia* species also contain $C_{17:0\ cyclo}$ and/or $C_{19:0\ cyclo\ \omega7c}$ in proportions ranging from 1 to 15% (Moss et al., 1990a; Weyant et al., 1995). Ubiquinone 10 is the major isoprenoid ubiquinone of *Afipia* (Moss et al., 1991).

Colonial and cultural characteristics *Afipia* strains grow in various common growth media, including heart infusion agar with 5% rabbit blood, trypticase soy agar with 5% sheep blood, tryptone glucose yeast extract agar, and BCYE. Broth media that support *Afipia* growth include heart infusion broth and nutrient broth. Growth occurs at 25, 30, and 35°C, but not at or above 42°C. Optimal growth is at pH 6.8 (Müller, 1995). Growth occurs under aerobic conditions and is not enhanced by increased CO_2. Growth does not occur in nutrient broth containing 6% NaCl and only rarely occurs on MacConkey agar. Growth is weakly enhanced by ferric pyrophosphate, cysteine-HCl, and α-ketoglutarate (Müller, 1995).

Optimal growth is observed on BCYE agar under aerobic conditions at an incubation temperature of 30–32°C. Growth is relatively slow, with colonies appearing between 48 and 72 hours of incubation under optimal conditions. Colonies are gray-white, glistening, convex, and opaque, with smooth edges. Colony diameters range from 0.5 to 1.5 mm. No hemolysis is observed on blood agar.

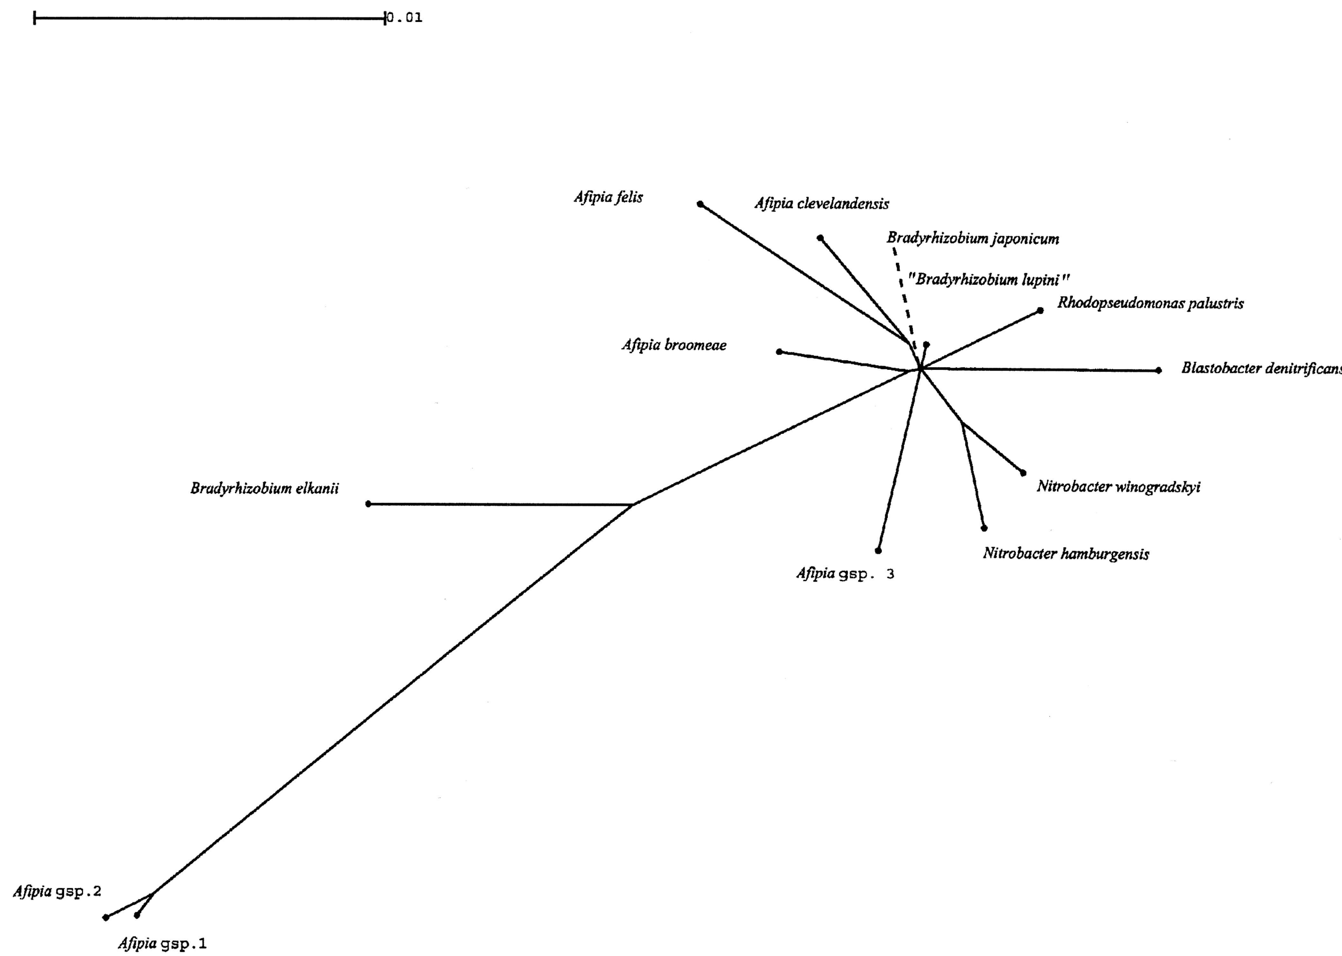

FIGURE BXII.α.172. Phylogenetic tree based on 16S rDNA sequence homologies between the type strains of *Afipia* species and type or reference strains of closely related taxa.

Genetics Mol% G + C content of the DNA ranges from 61.5 in *A. broomeae* to 69 in *Afipia* genomospecies 1 (Brenner et al., 1991a). All *A. felis* strains described by Brenner et al. (1991a) contained a 44-kb plasmid, while the other 5 species or genomospecies did not contain a plasmid.

Antibiotic sensitivity *In vitro* antibiotic sensitivity information for *Afipia* is subject to two limitations. The incubation temperature (30–32°C) differs from the standard 37°C used in the development of the National Committee for Clinical Laboratory Standards (1990); therefore, these standards cannot be used to describe resistance without further clarification. The second limitation is the small number of strains from which these data have been derived. The total published susceptibility literature for this genus consists of the original and five additional *A. felis* strains (Brenner et al., 1991a; Maurin et al., 1993), one *A. clevelandensis* strain, three *A. broomeae* strains, and one strain each of *Afipia* genomospecies 1, 2, and 3 (Brenner et al., 1991a). These studies report *A. felis* to be resistant to a wide variety of antimicrobial agents, including most beta-lactams, ciprofloxacin, and tetracycline, but susceptible to aminoglycosides and imipenem. *A. clevelandensis* and *A. broomeae* share similar susceptibility profiles with *A. felis*, except for slightly higher MICs (4–16 μg/ml) to aminoglycosides. *Afipia* genomospecies 1 and 2 are resistant to all antibiotics tested thus far including beta-lactams, ciprofloxacin, tetracycline, imipenem, and aminoglycosides. Conversely, *Afipia* genomospecies 3 is sensitive to all of the above antibiotic classes except cefoperazone, cefoxitin, and ceftazidime. These generalizations may change as more *Afipia* strains are isolated and tested.

Pathogenicity *A. felis* has been detected in lymph nodes of patients with cat scratch disease (CSD) by culture and PCR on at least four occasions (English et al., 1988; Birkness et al., 1992; Alkan et al., 1995; Giladi et al., 1998); however, the vast majority of CSD cases appear to be caused by *Bartonella henselae.* One of the criteria for differential diagnosis of CSD is a bite or scratch from a cat. *A. felis*, however, has not been isolated from a feline source. Although English reported that antibodies made to *A. felis* reacted with specimens from CSD patients (English et al., 1988), other investigators have reported that antibody titers to *A. felis* in CSD patients were similar to titers in control groups (Amerein et al., 1996).

A. felis is capable of intracellular growth in amoebae (La Scola and Raoult, 1999a) and in tissue culture with human monocytes, macrophages, HeLa cells, and HMEC-1 cells (Birkness et al., 1992). In human macrophages *in vitro, A. felis* survives in phagosomes apparently by inhibiting phagosome–lysosome fusion (Brouqui and Raoult, 1993).

The isolation history of the other *Afipia* species suggests that they may act as opportunistic pathogens in humans. *A. clevelandensis* ATCC 49720 was isolated from a tibial biopsy specimen of a patient with necrotizing pancreatitis (Hall et al., 1991). *A. broomeae* ATCC 49717 was isolated from human sputum while *A.*

broomeae ATCC 49719 grew in a culture of the synovial fluid of a diabetic man with arteriosclerosis (Brenner et al., 1991a). *Afipia* genomospecies 1 ATCC 49721 was isolated from pleural fluid and *Afipia* genomospecies 2 ATCC 49722 was cultured from a bronchial lavage (Brenner et al., 1991a). *Afipia* genomospecies 3 ATCC 49723 was cultured from a water sample from Indiana, and its pathogenicity is unknown (Brenner et al., 1991a).

Ecology The majority of confirmed strains of *Afipia* have been isolated from human clinical specimens, with insufficient exposure information to identify a primary source. Multiple lines of evidence indicate that these organisms reside in fresh water. The type strain of *Afipia* genomospecies 3 was isolated from fresh water (Brenner et al., 1991a), and *A. felis* has been isolated from potable water in a hospital (La Scola and Raoult, 1999a). Many of the *in vitro* characteristics of these organisms, including their preferred growth temperature (30–32°C), lack of growth enhancement by blood or blood products, and lack of growth in elevated NaCl concentrations are also consistent with a fresh water habitat.

Enrichment and Isolation Procedures

When incubated at 30–32°C under aerobic conditions, *Afipia* strains grow on a variety of nonselective media, including brain-heart infusion, heart infusion (with and without 5% rabbit blood), chocolate, potato dextrose, trypticase-soy (with and without 5% sheep blood), and BCYE agars. Liquid media that support *Afipia* growth include heart infusion, brain-heart infusion, and nutrient broth. Although no selective media have yet been described for these organisms, incubation of cultures at 25–30°C favors the growth of *Afipia* over many other taxa that prefer higher temperatures.

Primary isolation of *Afipia felis* strains from lymph nodes of patients with cat scratch disease is achieved by grinding tissues in equal volumes of phosphate buffered saline (pH 7.6) and sea sand, removing the sand by centrifugation at 500 × g for five minutes, then centrifuging the supernatant at 10,000 × g for ten minutes to obtain pelleted material. The pelleted material is then subcultured in biphasic brain-heart infusion media at 30–32°C and growth is observed between 1 and 6 days of incubation (English et al., 1988). Primary isolation is also achieved by cultivation of sonicated lymph node tissues on HeLa cell monolayers (Brenner et al., 1991a).

Maintenance Procedures

Long-term preservation of cultures may be achieved by suspending freshly grown cells in trypticase soy broth with 20% glycerol or defibrinated rabbit blood and freezing at −70°C or in vapor nitrogen. For short-term maintenance (less than one year), strains should be inoculated as stabs into semisolid motility medium deeps in screw-capped tubes, incubated at 30°C until growth is observed, then placed at room temperature with the caps tightly closed (Weyant et al., 1995).

Differentiation of the genus *Afipia* from other genera

Other taxa that are isolated from clinical specimens and share similar phenotypic characteristics with *Afipia* are given in Table BXII.α.145. *Legionella* species, *Francisella tularensis*, and *Bordetella pertussis* may all be isolated from clinical specimens by culture on BCYE agar. The lower preferred growth temperature, the ability to grow in nutrient broth, and the hydrolysis of urea differentiates *Afipia* from these organisms. *Bartonella* species are closely related to *Afipia* phylogenetically and may also be isolated from lymph node specimens of individuals with cat-scratch disease. Unlike *Afipia*, these organisms do not grow well on BCYE agar or nutrient broth. With the exception of *B. bacilliformis*, these species prefer warmer growth temperatures and are nonmotile. The presence of $C_{Br\text{-}19:1}$ as a predominating cellular fatty acid is also useful in differentiating *Afipia* from these other organisms.

Detailed phenotypic comparison studies including *Afipia* and its phylogenetic neighbors *Rhodopseudomonas*, *Bradyrhizobium*, *Rhizobium*, *Nitrobacter*, and *Blastobacter* have not yet been described. A limited analysis, including only type strains, indicates that *Bradyrhizobium* and *Blastobacter* acidify a wider range of carbohydrates (D-glucose, adonitol, D-galactose, D-mannose, and L-rhamnose) than *Afipia* (Weyant et al., unpublished findings). Neither the extracellular polysaccharide slime produced by *Bradyrhizobium* strains when grown on carbohydrate-containing media nor the branching or budding characteristic of *Blastobacter* cells have been observed with *Afipia* strains. *Rhodopseudomonas*, unlike *Afipia* and the other taxa in this phylogenetic cluster, is a phototroph.

Differentiation of the species of the genus *Afipia*

A biochemical characterization of 6 *Afipia* species is given in Table BXII.α.146. Characteristics useful in differentiating these species are given in Table BXII.α.147. The ability to reduce nitrate is a unique characteristic that differentiates *A. felis* from the other species. Likewise, the ability to alkalinize citrate is unique to *Afipia* genomospecies 1. *A. clevelandensis* is characterized by its inability to produce acid from carbohydrates. Demonstration of specific protease activity is useful in differentiating the remaining species.

List of species of the genus Afipia

1. **Afipia felis** Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger 1992, 327^{VP} (Effective publication: Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger, 1991, 2458.)

[a]Symbols: +, >90% species positive; (+), delayed positive; −, <10% species positive; v, 11–89% species positive; nd, not determined; for *B. pertussis* the symbols refer to strains. Data from Brenner, et al. (1991a) and Müller (1995).

The morphological and cultural characteristics are as described for the genus. Other characteristics for this species are given in Table BXII.α.146. Rare cases of cat scratch disease have been associated with this species. The natural reservoir of this species is unknown. Most confirmed isolates have been recovered from human clinical specimens. The type strain was isolated from a lymph node of a person with cat scratch disease.

The mol% G + C of the DNA is: 62.5 (T_m).

Type strain: BV, ATCC 53690, CDC B91-007352, DSM 7326.

2. **Afipia broomeae** Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger 1992, 327[VP] (Effective publication: Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger, 1991, 2458.)
broome' a.e. N.L. gen. n. *broomeae* named after Dr. Claire V. Broome in recognition of her contributions to the epidemiology and microbiology of cat scratch disease, legionellosis, listeriosis, toxic shock syndrome, Brazilian purpuric fever, and many other diseases.

The morphological and cultural characteristics are as described for the genus. Other characteristics of the species are given in Table BXII.α.146. The natural reservoir of this species is unknown. All confirmed strains have been isolated from human clinical material, including blood, lung tissue, and bone marrow. Presumptively pathogenic for humans. The type strain was isolated from human sputum in New Zealand in 1981.

The mol% G + C of the DNA is: 61.5 (T_m).

Type strain: ATCC 49717, CDC B91-007286, DSM 7327.

GenBank accession number (16S rRNA): U87759.

3. **Afipia clevelandensis** Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger 1992, 327[VP] (Effective publication: Brenner, Hollis, Moss, English, Hall, Vincent, Radosevic, Birkness, Bibb, Quinn, Swaminathan, Weaver, Reeves, O'Connor, Hayes, Tenover, Steigerwalt, Perkins, Daneshvar, Hill, Washington, Woods, Hunter, Hadfield, Ajello, Kaufmann, Wear and Wenger, 1991, 2457.)
cleve.land.en' sis. N.L. fem. adj. *clevelandensis* coming from Cleveland, Ohio, USA, where the type strain was isolated.

The morphological and cultural characteristics are as described for the genus. Other characteristics of the species are given in Table BXII.α.146. The natural reservoir of this species is unknown. The only known strain of this species was isolated from a tibial biopsy specimen of a human. Presumptively pathogenic for humans. The type strain was

isolated in 1988 from a tibial biopsy specimen taken from a 69-year-old man in Ohio, USA.

The mol% G + C of the DNA is: 64 (T_m).

Type strain: ATCC 49720, CDC B91-007353, DSM 7315.

4. *Afipia* genomospecies 1

The morphological and cultural characteristics are as described for the genus. Other characteristics for the species are given in Table BXII.α.146. The natural reservoir of this species is unknown. All confirmed strains have been isolated from human clinical material. Presumptively pathogenic for humans. ATCC 49721 was isolated at Oklahoma, USA, from human pleural fluid in 1981.

The mol% G + C of the DNA is: 69 (T_m).

Deposited strain: ATCC 49721, CDC B91-007287.

5. *Afipia* genomospecies 2

The morphological and cultural characteristics are as described for the genus. Other characteristics for the species are given in Table BXII.α.146. The natural reservoir of this species is unknown. All confirmed strains have been isolated from human clinical material. Presumptively pathogenic for humans. ATCC 49722 was isolated at Indiana, USA, from a human bronchial wash specimen in 1989.

The mol% G + C of the DNA is: 67 (T_m).

Deposited strain: ATCC 49722, CDC B91-007290.

6. *Afipia* genomospecies 3

The morphological and cultural characteristics are as described for the genus. Other characteristics for the species are given in Table BXII.α.146. The natural reservoir of this species appears to be fresh water. ATCC 49723 was isolated at Indiana, USA, from water in 1990.

The mol% G + C of the DNA is: 65.5 (T_m).

Deposited strain: ATCC 49723, CDC B91-00729.

Other Organisms

We have studied multiple clinical and non-clinical isolates that are phenotypically similar to *Afipia*, but fall into different DNA hybridization groups. These isolates have been provisionally designated *Afipia* genomospecies 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, and 14 (Weyant, unpublished findings). Phylogenetic analysis, using 16S rRNA sequence data indicate that genomospecies 4, 5, and 10 fall into the same *Rhodopseudomonas–Blastobacter–Nitrobacter* cluster as the 6 described species. Genomospecies 11, 13, and 14 associate most closely with *Caulobacter* and *Sphingomonas*, whereas the remaining genomospecies represent novel taxa. Additional phenotypic and chemotaxonomic studies are underway to clarify the appropriate taxonomic designation of these "*Afipia*" strains.

Genus III. **Agromonas** *Ohta and Hattori 1985, 223*[VP] *(Effective publication: Ohta and Hattori 1983, 43)*

Christina Kennedy

Ag.ro.mon'as. Gr. n. *agros* a field; Gr. n. *monas* a unit, monad; M.L. fem. n. *Agromonas* field monad.

Bent, branched, and/or budding rods, usually 0.6–1.0 × 2–7 µm, when grown in diluted nutrient broth (NB/100). Motile by a polar flagellum. Gram negative. Colonies are colorless to white. No spores or microcysts formed. Aerobic. **Oligotrophic**; grows under conditions of low organic carbon supply (<1 mg/ml). **Fixes N_2 under microaerobic conditions**. **Catalase and oxidase positive**. Cellulose and starch are not hydrolyzed. Casein and gelatin are not hydrolyzed. Cellular fatty acids consist mainly of a straight-chain unsaturated acid $C_{18:1}$, with smaller amounts of $C_{16:0}$ and $C_{19:1}$. Ubiquinone Q-10 is present. Isolated from rice paddy soils.

The mol% G + C of the DNA is: 65.1–66.0.

Type species: **Agromonas oligotrophica** Ohta and Hattori 1985, 223 (Effective publication: Ohta and Hattori 1983, 43.)

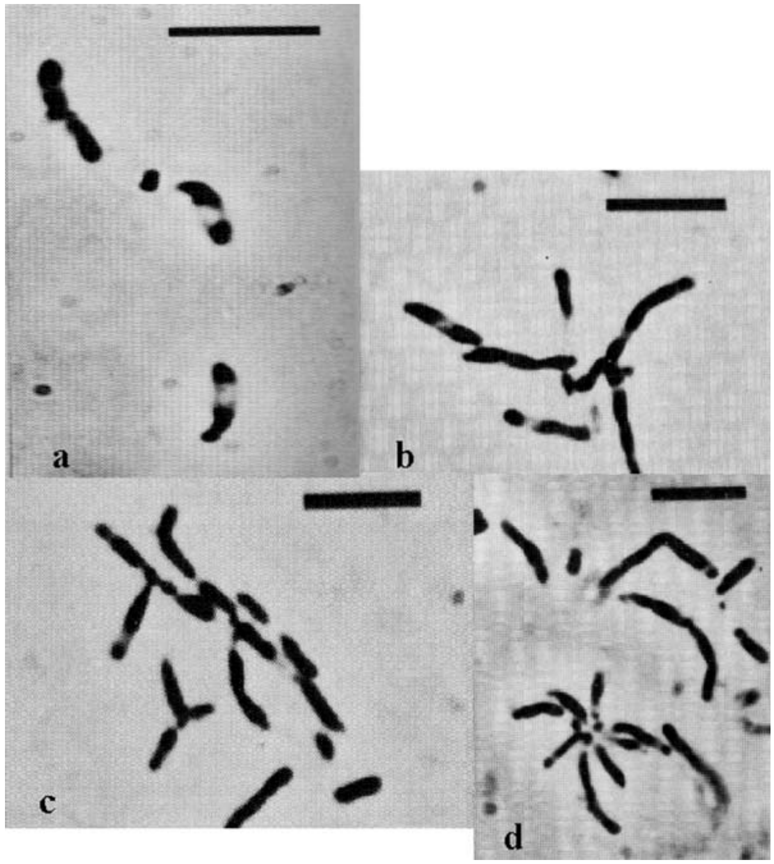

FIGURE BXII.α.173. Phase-contrast photomicrographs of 3-d-old (*a*, *b*) and 8-d-old (*c*, *d*) cultures of *A. oligotrophica* grown in NB/100 (*a*) and NB/10 (*b*, *c*, *d*) medium; (*a* and *b*) bent and budding rods in which both ends were darker than the rest of the cell; (*c*) branched rods; (*d*) a cell aggregate (rosette). Bar = 5 μm. (Reproduced with permission from H. Ohta and T. Hattori, Antonie van Leeuwenhoek *49:* 429–446, 1983, ©Kluwer Academic Publishers, Dordrecht, Netherlands.)

Further descriptive information

Cell morphology Cells have an irregular rod-shaped morphology of dimensions 0.6–1.0 × 2–7 μm (Ohta and Hattori, 1983). The irregular shape of the cells is shown in Fig. BXII.α.173. Cell division is by irregular budding and/or elongation and pinching off, not by the usual septum formation (Hattori et al., 1995).

Cell envelope Outer layers are typical for *Proteobacteria*. Electron microscopy shows a multilayered envelope structure consisting of an outer layer connected to a dark thin peptidoglycan layer, a double-layered cytoplasmic membrane, and a light space between outer and inner layers (Hattori et al., 1995) (Fig. BXII.α.174a).

Fine structure The cytoplasm is unusually divided into several compartments surrounded by the cytoplasmic membrane (Hattori et al., 1995) (Fig. BXII.α.174b). Compartmentalization develops through invagination and growth of the cytoplasmic membrane. Compartments are often connected with each other and spaces between are frequently filled with electron-dense material (Fig. BXII.α.174c). Formation of compartments is inhibited by NaCl in PM/100 medium[1] and does not occur in PM/10, although growth occurs normally in the latter medium. These findings suggest that the developed cytoplasmic membrane and the compartmentalization of cytoplasm are not required for rapid growth but rather for growth in highly diluted nutrients. Another unusual feature is that electron-dense cores are visible in the cytoplasm, numbering from three to five. They probably represent nucleoids, as indicated by staining with the DNA-specific stain DAPI (4,6-diamidino-2-phenylindole) (Hattori et al., 1995).

Colonial or cultural characteristics: nutrition and growth Colonies are colorless/white, punctiform, pulvinate, and small (<0.5 mm diameter) (Ohta and Hattori, 1983). Growth is very sensitive to supply of organic compounds and occurs only in dilute media. Growth can occur in 1/10,000 nutrient broth (NB/10,000),[2] with cells reaching a density of $>10^5$ cells/ml. Growth also occurs on NB/1000, NB/100, NB/10, but not on NB. The linear relationship between the dilution of NB and cell yield indicates that growth is dependent on supplied organic carbon and is not autotrophic. Cultures reach a density of 1–5 $\times 10^8$ cells/ml after 7–8 d growth on NB/100 or NB/10 (Ohta and Taniguchi, 1988a). The optimal growth temperature is 25–27°C.

Utilizable carbon sources are shown in Table BXII.α.148. The phenolic acids ferulic, *p*-coumaric, and *p*-anisic, but not benzoic,

1. Full-strength PM medium consists (g/l): peptone, 10.0; and meat extract. 10.0.

2. Full-strength NB contains (g/l of tap water): peptone, 10.0 g; meat extract, 10.0 g; and NaCl, 5.0 g; pH 7.0–7.2.

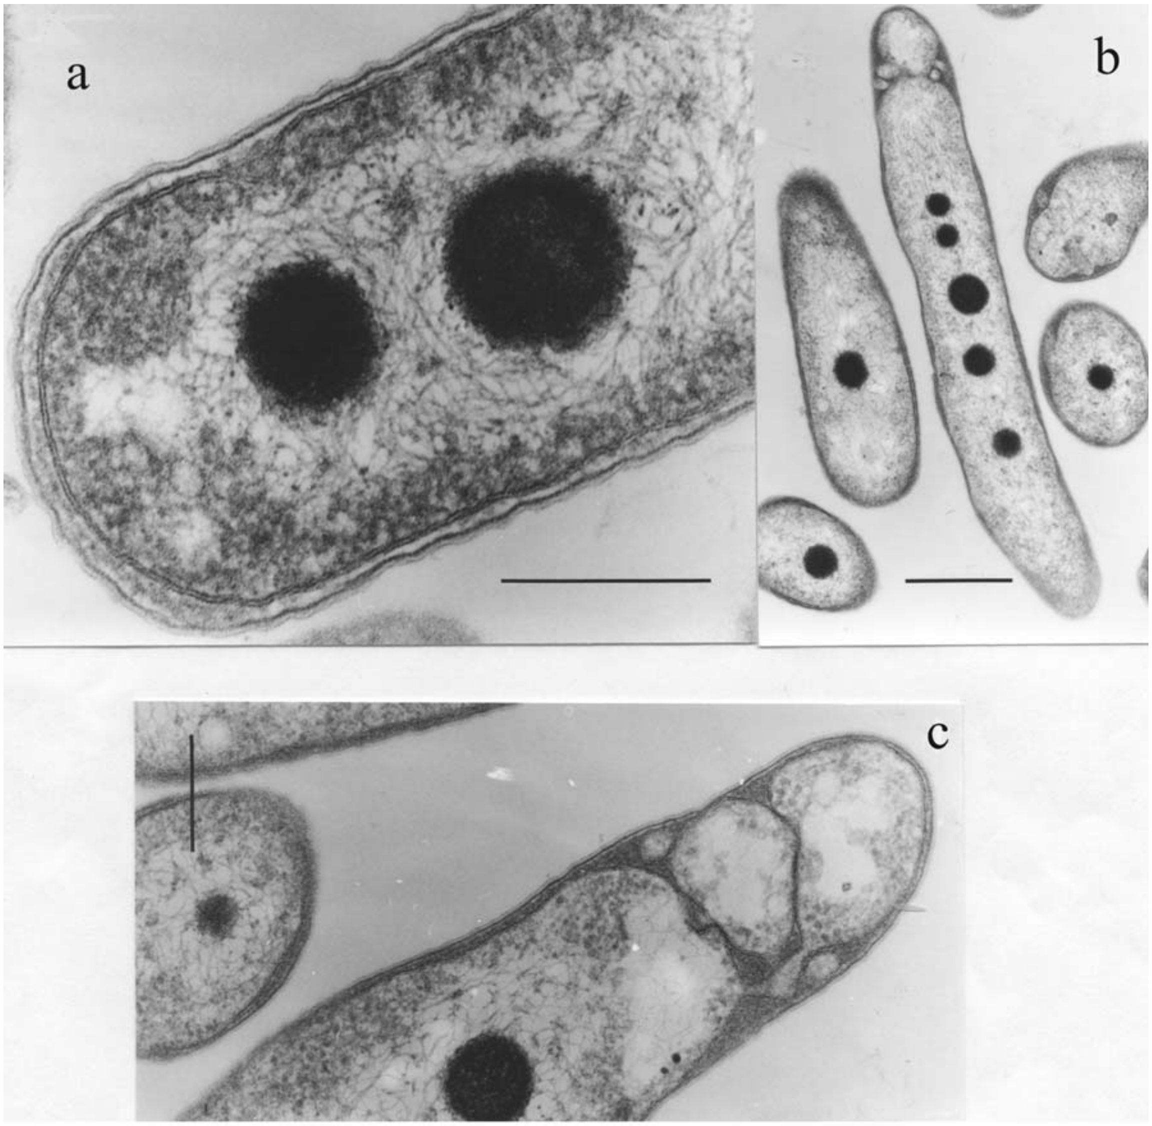

FIGURE BXII.α.174. Electron micrograph of *Agromonas oligotrophica* grown in PM/100. Sections were stained with 2% (w/v) aqueous uranyl acetate and saturated lead citrate. (*a*) The multilayered structure of cell envelope and the nucleoid-like structures in cytoplasm. Bar = 0.2 μm. (*b*) Growing cells; note that the cytoplasm is divided into compartments with electron-dense cores in nuclear zones. Bar = 1 μm. (*c*) Compartments can be separate or connected. Bar = 0.2 μm. support growth. Ferulic acid degradation requires organic nutrients to be present in the growth medium. The pathway includes conversion of ferulic acid to vanillate and then probably to protocatechuate (Ohta, 2000).

Growth occurs microaerobically on nitrogen-free medium (NF).[3] On NF semi-solid medium, cells grow at a depth of 18–25 mm below the surface. On media supplemented with 50 mg/l $(NH_4)_2SO_4$, growth occurs at a depth of 8–12 mm (Ohta and Hattori, 1983), indicating use of ammonium as the N source at a higher pO_2 than for utilization of N_2. Acetylene reduction occurs, verifying nitrogen fixation by *A. oligotrophica*; the specific activity is ~10 nmoles/min/mg protein, similar to the activity in many other free-living diazotrophs. Nitrate is reduced to nitrite.

Metabolism and metabolic pathways *A. oligotrophica* is an aerobic/microaerobic organism not extensively characterized in terms of metabolic features. In one study of respiratory characteristics, growth of *A. oligotrophica* on 1% trypticase peptone plus 0.1% yeast extract was biphasic (Ohta and Taniguchi, 1988b). The molar growth yield on oxygen consumed in the first phase increased 1.7-fold in the second phase. Cytochromes of the *a*, *b*, and *c* type are present, as well as a CO-binding *b*-type cytochrome, thought to be cytochrome *o*. The pattern was not detectably changed by medium dilution.

Ecology Strains of *Agromonas oligotrophica* have been isolated from rice paddy soils. They may play a role in decomposing organic matter such as the phenolic acids, ferulic, and coumaric,

3. NF medium contains (per liter of distilled water): K_2HPO_4, 50 mg; $MgSO_4 \cdot 7H_2O$, 10 mg; NaCl, 5 mg; $CaCl_2$, 0.1 mg; $FeCl_3$, 0.1mg; $NaMoO_4 \cdot 2H_2O$, 0.2 mg; 2-oxoglutaric acid, 0.3 or 1 g; pH 6.8–7.5. The carbon source—2-oxoglutaric acid—is sterilized by filtration and added aseptically to the autoclaved medium.

and recycling other nutrients in environments low in organic substrates. Nitrogen fixation may be of ecological significance, allowing occupation of this niche.

Ohta and Hattori (1983) reported that irregular rod-shaped, oligotrophic bacteria, many of which were identical to *A. oligotrophica*, were abundant in the roots of rice plants numbering 10^8–10^9 cells/g dry matter. Whether fixed nitrogen can be provided for plant nutrition is not known.

Fatty acid composition The predominant fatty acid in five strains tested is an 18-carbon straight-chain unsaturated acid with one double bond ($C_{18:1}$) (Ohta and Hattori, 1983). Present also among the isolates was a $C_{16:0}$ fatty acid (at 9–14% of total) and $C_{19:1}$ fatty acid (6–18% of total). Ubiquinone Q-10 was found in all isolates.

Enrichment and Isolation Procedures

Oligotrophic bacteria are widely distributed in nature and share the ability to grow on low nutrient media. At microsites of soil, selective growth of oligotrophic bacteria occurs at higher probabilities with lower concentrations of nutrients and at lower probabilities with higher concentrations of nutrients (Hattori, 1981). Consequently, the isolation of *Agromonas* is based on this feature. Soil suspensions are diluted 10^{-3} and 10^{-4}; 1 ml of each dilution is plated onto NB/100 medium containing 1% agar. After 1 week to 1 month, colonies are tested for sensitivity to nutrients by plating on 1× NB. NB-sensitive colonies are then examined for other characteristics as described.

Maintenance Procedures

The medium for maintenance is NB/100 containing 0.3–0.4% agar, dispensed in screw-cap tubes. Cells are kept as a stabbed culture at room temperature. Cells remain viable for several years; transfer every 3–4 years is recommended. An alternative method is the suspension of cells in 20% glycerol followed by storage at −80°C. Cells stored this way are less viable in the long term than those described above (H. Ohta, personal communication).

Differentiation of the genus *Agromonas* from other genera

The organisms most closely related to *Agromonas*, as indicated by 16S rDNA analysis, are species of *Blastobacter*, *Bradyrhizobium*, and the unclassified DNB strains described by Saito et al. (1998) (see Taxonomic Comments). Table BXII.α.149 summarizes the differential features of these organisms.

Taxonomic Comments

Based on comparison of morphological and physiological characteristics, Ohta and Hattori (1983) placed five paddy soil isolates in a new genus, *Agromonas*, and a new species, *Agromonas oligotrophica*. The morphological and physiological characteristics were most similar to those of the genera *Xanthobacter* and *Azospirillum*, but 16S rDNA analysis (Saito et al., 1998) indicated a close relationship between *Agromonas oligotrophica* and *Blastobacter denitrificans*, which form a group (Fig. BXII.α.175). *B. denitrificans* does not fix nitrogen and, unlike *A. oligotrophica*, it can utilize methanol and denitrify (Hirsch and Müller, 1985). However, *B. denitrificans* is oligotrophic and the rod-shaped cells are bent and budding like those of *A. oligotrophica*. Other oligotrophs, called DNB (dilute nutrient broth) bacteria, are also placed in this group (Saito et al., 1998). These DNB strains were isolated from grassland soil by Ohta and Hattori (1980), and only 1 of 11 was able to fix N_2. The DNB isolates were similar to each other in a number of ways but were not assigned a genus or species name. The group containing *B. denitrificans*, *A. oligotrophica*, and the unclassified DNB bacteria is most closely related to a *Bradyrhizobium* sp. Unlike the latter species, neither *A. oligotrophica* nor the DNB bacteria can nodulate siratro (*Macroptilium atropurpureum*). In DNA–DNA hybridization tests, the DNB bacteria appeared more closely related to the *Bradyrhizobium* sp. than to *A. oligotrophica*. The taxonomic cluster carrying *A. oligotrophica*, *B. denitrificans*, the DNB strains, and the *Bradyrhizobium* sp. is related most closely with a group composed of *Rhodopseudomonas palustris*, two *Nitrobacter* species, and the genus *Afipia* (together named the BANA domain; Saito et al., 1998). *Agromonas oligotrophica* is a member of the phylum *Proteobacteria*, order *Rhizobiales*, and the family *Bradyrhizobiaceae*.

Acknowledgments

I am grateful to Drs. T. Hattori, K. Minamisawa, R. Hattori, and H. Ohta for their cooperation in providing clarifying information, reprints, and electron micrographs, and for their helpful comments concerning the manuscript. Their work allowed *Agromonas oligotrophica* to be known to the world.

The phylogenetic tree was constructed using the neighbor-joining method. Bootstrap values are shown at nodes. The scale bar indicates substitutions per site. The group DNB are unclassified oligotrophs, mostly non-nitrogen fixing, isolated from grassland soil (Saito et al., 1998).

other, forming a rosette. Colonies are colorless/white, punctiform, pulvinate, and entire.

NaCl, KCl, Casamino acids, peptone, and meat extract inhibit growth at 0.5–1.0%. Several sugars and organic acids are utilized. The aromatic acids ferulic, *p*-coumaric, and *p*-anisic can be utilized, but not benzoic acid. Neither acid nor gas is produced from glucose. Cellulose and starch are not hydrolyzed.

The mol% G + C of the DNA is: 65.1–66.0 (T_m).

Type strain: ATCC 43045, DSM 12412, JCM1494.

GenBank accession number (16S rRNA): D78366.

Genus IV. **Blastobacter** *Zavarzin 1961, 962[AL] emend. Sly 1985, 44*

LINDSAY I. SLY AND PHILIP HUGENHOLTZ

Blas.to.bac′ter. Gr. n. *blastos* bud, shoot; M.L. n. *bacter* equivalent of Gr. masc. n. *bactrum* rod; M.L. masc. n. *Blastobacter* a budding rod.

Cells **ovoid rods, wedge or club shaped**, or pleomorphic, **often slightly curved and occasionally branched**. Cell poles are rounded or slightly tapering on one pole. Cell size range is 0.5–1.0 × 1.0–4.5 μm. Cells **may form rosettes**. **Gram negative**. New **cell formation and multiplication occur by budding** on the free cell pole, subpolarly or laterally. Young **buds initially rod shaped, ovoid,**

or spherical to oblong. Buds may be released or remain attached. **Motile, flagellated swarmer cells may occur** in some species. Do not form spores or cysts. Some strains produce large amounts of exopolymer. Grow in liquids as turbidity, pellicle, or precipitate. Colony pigmentation may be yellow, or colorless, becoming brown in older cultures.

Aerobic. **Heterotrophic**. **Oxidase, catalase, and peroxidase positive**. Some species grow chemolithotrophically with hydrogen. Some species may fix CO_2 reductively when grown on methanol or methylated amines. Optimal pH between 6.8 and 7.8. Temperature range for growth is 10–46°C. Carbon and energy sources may be alcohols, sugars, organic acids, or some amino acids. Ammonium, nitrate, urea, peptone, yeast extract, or casein hydrolysate may be utilized as nitrogen sources. May reduce nitrate to nitrite, or denitrify.

Isolated from freshwater lakes, ponds, and groundwater, as well as activated sludge.

The mol% G + C of the DNA is: 59–69.

Type species: **Blastobacter henricii** Zavarzin 1961, 962.

Further descriptive information

Cells of *Blastobacter* generally have a rod-shaped morphology and reproduce by budding at the poles or laterally, with cells often attaching at the nonreproductive pole to form rosettes (Fig. BXII.α.176). The characteristics of the species of *Blastobacter* are mainly based on the study of the type strains of the five species and little is known of the diversity within each species. All strains have yet to be characterized over a constant range of tests in a single polyphasic study, making it difficult at this time to compare the species. A continuing difficulty is the absence of a culture for the type species *B. henricii*, whose description is based solely on morphological characteristics obtained from examination of an enrichment culture (Zavarzin, 1961). 16S rRNA sequences are available for the three validly published species *B. aggregatus*, *B. capsulatus*, and *B. denitrificans*, but not for the two species *"B. aminooxidans"* and *"B. viscosus"* that have not been validated.

Hirsch and co-workers have searched for *Blastobacter* cultures from various freshwater habitats and obtained pure cultures from lakes and ponds (Hirsch and Müller, 1985), resulting in the description of three new species—*B. aggregatus*, *B. capsulatus*, and *B. denitrificans*—which together with *B. henricii* are the only validly described species. In the absence of a type culture for *B. henricii*, Hirsch and Müller (1985) argued that their new species belonged to the genus *Blastobacter* based on cellular morphological similarity, and physiological differences with other budding bacteria such as *Rhodopseudomonas*, *Nitrobacter*, and *Methylosinus trichosporium*.

FIGURE BXII.α.176. Photomicrograph of actively growing culture of *Blastobacter aggregatus* on PYG medium, showing budding, rod-shaped cells, and rosette formation. Bar = 10 μm.

Morphologically, cells of *B. aggregatus*, *B. capsulatus*, and *B. denitrificans* exhibit budding, and no cross-septation occurs without prior budding (Hirsch and Müller, 1985). Cells of these species are essentially rod shaped and of varying length; shorter cells are often ovoid. Cells of *B. capsulatus* IFAM 1004 have a tendency to bend or even twist helically (Hirsch and Müller, 1985). Of these, only *B. aggregatus* IFAM 1003 forms rosettes, and is therefore most morphologically similar to the description of the type species *B. henricii*. Two species, *B. aggregatus* and *B. denitrificans*, produce motile swarmer cells with flagella while *B. capsulatus* and *B. henricii* are nonmotile.

B. aggregatus, *B. capsulatus*, and *B. denitrificans* utilize D-glucose, D-fructose, lactose, D-ribose, D-galactose, mannitol, glycerol, pyruvate, α-oxoglutarate, acetate, L-glutamate, and L-histidine as carbon compounds, but are unable to utilize maltose, starch, dextrin, inulin, fumarate, lactate, caproate, citrate, propionate, indole, phthalate, D,L-phenylalanine, L-aspartate, leucine, L-serine, glycine, and alanine. These species are reported to produce acid but no gas anaerobically from D-fructose, and D-galactose in the Hugh and Leifson fermentation test (Hirsch and Müller, 1985). Production of acid aerobically from D-glucose and mannitol varies among species (Table BXII.α.150). In addition to the generic characters, these species do not decarboxylate arginine or lysine, deaminate lysine, or phenylalanine, hydrolyze gelatin or cellulose, or produce acetoin, indole, or H_2S. Ammonium, nitrate, and methane are not oxidized. Litmus milk is not acidified, peptonized, or coagulated (Hirsch and Müller, 1985).

Two nomenclaturally invalid species, *"B. aminooxidans"* and *"B. viscosus"*, were isolated from activated sludge and studied extensively for their morphological and physiological characteristics (Loginova and Trotsenko, 1979; Doronina et al., 1983).* These species grow on C_1 compounds as carbon and energy sources and are facultative autotrophs capable of chemolithotrophic growth with hydrogen. Strains of *"B. viscosus"* (Loginova and Trotsenko, 1979) were isolated from activated sludge of the purifying installation of the Baikal Pulp and Paper Combine in Russia. Studies on the formation of the bud in *"B. viscosus"* show that budding begins with a centripetal ingrowth of the plasma membrane and the cell wall with full delimitation of the bud from the maternal cell. Incomplete separation and multiple budding leads to the formation of pleomorphic cells. Crystalloid formations consisting of parallel arrangements of electron dense and electron transparent filamentous structures are observed in the region of bud formation (Loginova and Trotsenko, 1979).

When grown on a medium with methanol as carbon source, *"B. viscosus"* produces a heteropolysaccharide consisting of galactose, glucose, rhamnose, xylose, and glucuronic acid (Loginova and Trotsenko, 1979).

"B. viscosus" grows weakly with methylamine, dimethylamine, formate, formamide, and dimethylformamide, but not trimethylamine, formaldehyde, dimethyl sulfoxide, or dimethylsulfone as carbon sources (Loginova and Trotsenko, 1979).

Ribulose phosphate carboxylase is induced in *"B. viscosus"* when C_1 compounds are utilized, but no activities of specific

**Editorial Note:* Recently *"Blastobacter viscosus"* and *"Blastobacter aminooxidans"* have been reclassified as *Xanthobacter viscosus* and *Xanthobacter aminoxidans* (Doronina and Trotsenko, 2003).

TABLE BXII.α.150. Differential characteristics of the genus *Blastobacter* species and other heterotrophic, Gram-negative, rod-shaped budding bacteria[a]

[a]Data from Loginova and Trotsenko (1979), Doronina et al. (1983), Hirsch and Müller (1985), Rothe et al. (1987), Trotsenko et al. (1989), and Saito et al. (1998).

[b]nd, not determined.

enzymes of the serine and hexulose monophosphate pathways characteristic of methylotrophs were observed. *"B. viscosus"* is apparently able to utilize the carbon from methanol autotrophically after its oxidation to CO_2 (Loginova and Trotsenko, 1979).

Like *"B. viscosus"*, *"B. aminooxidans"* was also isolated from activated sludge. *"B. aminooxidans"* was the first organism in which autotrophic assimilation of methylated amines was shown. As well as the ability to utilize methylated amines, *"B. aminooxidans"* is able to grow chemolithotrophically with hydrogen (Doronina et al., 1983). Trimethylamine is oxidized to dimethylamine and formaldehyde by dehydrogenase (phenazine methosulfate). Methylamine is further oxidized to formaldehyde and ammonia, and the formaldehyde is oxidized via formate to CO_2. The CO_2 is assimilated by the ribulose bisphosphate pathway. The serine and hexose monophosphate pathways are not present. The cells possess enzymes of the tricarboxylic acid cycle and the glyoxylate shunt. Ammonium is assimilated via reductive amination of α-glutarate, pyruvate, and glyoxylate, and via the glutamate cycle (Doronina et al., 1983).

In *"B. aminooxidans"*, trimethylamine and methylamine are oxidized by a monooxygenase (NADH or NADPH). Formaldehyde is oxidized via formate to CO_2 by dehydrogenases: the CO_2 is refixed into 3-phosphoglyceric acid by using the autotrophic ribulose-1,5-bisphosphate pathway (Trotsenko et al., 1989). Phosphoribulose kinase is also present and active. In *"B. viscosus"* autotrophic growth occurs in an atmosphere of $H_2/O_2/CO_2$ or with methanol. In both cases, cells assimilate CO_2 via the ribulose bisphosphate pathway and show active phosphoribulokinase (PRK) and ribulose bisphosphate carboxylase (RBPC). In contrast to PRK, the RBPC is completely repressed in glucose-grown cells. The primary CO_2 acceptor is regenerated by transaldolase and transketolase activity (Trotsenko et al., 1989).

Cells of *"B. viscosus"* possess dehydrogenase activity, catalyzing methanol oxidation via formaldehyde and formate to CO_2. The serine and hexulose-phosphate pathways of C_1 metabolism do not operate due to absence of hydroxypyruvate reductase, serine-glyoxylate aminotransferase, ATP malate lyase, and hexulose-phosphate synthase. Fructose-1,6-bisphosphate aldolase and glyceraldehyde-phosphate dehydrogenase (NAD) play an important role in metabolic conversions of phosphotrioses. The cells contain all enzymes of the citric acid cycle with lower levels in methanol-grown cells than in glucose-grown cells. C_4 compounds are resynthesized mainly by carboxylation of pyruvate and phosphoenolpyruvate (Trotsenko et al., 1989).

Enrichment and Isolation Procedures

A low-nutrient medium containing glucose, peptone, and yeast extract such as that described by Staley (1981b) is suitable for the enrichment and isolation of *Blastobacter*. Cultures may be isolated by direct plating of environmental samples, or after enrichment. Alternatively, water samples may be enriched with 0.005% peptone and incubated aerobically at 18–23°C for 1–3 weeks (Hirsch and Müller, 1985; Trotsenko et al., 1989). *"Blastobacter viscosus"* was isolated from activated sludge after enrichment in mineral salts medium containing 1% methanol at 30°C for 7 d (Loginova and Trotsenko, 1979).

Maintenance Procedures

Cultures of *B. aggregatus*, *B. capsulatus*, and *B. denitrificans* are reported (Hirsch and Müller, 1985) to grow well on dilute peptone–yeast extract–glucose (PYG) medium (Staley, 1981b). *"B. viscosus"* grows well on media with methanol as the carbon source (Loginova and Trotsenko, 1979), and *"B. aminooxidans"* may be grown on media with trimethylamine as the carbon source or on glucose potato agar (Doronina et al., 1983). Cultures may be preserved by cryogenic storage in liquid nitrogen when suspended in sucrose peptone broth containing 10% glycerol, and by freeze-drying in glucose peptone broth containing horse serum.

Differentiation of the genus *Blastobacter* from other genera

Budding of bacteria is widespread throughout the *Proteobacteria* and occurs in phylogenetically diverse genera with widely different physiological characteristics (Rothe et al., 1987; Hugenholtz et al., 1994; Sly and Cahill, 1997) including *Agromonas*, *Blastobacter*, *Blastomonas*, *Gemmobacter*, *Rhodopseudomonas*, *Methylosinus*, and *Nitrobacter*. Table BXII.α.150 gives the characteristics that are useful in differentiating the species of Gram-negative, heterotrophic rod-shaped budding bacteria.

Taxonomic Comments

The taxonomy of the genus *Blastobacter* Zavarzin 1961 is in need of revision. The polyphyletic nature of the genus is well established (Hugenholtz et al., 1994; Sly and Cahill, 1997), and emphasizes that morphological characteristics such as budding cell division, which define the genus, are not phylogenetically useful features at the genus level and may group distantly related species in the genus as currently defined (Zavarzin, 1961; Sly, 1985; Trotsenko et al., 1989). Cell division by nonprosthecate budding is confined to the *Alphaproteobacteria* but is widely distributed in physiologically diverse genera within the class. As reported previously (Hugenholtz et al., 1994; Sly and Cahill, 1997), resolution of the taxonomic confusion is impeded by the lack of a type strain for the type species, *Blastobacter henricii* (Zavarzin, 1961; Skerman et al., 1989), which was never obtained in pure culture.

The genus *Blastobacter* was proposed by Zavarzin (1961) to include rosette-forming, budding, rod-shaped or wedge-shaped bacteria that were observed in a filter paper enrichment of reduced iron-containing water from a northern Russian forest brook. Zavarzin was unable to isolate the cells in pure culture, and the description of *Blastobacter henricii* is based on drawings and observations.

Several additional *Blastobacter* species have been validly described since 1961 (Moore and Moore, 1992). These include *Blastobacter aggregatus*, *Blastobacter capsulatus*, *Blastobacter denitrificans* (Hirsch and Müller, 1985), and *Blastobacter natatorius* (Sly and Hargreaves, 1984; Sly, 1985). *Blastobacter natatorius* was later transferred and became the type species of the genus *Blastomonas* in the first step to clarify the taxonomy of the genus *Blastobacter* (Sly and Cahill, 1997). Other taxonomically invalid species include *"Blastobacter aminooxidans"* (Doronina et al., 1983), *"Blastobacter viscosus"* (Loginova and Trotsenko, 1979), and *"Blastobacter novus"* (Rezanka et al., 1991). Several authors have demonstrated that there is a high degree of heterogeneity in the genus *Blastobacter* with respect to phenotype (Trotsenko et al., 1989), cellular fatty acids and phospholipids (Sittig and Hirsch, 1992), and molecular phylogeny (Rothe et al., 1987; Green and Gillis, 1989; Hugenholtz et al., 1994; Sly and Cahill, 1997; Willems et al., 2001).

Fig. BXII.α.177 shows the phylogenetic relationships of the species of *Blastobacter* for which 16S rRNA sequences are available. An analysis of the 16S rRNA sequences of the validated species shows that species of *Blastobacter* are polyphyletic and belong to

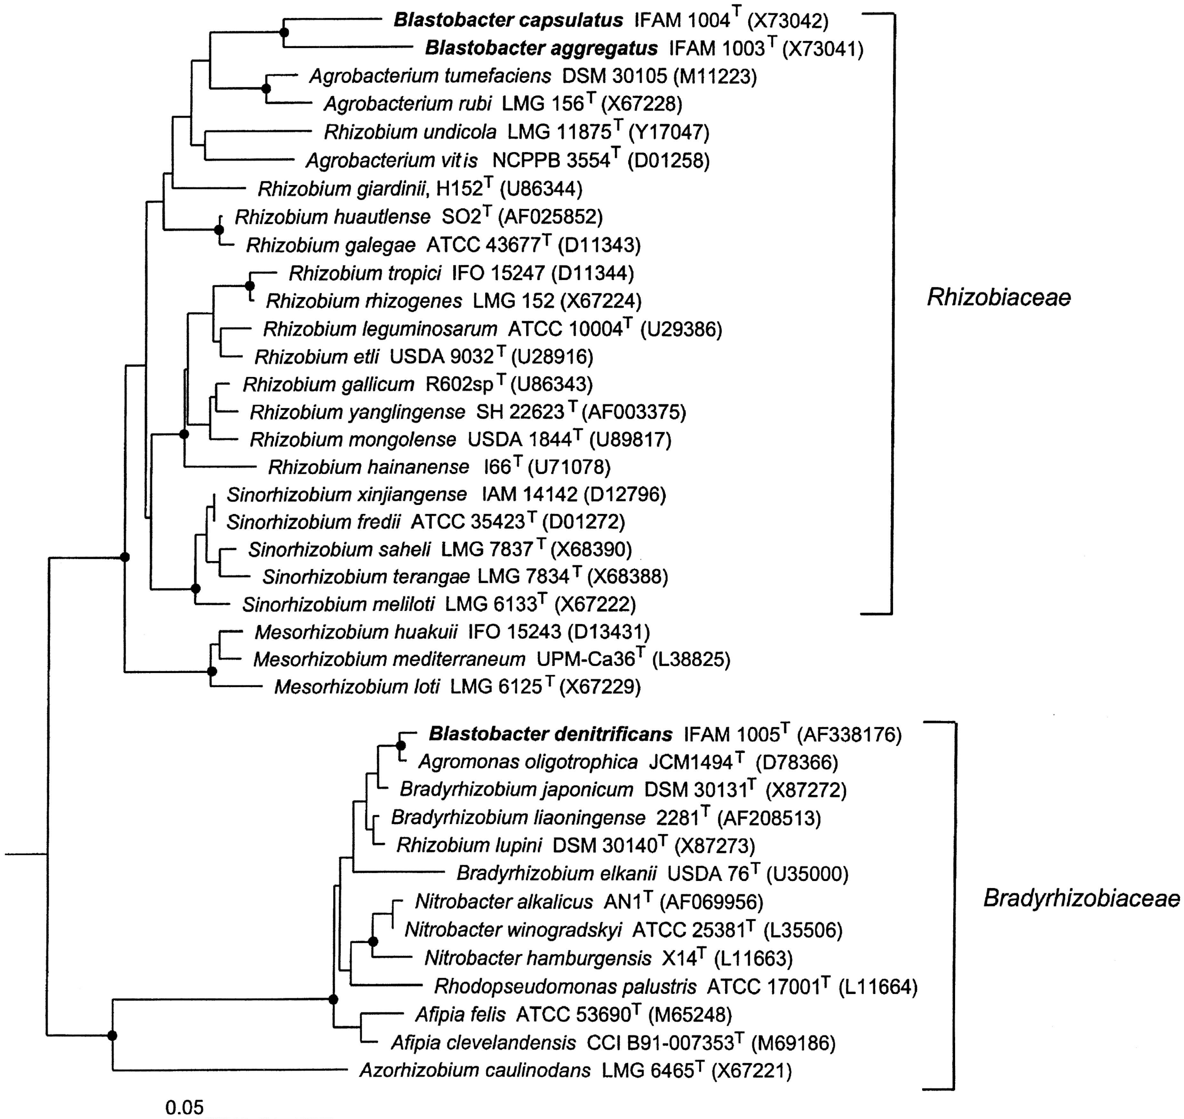

FIGURE BXII.α.177. Phylogenetic tree showing the polyphyletic positions of *Blastobacter* species in the *Alphaproteobacteria* based on 16S rRNA sequence similarities.

separate lineages in the *Alphaproteobacteria. Blastobacter aggregatus* and *Blastobacter capsulatus* are close phylogenetic relatives belonging to a strongly supported branch of the family *Rhizobiaceae,* whereas *Blastobacter denitrificans* belongs to a cluster containing the genus *Bradyrhizobium* and *Agromonas oligotrophica* in the family *Bradyrhizobiaceae. Blastobacter aggregatus* and *Blastobacter capsulatus* are closely related to each other (96.6% sequence similarity) and to *Agrobacterium tumefaciens* (96.0–96.9% sequence similarity). This confirms the previous finding of Rothe et al. (1987) concerning the close relationship between *Blastobacter aggregatus* and *A. tumefaciens* determined by rRNA oligonucleotide catalogue analysis. *Blastobacter denitrificans* on the other hand is most closely related to the type species of the nitrogen-fixing genus *Agromonas* from paddy soil, *Agromonas oligotrophica,* and to *Bradyrhizobium japonicum.* The relationship of *Blastobacter denitrificans* to *Bradyrhizobium japonicum* was first observed by Willems and Collins (1992) based on 16S rRNA sequence similarities and by Green and Gillis (1989) based on rRNA cistron similarities. Willems et al. (2001) showed that the 16S rRNA sequences of photosynthetic *Bradyrhizobium* strains, *Agromonas oligotrophica,* and *Blastobacter denitrificans* belong to a well-supported cluster and may represent a separate genus. Further data on the DNA–DNA hybridization levels between the species in this cluster are required to determine the relationships between the members of this phylotype.

Correction of the taxonomic problems within *Blastobacter* is not straightforward because a culture of the type species *Blastobacter henricii* was never isolated. Hugenholtz et al. (1994) proposed that a new type species for the genus be designated. In the absence of physiological and phylogenetic information about the type species, there is no way of knowing to which phylogenetic lineage the true blastobacters as described by Zavarzin (1961) belong. One solution is to reserve the genus *Blastobacter* at this time for *Blastobacter henricii* in case a culture matching the description can be isolated from the same habitat in the future, and to describe new genera for the other species. Given that the description of *B. henricii* is too limited for reliable assignment of isolates to the species, a better solution is to retain the genus for one of the phylotypes of extant species. Circumscription of the

genus to include *B. henricii*, *B. aggregatus*, and *B. capsulatus* would be straightforward. The taxonomic position of *Blastobacter denitrificans*, on the other hand, is more problematic given its close relationship with the budding bacterium *Agromonas oligotrophica* and photosynthetic *Bradyrhizobium* strains. A reasonable taxonomic solution, therefore, will be to retain *Blastobacter aggregatus* and *Blastobacter capsulatus* in the genus *Blastobacter* on the grounds that they belong to a well-supported phylogenetic group sufficiently distant from related taxa at the genus level and that *Blastobacter aggregatus* appears to have characteristics closest to the original description of *Blastobacter* (Hirsch and Müller, 1985). We propose that the species *B. henricii*, *B. aggregatus*, and *B. capsulatus* be retained in the genus *Blastobacter* and that *Blastobacter denitrificans* be transferred to the genus *Agromonas*. DNA–DNA hybridization between *Blastobacter denitrificans* and *Agromonas oligotrophica* will be required to determine species relationships and nomenclatural priority within the genus *Agromonas*. The budding bacterium *Gemmobacter aquatilis* was shown to be most closely related to *Rhodobacter capsulatus* by rRNA catalogue analysis (Rothe et al., 1987). A complete 16S rRNA sequence is required to determine the exact phylogenetic position of this phenotypically and phylogenetically related species. Determination of the phylogenetic positions of the invalid species *"B. aminooxidans"* and *"B. viscosus"* will be required to resolve the remaining taxonomic uncertainty in the genus.

List of species of the genus Blastobacter

1. **Blastobacter henricii** Zavarzin 1961, 962^{AL}
hen.ri' ci.i. M.L. gen. n. *henricii* of Henrici; named for A. Henrici, an American microbiologist who may have been the first to see bacteria belonging to the genus *Blastobacter*.

Cells are rod-, wedge-, or club-shaped, 0.7–1.0 × 2.0–4.5 μm. Cells form rosettes by attaching to each other with the nonreproductive, frequently tapered pole. A glistening corpuscle was seen in the center of the rosette. Single buds (spherical to oblong) are formed terminally on the blunt cell pole. Released buds are 0.3 μm wide and nonmotile. Originally found in a cylinder containing iron-rich forest brook water from Northern Russia and to which shreds of filter paper had been added. Growth was best in a zone of reduced iron at a pH of 6.2. A pure culture was not obtained.

The mol% G + C of the DNA is: unknown.

Type strain: No culture has been isolated.

2. **Blastobacter aggregatus** Hirsch and Müller 1986, 354^{VP} (Effective publication: Hirsch and Müller 1985, 284.)
ag.gre.ga' tus. L. adj. *aggregatus* joined together, referring to the frequent formation of rosettes.

Cells are 0.6–0.8 × 1.5–2.3 μm, ovoid to rod shaped. Multiplication by rod-shaped buds formed at the narrow and unattached cell pole. Bud cells are motile and attach to each other to form rosettes. Colonies colorless to slightly beige or brownish, round with entire edges, dull to shiny. Liquid cultures turbid. Grow well in dilute media containing peptone, yeast extract, and glucose. Vitamins not required. Grow in presence of up to 36 g/l NaCl. Further characteristics are given in Table BXII.α.150. Isolated from surface water of Lake Höftsee (Holstein, Germany).

The mol% G + C of the DNA is: 60 (T_m).

Type strain: Müller 161, ATCC 43293, DSM 1111, IFAM 1003.

GenBank accession number (16S rRNA): X73041.

3. **Blastobacter capsulatus** Hirsch and Müller 1986, 354^{VP} (Effective publication: Hirsch and Müller 1985, 285.)
cap.su.la' tus. L. n. *capsula* a small chest, capsule; M.L. neut. n. *capsulatus* encapsulated.

Cells are 0.7–0.9 × 1.5–2.3 μm, rod shaped to short ovoid, often bent and narrowing on one cell pole. Older cells frequently Y shaped. Buds are produced terminally on the narrow cell pole or occasionally laterally. Cells form capsules. Nonmotile. Rosettes not formed. Grow in liquids as turbidity or pellicle. Exopolymer produced. Nitrate is reduced without gas formation. Growth occurs in the presence of up to 27 g/l NaCl. Grow well in dilute media containing peptone, yeast extract, and glucose. Vitamins not required. Further characteristics are given in Table BXII.α.150. Isolated from a shallow eutrophic pond near Westensee (Kiel, Germany).

The mol% G + C of the DNA is: 59 (T_m).

Type strain: Müller 216, ATCC 43294, DSM 1112, IFAM 1004.

GenBank accession number (16S rRNA): X73042.

4. **Blastobacter denitrificans** Hirsch and Müller 1986, 354^{VP} (Effective publication: Hirsch and Müller 1985, 285.)
de.ni.tri' fi.cans. L. prep. *de* away from; L. n. *nitrum* soda; M.L. n. *nitrum* nitrate; M.L. v. *denitrifico* denitrify; M.L. part. adj. *denitrificans* denitrifying.

Cells are 0.6–0.8 × 1.5–2.3 μm, rod shaped with rounded poles. Rod-shaped buds formed subpolarly, motile with 1–3 subpolar flagella. Do not produce capsules. Rosettes not formed. Growth in liquid media is turbid. Colonies glistening, round with entire edges, initially colorless, later beige to brownish in transmitted light. Grow well in dilute media with peptone, yeast extract, and glucose. Grow well with C_1 compounds such as methanol, formate, or formamide. Denitrification occurs with nitrogen gas formed from nitrate anaerobically. Growth occurs in the presence of up to 27g/l NaCl. Further characteristics are given in Table BXII.α.150. Isolated from surface water of Lake Plussee (Holstein, Germany).

The mol% G + C of the DNA is: 65 (T_m).

Type strain: Müller 222, ATCC 43295, DSM 1113, IFAM 1005.

GenBank accession number (16S rRNA): X66025.

5. **"Blastobacter aminooxidans"** Doronina, Govorukhina and Trotsenko 1983, 552.
a.mi.no.ox' i.dans. M.L. n. *aminum* amine; M.L. v. *oxido* make acid, oxidize; M.L.part. adj. *aminooxidans* oxidizing amines.

Cells are 0.8–1.0 × 1.5–3.0 μm, rod shaped, often pleomorphic, forming Y-shaped cells. Cells frequently possess minute tube-like appendages on one pole. Multiplication is by nonmotile, oval buds formed terminally or laterally. Rosettes not formed. Colonies on agar media with trimethylamine or glucose are yellow, 2 mm in diameter, convex, round, glistening, and opaque. Colonies have a smooth surface, an entire edge, uniform consistency, and are vis-

cous. Exopolymer not produced. Vitamins are not required. Gelatin and starch are hydrolyzed; milk is alkalinized, but not peptonized or coagulated. Nitrates are reduced to nitrite. Acid but no gas produced from glucose. Methyl red and Voges–Proskauer tests are negative. Carbon sources utilized include monomethylamine, dimethylamine, or trimethylamine, ethanol, butanol, mannitol, xylose, glucose, raffinose, fumarate, malate, and lactate. Nitrogen sources utilized are ammonium, nitrate and peptone, methylated amines, and certain amino acids, but not nitrite. Autotrophic growth occurs in an atmosphere of $H_2/CO_2/O_2$. The main fatty acids of whole cells are $C_{18:1}$ (48%) and $C_{19:0}$ (27%). Further characteristics are given in Table BXII.α.150. Isolated from activated sludge of a sewage purification system at a pulp and paper mill.

The mol% G + C of the DNA is: 69 (T_m).

Deposited strain: 14a (Culture Collection Institute of Microbial Biochemistry and Physiology, Academy of Sciences, Russia.)

6. **"Blastobacter viscosus"** Loginova and Trotsenko 1979, 650. *vis.co′sus.* L. adj. *viscosus* sticky.

Cells are rod shaped to pleomorphic, often bent, and occasionally branched. Microcapsules may be present. Cell size range is 0.5–0.9 × 1.0–3.2 μm. Buds are produced polarly and laterally and are ovoid and nonmotile. Rosettes not formed. Colonies on agar containing peptone and glucose are 3–4 mm in diameter, round, convex, shiny, and opaque, with an even edge, smooth surface, and a slimy consistency. Colony pigmentation is yellow. In liquid medium with methanol and glucose, growth occurs as turbidity and a slimy sediment. Vitamins not required. Exopolysaccharide containing galactose, glucose, rhamnose, xylose, and glucuronic acid is formed. Carbon sources utilized are galactose and sucrose but not methane, alanine, or glycine. Autotrophic growth occurs in an atmosphere of $H_2/O_2/CO_2$ or with methanol. Utilizes ammonium, peptone, and amino acids as nitrogen sources. Gelatin, starch, and cellulose are not hydrolyzed. Acid but no gas produced from glucose. Milk alkalinized but not peptonized or coagulated. Acetoin, indole, or H_2S not produced. The main fatty acids of PYG agar-grown cells are $C_{18:1}$ (63%) and $C_{16:0}$ (14%). Isolated from activated sludge of the drainage system of the Baikal paper mill in Russia.

The mol% G + C of the DNA is: 66 (T_m).

Deposited strain: 7d, UCMV-1439D (Culture Collection, Institute Microbial Biochemistry and Physiology, Academy of Sciences, Pushchino, Russia.)

Genus V. **Bosea** *Das, Mishra, Tindall, Rainey and Stackebrandt 1996, 985*[VP]

SUBRATA K. DAS

Bos′e.a. M.L. gen. n. *Bosea* named after Sir J.C. Bose, the founder of Bose Institute, Calcutta, India.

Rod shaped cells, 0.85 × 1.4-1.6 μm. Gram negative. **Aerobic**. Occurring singly. **Motile by a single polar flagellum**. Optimal temperature for growth: 30–32°C, range; 20–37°C. Optimal pH: 7.5–8.0; range, 6.0–9.0. **Chemolithoheterotrophic**, able to obtain energy from the oxidation of reduced sulfur compounds in the presence of organic carbon. No autotrophic growth occurs. Catalase- and oxidase-positive. Found in cultivated soil.

The mol% G + C of the DNA is: 68.2.

Type species: **Bosea thiooxidans** Das, Mishra, Tindall, Rainey and Stackebrandt 1996, 985.

FURTHER DESCRIPTIVE INFORMATION

Colonies on GYM medium[1] supplemented with $Na_2S_2O_3{\cdot}5H_2O$ and an organic substrate (Das et al., 1996) are round, circular, smooth, mucoid, and cream colored. *Bosea thiooxidans* has a single polar flagellum, which is observed with electron microscopy (Fig. BXII.α.178). Pigments are not produced.

The phospholipid composition consists of phosphatidyl glycerol, phosphatidyl ethanolamine, phosphatidyl choline, diphosphatidyl glycerol, and an amino lipid. The cellular fatty acid composition of *B. thiooxidans* strain BI-42 is presented in Table BXII.α.151.

Neither ammonia nor nitrate serves as the sole nitrogen source for growth. *B. thiooxidans* lacks glutamate synthase activity and therefore is a glutamate auxotroph.

In batch culture, growth and thiosulfate oxidation by this organism in GYM medium without any extra carbon source is gratuitous, since it does not increase the growth yield. The low cell yield indicates that, like other chemolithoheterotrophic organisms such as *Thiobacillus* Q (Gommers and Kuenen, 1988) and *Catenococcus thiocycli* (Sorokin, 1992), *B. thiooxidans* cannot assimilate carbon dioxide autotrophically; a failure to detect ribulose 1,5-bisphosphate carboxylase is consistent with this conclusion. A marked stimulation of growth does occur when GYM medium is supplemented with sodium succinate in addition to thiosulfate. The growth yield varies with the final concentration of thiosul-

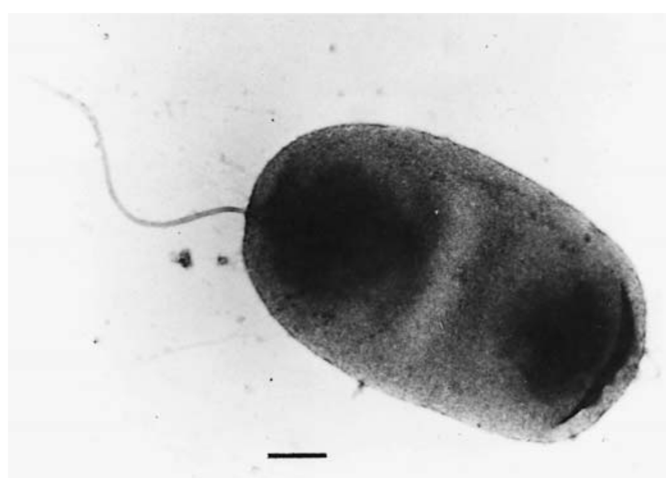

FIGURE BXII.α.178. Transmission electron micrograph of *Bosea thiooxidans* showing the single, polar flagellum. Bar = 200 nm. (Reprinted with permission from S.K. Das et al, International Journal of Systematic Bacteriology *46:* 981–987, 1996, ©Society for General Microbiology.)

1. GYM-medium (Glutamate–yeast extract–mineral salts medium), g/l distilled water: Na_2HPO_4, 4.0; KH_2PO_4, 1.5; $MgCl_2{\cdot}5H_2O$, 0.1; sodium glutamate, 0.5; and yeast extract powder, 0.1. Final pH, 8.0.

TABLE BXII.α.151. Cellular fatty acid composition of *Bosea thiooxidans* (strain BI-42)

Fatty acids	Designation	%[a]
Nonhydroxylated acids:		
Pentadecanoic acid	$C_{15:0}$	2.33
cis-Hexadec-9-enoic acid	$C_{16:1\ \omega7c}$	3.7
Hexadecanoic acid	$C_{16:0}$	7.58
cis-Hepta-9-enoic acid	$C_{17:1\ \omega8c}$	3.56
cis-9,10-Methylene hexadecanoic acid	$C_{17:0\ cyclo}$	2.08
Heptadecanoic acid	$C_{17:0}$	4.82
cis-Octadec-9-enoic acid	$C_{18:1\ \omega7c}$	61.55
Octadecanoic acid	$C_{18:0}$	0.67
cis-Cyclo-10,11-methylene octadecanoic acid	$C_{19:0\ cyclo\ \omega8c}$	8.35
10-Methyl octadecanoic acid	$C_{19:0\ 10CH_3}$	0.71
Hydroxylated acids:		
3-Hydroxypentadecanoic acid	$C_{15:0\ 3OH}$	0.49
3-Hydroxyhexadecanoic acid	$C_{16:0\ 3OH}$	3.25
3-Hydroxyheptadecanoic acid	$C_{17:0\ 3OH}$	0.9

fate; maximum growth (A_{660}, 1.2–1.3) occurs at a concentration of 5 g/l. Under these growth conditions there is a stoichiometric conversion of thiosulfate to sulfate with a concurrent decrease in the pH of the medium from 8.0–6.6. The thiosulfate is almost consumed within 36 h and its oxidation enhances heterotrophic carbon assimilation. Cytochrome *c*, *b*, and aa_3 are present. Cytochrome *c* occurs in both the soluble and membrane fractions whereas cytochrome *b* is membrane bound only. The genetic regulation of thiosulfate metabolism by *B. thiooxidans* has been studied by transposon insertion mutagenesis (Das and Mishra, 1996). Several thiosulfate metabolism defective mutants were isolated and a comparative enzymatic study with the wild type strain suggested that the enzymes thiosulfate oxidase, sulfite oxidase, and cytochrome $c_{550–552}$ are mainly responsible for thiosulfate oxidation.

The MICs (minimum inhibitory concentrations) of several antibiotics for the type strain are (μg/ml): streptomycin, 120; tetracycline, 10; neomycin, 40; chloramphenicol, 20; and rifampicin, 15. Ampicillin fails to inhibit growth even at 200 μg/ml.

Enrichment and Isolation Procedures

For isolation, use cultivated soil from different agricultural fields. Place the soil samples (25 g) in Petri plates and moisten with sterile distilled water. Enrich by adding sodium thiosulfate, sodium sulfite, and S^0. After thorough mixing, incubate the plates at 30°C for 10 d. Further enrich in mineral salt broth (pH 8.0) supplemented with phenol red (0.02 g/l) and either $Na_2S_2O_3 \cdot 5H_2O$ (5 g/l) or thiosulfate plus yeast extract (5 g/l). The mineral salts medium contains (per liter): Na_2HPO_4, 4.0 g; KH_2PO_4, 1.5 g; $MgCl_2 \cdot 5H_2O$, 0.1 g; NH_4Cl, 1.0 g; and trace metal solution (Vishniac and Santer, 1957), 2 ml. Adjust the pH to 8.0 with 4 N NaOH. Inoculate 1 g of enriched soil from each Petri plate into a 250-ml flask containing 50 ml of enrichment medium and incubate in a water bath shaker at 220 rpm at 30°C. After two days, if a yellow color develops (indicating acid formation), plate serial dilutions onto mineral salts-thiosulfate agar and mineral salts-thiosulfate-yeast extract agar. After 4 days at 30°C a few colonies surrounded by yellow halos should appear on mineral salts-thiosulfate-yeast extract agar (but not on the mineral salts-thiosulfate agar). Select these colonies individually, streak and restreak onto similar media until a pure culture is obtained.

Maintenance Procedures

For short-term preservation, streak cultures onto mixed substrate agar or Luria agar plates, and incubate until growth becomes visible. Store the plates at 4°C and transfer at two-month intervals. Alternatively, grow cultures to the early stationary growth phase, freeze them in the growth medium with 15% glycerol, and store at −20°C. The cultures should remain viable for several months to a year or more. Lyophilization is the method of choice for long-term preservation.

Differentiation of the genus *Bosea* from other genera

Bosea is similar to the genus *Thiobacillus* in regard to mol% G + C content of its DNA, respiratory quinones, and ability to oxidize inorganic sulfur compounds. However, it possesses hydroxy fatty acids in combination with 10-methyl and cyclic fatty acids—a feature that is not found in autotrophic and facultatively chemolithoautotrophic sulfur oxidizers or any other member of the alpha group of the *Proteobacteria*. The presence of ubiquinone (Q-10), phosphatidyl choline and a high content of unsaturated nonhydroxy fatty acid $C_{18:1\ \omega7c}$ is similar to that of *Methylobacterium*; however, the latter is not able to oxidize inorganic sulfur compounds. Unlike *Thiobacillus* sp., *Bosea* grown on mixed substrate agar does not produce sulfur deposits on colony surfaces even though both have a chemolithoheterotrophic mode of thiosulfate oxidation. Although both *Bosea* and *Thiobacillus versutus* denitrify under heterotrophic growth conditions, the absence of denitrification under mixed substrate growth conditions differentiates *Bosea* from *Thiosphaera pantotropha* and *T. versutus*.

Taxonomic Comments

16S rDNA sequence analysis of the type strain indicates that *Bosea* constitutes a new genus of the *Alphaproteobacteria*. The 16S rDNA sequence has been deposited in the EMBL database under accession number X81044. A total of 1377 nucleotides of the 16S rDNA of the type strain were amplified and sequenced. The sequence was most similar to that of *Beijerinckia indica* (level of similarity, 92.8%) and to those of *Rhodopseudomonas palustris*, *Nitrobacter winogradskyi*, *Blastobacter denitrificans*, and *Bradyrhizobium japonicum* (levels of similarity 92.0–92.5%) of the *Alphaproteobacteria*. The distance matrix phylogenetic tree based on dissimilarity values of *B. thiooxidans* as compared to those of nineteen reference strains of the *Alphaproteobacteria* indicated a new lineage located between the methylotrophs, the genus *Beijerinckia*, and the *R. palustris* group (Fig. BXII.α.179). No close relationship was found between *B. thiooxidans* and other sulfur oxidizing bacteria such as *Thiobacillus acidophilus* and *Acidiphilium* species (levels of 16S rDNA similarity were less than 88%).

List of species of the genus Bosea

1. **Bosea thiooxidans** Das, Mishra, Tindall, Rainey and Stackebrandt 1996, 985[VP]

thi.o.ox′i.dans. Gr. n. *thion* sulfur; M.L. v. *oxido* make acid, oxidize; M.L. part. adj. *thiooxidans* oxidizing sulfur.

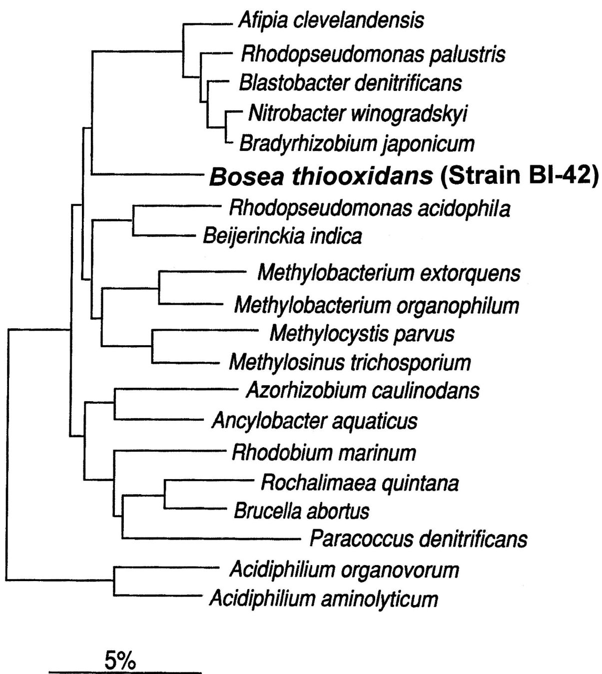

FIGURE BXII.α.179. Phylogenetic tree based on dissimilarity values, showing the relationships between *Bosea thiooxidans* (strain BI-42) and related reference organisms. Note that *Rochalimaea quintana* has been transferred to *Bartonella* and is now *Bartonella quintana*. Bar = 5% nucleotide difference. (Reprinted with permission from S.K. Das et al, International Journal of Systematic Bacteriology *46:* 981–987, 1996, ©Society for General Microbiology.)

Characteristics are as described for the genus. Glutamate, glutamine, and aspartate, but not ammonium salts, nitrate, or urea, can serve as nitrogen sources. Glutamate auxotrophy occurs and the organisms require yeast extract powder (0.1 g/l) for growth. There is no anaerobic growth in the presence or absence of nitrate; however, under microaerobic conditions denitrification occurs with gas production in GYM medium containing malate, succinate, glucose, or sucrose. Gas is not formed after the addition of thiosulfate to the above growth media.

Organic compounds supporting heterotrophic growth include glucose, fructose, sorbose, xylose, pyruvate, rhamnose, ribose, arabinose, galactose, citrate, gluconate, succinate, malate, acetate, glutamine, proline, aspartic acid, cysteine, serine, asparagine, alanine, and lysine. The following do not support growth: formate, glycerol, mannitol, raffinose, leucine, glycine, isoleucine, methionine, tyrosine, tryptophan, phenylalanine, glyoxylate, lactate, propionate, salicylate, butyrate, cyclohexanol, *p*-amino benzoate, or methanol.

Growth occurs on Simmons citrate agar and MacConkey agar. Tests using methyl red, urease, starch hydrolysis, indole production, H_2S production, Voges–Proskauer, gelatin hydrolysis, and pigment production are negative.

Tetrathionate is oxidized slowly. Sulfite, thiocyanate and S^0 do not support growth.

Ubiquinone 10 is the major ubiquinone.

Isolated from agricultural field soil near Calcutta, India.

The mol% G + C of the DNA is: 68.2 (T_m).

Type strain: BI 42, ATCC 700366, DSM 9653.

GenBank accession number (16S rRNA): X81044.

Genus VI. **Nitrobacter** *Winogradsky 1892, 127[AL] Nom. Cons. Opin. 23 Jud. Comm. 1958, 169*

Eva Spieck and Eberhard Bock

Ni.tro.bac′ter. L. n. *nitrum* nitrate; M.L. n. *bacter* the masc. form of Gr. neut. n. *bactrum* a rod; M.L. masc. n. *Nitrobacter* nitrate rod.

Pleomorphic rod- or pear-shaped cells 0.5–0.9 × 1.0–2.0 μm. Cells reproduce by budding or binary fission. **Intracytoplasmic membranes occur as a polar cap of flattened vesicles** in the cell periphery. Gram negative. Cells may be motile by means of a single polar to subpolar flagellum. **Grows lithoautotrophically and chemoorganotrophically. Under oxic conditions, nitrite is the preferred energy source and carbon dioxide is the main source of carbon. Aerobic, but also capable of anaerobic respiration with nitrate.** Under anoxic conditions nitrate is reduced to nitrite, nitric oxide, and nitrous oxide. Occurs in aerobic and microaerophilic habitats where organic matter is mineralized.

The mol% G + C of the DNA is: 59–62.

Type species: **Nitrobacter winogradskyi** Winslow, Broadhurst, Buchanan, Krumwiede, Rogers and Smith 1917, 552 emended mut. char. Watson 1971, 264.

Further descriptive information

Nitrobacter cells are facultative lithoautotrophs that obtain energy from the oxidation of nitrite to nitrate during lithoautotrophic growth. The main source of carbon is carbon dioxide. Alternatively, pyruvate, formate and acetate can serve as energy and carbon sources even in the absence of nitrite. The optimal pH range for growth is 7.5–8.0; the temperature range for growth is 5–37°C with an optimum between 28 and 30°C. Heterotrophic growth is often unbalanced and is accompanied by the formation of large quantities of poly-β-hydroxybutyrate granules. Glycogen and polyphosphates granules are also found as cytoplasmic inclusions. Carboxysomes are present in most but not all species of *Nitrobacter*.

Additional details and a comparison of the biochemical properties of *Nitrobacter* to those of other nitrite-oxidizing genera can be found in the introductory chapter "Lithoautotrophic Nitrite-Oxidizing Bacteria." Details about the ecology of nitrite-oxidizing bacteria and of the phylogeny of these organisms are described in the introductory chapter, Nitrifying Bacteria.

Nitrobacter cells may be either rod-shaped (Fig. BXII.α.180) or pear-shaped. A pear-shaped cell of *Nitrobacter* with a polar cap of intracytoplasmic membranes is shown in Fig. BXII.α.181. The cell wall differs from that found in other Gram-negative bacteria in that the inner side of the wall is more electron dense than the outer one. A similar asymmetry occurs in the cytoplasmic and intracytoplasmic membranes (Fig. BXII.α.181); carboxysomes are formed (Fig. BXII.α.181). Freeze-etched or negatively stained preparations reveal that the inner surface of these mem-

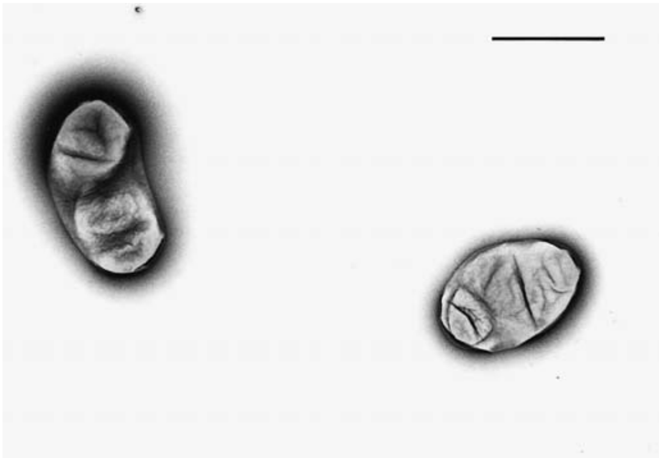

FIGURE BXII.α.180. Negatively stained short rods of *Nitrobacter winogradskyi* Engel. Bar = 1 μm.

branes is covered with densely packed particles with a size of 8–10 nm (Tsien et al., 1968, Remsen and Watson, 1972, Sundermeyer and Bock, 1981, Sundermeyer-Klinger et al., 1984). These particles are composed of the nitrite oxidoreductase enzyme (NOR). Electron microscopy of the isolated enzyme reveals uniform particles with a size of 8 nm (Meincke et al., 1992). Particulate membranes have been labeled with monoclonal antibodies recognizing the α- and β-subunits of the NOR (Spieck et al., 1996a). The particle locations correlate with immunogold-labeling of the α- and β-subunits of nitrite oxidoreductase; labeling of the α-subunit in *Nitrobacter hamburgensis* is shown in Fig. BXII.α.182. The enzyme forms a periodic arrangement in paired rows (Fig.BXII.α.183); a digital image processing analysis of this two-dimensional structure is shown in Fig. BXII.α.184. The molecular weight of a single particle is 186 kDa, suggesting that it is most likely composed of an αβ-heterodimer (Spieck et al., 1996b); the α-subunit has a mass of 115–130 kDa and the β-subunit a mass of 65 kDa.

Lithotrophic growth is slow. The generation time varies from 8 h to several days.

In *Nitrobacter* the concentration of NOR varies with growth conditions. Synthesis of the enzyme is induced by nitrite or nitrate, and the enzyme is the major constituent of nitrite-oxidizing membranes (Bock et al., 1991). In *Nitrobacter hamburgensis* the nitrite-oxidizing activity of mixotrophically grown cells is higher than that of autotrophically grown cells (Milde and Bock, 1985). During heterotrophic growth the NOR is repressed by a factor of more than 90%. When O_2 is absent, NOR shows nitrate reductase activity (Sundermeyer-Klinger et al., 1984). Furthermore, a membrane-bound nitrite reductase which transformed nitrite to NO in low oxygen conditions has been copurified with the NOR (Ahlers et al., 1990). Depending upon the isolation procedure, the NOR is obtained as complexes containing 2–3 subunits (Tanaka et al., 1983; Sundermeyer-Klinger et al., 1984). The membrane-associated α-subunit (115–130 kDa) and β-subunit (65 kDa) can be solubilized by heat treatment at 55°C. Investigations by electron paramagnetic resonance spectroscopy (EPR) showed that the catalytically active enzyme includes molybdenum and iron-sulfur centers which are involved in the transformation of nitrite to nitrate (Meincke et al., 1992). The cytochromes a_1 and c_1 have been coisolated with NOR in procedures employing different detergents. Additional major proteins of the intracellular membranes had molecular masses of 14, 28, and 32 kDa. The 32-kDa protein is the γ-subunit of the NOR (Sundermeyer-Klinger et al., 1984). Tanaka et al. (1983) suggested that the subunit structure of the NOR (cytochrome a_1c_1) of *Nitrobacter winogradskyi* (254 kDa) consists of proteins with molecular masses of 55, 29 and 19 kDa. The pH optimum of the isolated enzyme was 8.0, and the Km value for nitrite was determined to be 0.5–2.6 mM by Tanaka et al. (1983) and 3.6 mM by Sundermeyer-Klinger et al. (1984). A Km value of about 0.9 mM was calculated for the reduction of nitrate. Kirstein and Bock (1993) identified the genes of the NOR and obtained the amino acid sequence of the NOR β-subunit of *Nitrobacter hamburgensis* X14. This protein contained four cysteine clusters (probably three [4Fe-4S] and one [3Fe-4S]) and shared significant sequence similarities with the β-subunits of the dissimilatory nitrate reductases (NRA, NRZ) of *Escherichia coli.* The β-NOR is thought to function as an electron-channeling protein between the nitrite-oxidizing α-subunit and the membrane-integrated electron transport chain. Recently, the genes encoding the α-subunit of the NOR were sequenced in the four described species of *Nitrobacter* (Degrange, personal communication). As in the case of the β-NOR, the *Nitrobacter* α-NORs possess significant sequence similarities to the α-subunits of several dissimilatory nitrate reductases (e.g., *Escherichia coli* or *Pseudomonas* species).

Enrichment and Isolation Procedures

Nitrite oxidizers can be isolated using a mineral medium containing nitrite; the compositions of media for lithotrophic, mixotrophic, and heterotrophic growth are given in Table BXII.α.152. Serial dilutions of enrichment cultures must be incubated for one to several months in the dark. Since nitrite oxidizers are sensitive to high partial pressures of oxygen, cell growth on agar surfaces is limited. Pure cultures of *Nitrobacter alkalicus* were obtained by multiple passages in liquid medium of colonies from nitrite agar (Sorokin et al., 1998). Nitrite oxidizers can be separated from heterotrophic contaminants by Percoll gradient centrifugation and subsequent serial dilution (Ehrich et al., 1995).

Maintenance Procedures

Nitrifying organisms can survive starvation for more than one year when kept at 17°C in liquid medium. Nevertheless, cells should be transferred to fresh media every four months. Table BXII.α.152 lists three different growth media for nitrite oxidizers. Freezing in liquid nitrogen is a suitable technique for maintenance of stock cultures suspended in a cryoprotective buffer containing sucrose and histidine. When freeze-dried on lavalite or polyurethane, about 0.5% of *Nitrobacter* cells survive for one year (L. Lin, personal communication). Another possibility for the storage of *Nitrobacter* for several years is cultivation in 1l-bottles filled to the top with complex medium and closed by a screw top. Glycerol should be used instead of pyruvate to keep the pH-value stable for a long period. Since the bacteria are able to oxidize nitrite to nitrate aerobically and subsequently able to reduce the nitrate anaerobically, a high cell yield can be obtained using this method (Freitag et al., 1987).

Differentiation of the genus *Nitrobacter* from other genera

The nitrite oxidizers are a diverse group of long or short rods, cocci, and spirilla. The genera *Nitrobacter* and *Nitrococcus* possess

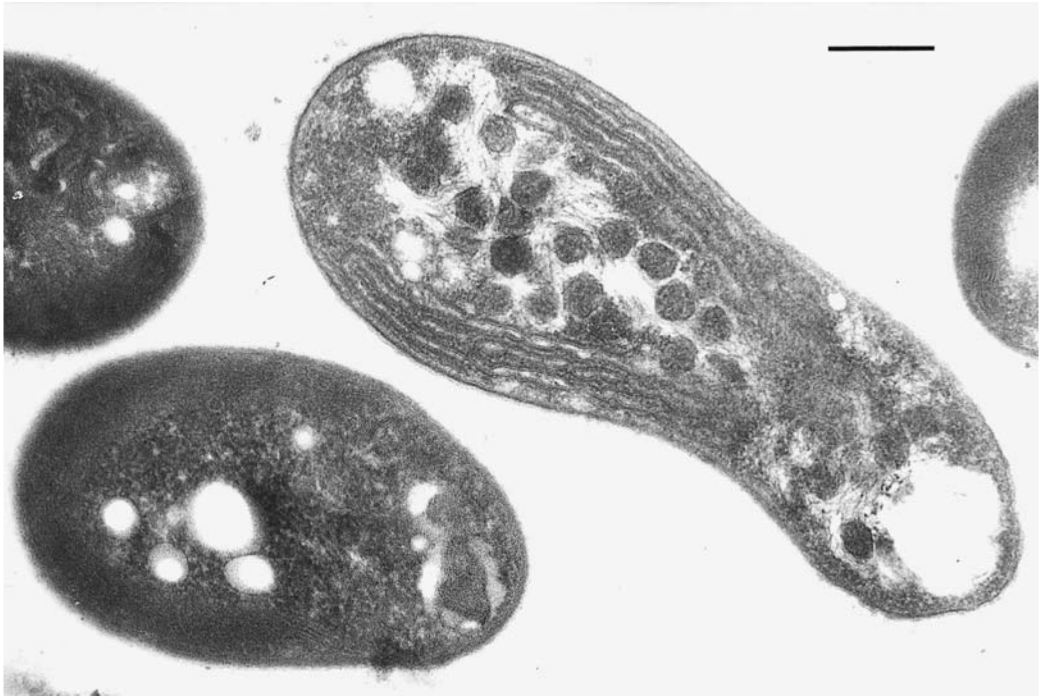

FIGURE BXII.α.181. Ultrathin section of *Nitrobacter vulgaris* strain nevada with intracytoplasmic membranes and carboxysomes. Bar = 250 nm.

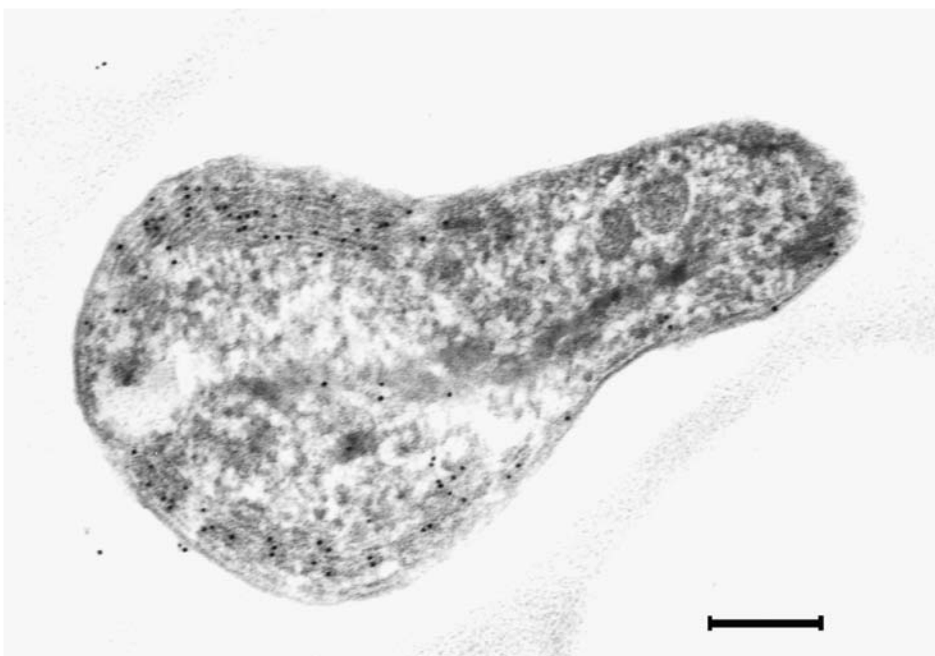

FIGURE BXII.α.182. Ultrathin section of *Nitrobacter hamburgensis* × 14. The nitrite oxidoreductase (NOR) was localized by immunogold-labeling at the cytoplasmic and intracytoplasmic membranes with monoclonal antibodies (MAbs 153-2) recognizing the α-subunit. (Reproduced with permission from E. Spieck et al., FEMS Microbiology Letters *139:* 71–76, 1996, ©Elsevier Science B.V., Amsterdam.) Bar = 250 nm.

a complex arrangement of intracytoplasmic membranes in the form of flattened vesicles or tubes. The taxonomic categorization is based on the work of Sergei and Helene Winogradsky (Winogradsky, 1892). Traditionally, the classification of genera is performed primarily on cell shape and arrangement of intracytoplasmic membranes. So far, four morphologically distinct genera (*Nitrobacter*, *Nitrococcus*, *Nitrospina*, and *Nitrospira*) have been described; the four genera contain a total of eight species (Watson

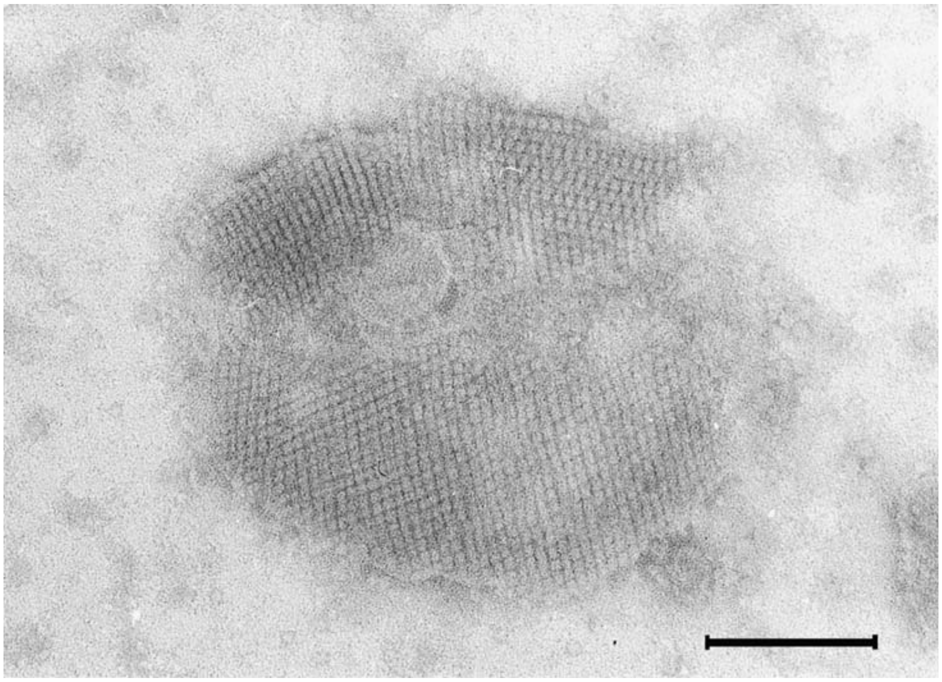

FIGURE BXII.α.183. Isolated negatively stained nitrite-oxidizing membrane of *Nitrobacter hamburgensis* × 14 with crystalline arrays of NOR particles. Bar = 100 nm..(Reproduced with permission from E. Spieck et al., Journal of Structural Biology *117:* 117–123, 1996, Academic Press Inc., Orlando.)

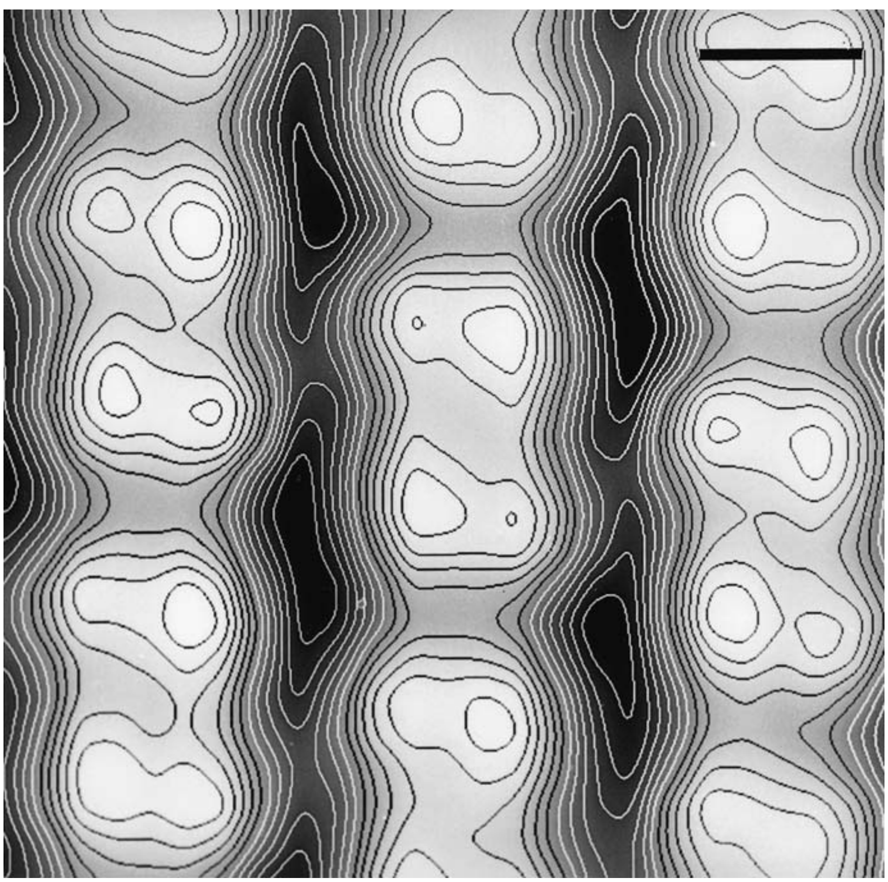

FIGURE BXII.α.184. Image reconstruction of the NOR of *Nitrobacter hamburgensis* × 14 by correlation averaging. The two-dimensional lattice is composed of particle-dimers, arranged in rows. et al., 1989; Bock and Koops, 1992; Ehrich et al., 1995; Sorokin et al., 1998). Three new species belonging to the genera *Nitrobacter*, *Nitrospina*, and *Nitrospira* are known but remain to be described in the literature. Differential traits of the four genera of nitrite-oxidizing bacteria are given in Table BXII.α.153, further properties in Table BXII.α.154, and fatty acid profiles in Table BXII.α.155. Motility and carboxysomes have been observed in *Nitrobacter* and *Nitrococcus* (Tables BXII.α.153 and BXII.α.154).

Nitrobacter can be separated from the other genera by means of monoclonal antibodies that recognize the key enzyme (Table BXII.α.153). Aamand et al. (1996) developed three monoclonal antibodies (MAbs) that recognize the α- and the β-subunit of the NOR of *Nitrobacter*. The key enzyme NOR is ubiquitous in *Nitrobacter* species; homologous reactions of the MAbs with the NOR of *Nitrobacter winogradskyi* and the NORs of *Nitrobacter vulgaris*, *Nitrobacter hamburgensis*, and *Nitrobacter alkalicus* were demonstrated. *Nitrobacter* sp. BS 5/6, identified as a new species by DNA–DNA hybridization (Koops, personal communication), was not recognized by the otherwise genus-specific MAb Hyb 153-2. This antibody targets the α-NOR of *Nitrobacter*, whereas MAb Hyb 153-1 recognizes the β-NOSs of both *Nitrobacter* and *Nitrococcus*. The MAb Hyb 153-3 recognizes the β-NOSs of *Nitrobacter*, *Nitrococcus*, *Nitrospina* and *Nitrospira* (Bartosch et al., 1999). Thus, the suite of MAbs permits detection of all known nitrite oxidizers and allows discrimination of *Nitrobacter* and *Nitrococcus* from *Nitrospina* and *Nitrospira*.

Taxonomic Comments

16S rDNA sequence analysis showed that all characterized strains of *Nitrobacter* form a closely related assemblage within the *Alphaproteobacteria* (Woese et al., 1984b) and that *Nitrobacter* strains cluster with species of the genera *Rhodopseudomonas*, *Bradyrhizobium*, *Blastobacter* and *Afipia* (Teske et al., 1994) in the family *Bradyrhizobiaceae*. (See Fig. 1 [p. 138] of the introductory chapter "Ni-

trifying Bacteria", Volume 2, Part A.) Common traits of *Nitrobacter*, *Rhodopseudomonas*, and *Blastobacter* include the ability to carry out denitrification and cell division by budding. The oligonucleotide data of Seewaldt et al. (1982) demonstrate a close relationship between the 16S rRNAs of *Nitrobacter winogradskyi*, *Nitrobacter hamburgensis* strain X14, and *Rhodopseudomonas palustris*. *Nitrobacter hamburgensis* strain X14 contains an unusual lipid A with 2,3 diamino-2,3-dideoxyglucose similar to that of *Rhodopseudomonas palustris*; this is significant because lipid A structure is considered to be conserved phylogenetically (Mayer et al., 1983). Furthermore, the soluble cytochrome *c* of *Nitrobacter* resembles the cytochrome c_2 of *Rhodopseudomonas viridis* (Yamanaka and Fukumori, 1988). The fact that both *Nitrobacter* spp. and *Rhodopseudomonas palustris* possess complex internal membrane systems suggests a common evolutionary origin. Similar membranes are also present in *Methylobacterium*, the closest methylotrophic relative of *Nitrobacter*.

Acknowledgments

We thank Wolfgang Ludwig (Technical University in Munich, Germany) for phylogenetic trees and Dimitry Sorokin (Institute of Microbiology in Moscow, Russia) for providing cultures of *Nitrobacter alkalicus*.

Differentiation of the species of the genus *Nitrobacter*

Cells of the genus *Nitrobacter* have a comparable shape, size and ultrastructure. Since most strains are phenotypically similar, species differentiation is based on the mol% G + C content of the DNA, DNA–DNA hybridization, serological properties, patterns of membrane-bound heme proteins, and slight differences in growth characteristics. Differential characteristics are given in Table BXII.α.154 and fatty acid profiles in Table BXII.α.155. *Nitrobacter hamburgensis* and *Nitrobacter vulgaris* differ from *N. winogradskyi* in that mixotrophic growth of *N. hamburgensis* and *N. vulgaris* is more rapid than lithoautotrophic growth; *Nitrobacter*

alkalicus can be separated from the other species by its ability to oxidize nitrite under alkaline conditions.

The DNA–DNA hybridization values between the pairs of species range from 20–49% (Bock et al., 1990). The mol% G + C of the DNA of *Nitrobacter* species ranges from 59–62%. Navarro et al. (1992) investigated the genomic relationships within this genus by examination of rRNA gene restriction patterns and by DNA–DNA hybridization. These authors differentiated three genomic species, two of which corresponded to the described species *N. winogradskyi* and *N. hamburgensis.* (No strains of *N. vulgaris* were examined in that study.) High-resolution phylogenetic investigations of *Nitrobacter* have also been carried out using 16S–23S rRNA intergenic spacer region sequences and partial sequences of the 23S rRNA gene (Grundmann et al., 2000). Analysis of 16S rDNA sequences showed that species of *Nitrobacter* form a coherent cluster with sequence similarities of 99.2–99.6% (Orso et al., 1994). Seewaldt et al. (1982) obtained an S_{AB} value of 0.82 for *N. winogradskyi* and *N. hamburgensis* X14. The 16S rRNA similarity between the newly described species *Nitrobacter alkalicus* and both *N. winogradskyi* and *N. hamburgensis* was 98.6–99.9% (Sorokin et al., 1998). The closest relative of the alkaliphilic species is *N. winogradskyi.* DNA–DNA hybridization studies of strains of *N. vulgaris* indicated that this species might contain subspecies. The hybridization values obtained in this study ranged between 55–97%; the distribution of hybridization values among strains agreed with the distribution of variable physiological traits; both sorts of variation may reflect adaptation to special environments (Bock et al., 1990).

List of species of the genus Nitrobacter

1. **Nitrobacter winogradskyi** Winslow, Broadhurst, Buchanan, Krumwiede, Rogers and Smith 1917, 552[AL] emended mut. char. Watson 1971b, 264.
wi.no.grad′ sky.i. M.L. gen. n. *winogradskyi* of Winogradsky; named after Winogradsky, the microbiologist who first isolated these bacteria.

Short rods, often pear-shaped, sometimes coccoid with a size of 0.6–0.8 × 1.0–2.0 μm. Carboxysomes occur as cytoplasmic inclusions. Cells may be motile by a single subpolar to lateral flagellum. Many strains are facultative lithoautotrophs. During mixotrophic growth, nitrite is oxidized first, followed by the oxidation of organic material. Cells can also grow heterotrophically with pyruvate, acetate, and glycerol as energy sources and with yeast extract, casamino acids, peptone, ammonia, and nitrate as nitrogen sources. Under lithoautotrophic and mixotrophic conditions, the generation time varies from 8–14 h and under heterotrophic conditions from 70–100 h. The organism is able to grow anaerobically with nitrate as the electron acceptor (Bock et al., 1988) and forms nitrite, nitric oxide (NO), and nitrous oxide (N_2O). The cells are slightly sensitive to oxygen when undergoing a shift from anoxic to oxic conditions. Nitric oxide may be an alternative substrate for the aerobic oxidation to nitrate. The type strain was isolated from soils. Other habitats are fresh water, oceans, sewage disposal systems and compost piles.

The mol% G + C of the DNA is: 61.7 (Bd).

Type strain: ATCC 25391.

2. **Nitrobacter alkalicus** Sorokin, Muyzer, Brinkhoff, Kuenen and Jetten 1999, 1325[VP] (Effective publication: Sorokin, Muyzer, Brinkhoff, Kuenen and Jetten 1998, 352.)
al.ka′ li.cus. M.L. adj. *alkalicus* alkaline.

Pear-shaped cells 0.6–0.9 ×1.2–1.8 μm. Cell wall contains an additional external layer with a regular subunit arrangement. In contrast to the other species of this genus, no carboxysomes have been detected. Lithoautotrophic growth with nitrite occurs in a broad pH range from 6.5–10.2 with an optimum at 9.5. Heterotrophic growth not observed. Obligately dependent on the presence of carbonate ions. Strains were isolated from the sediments of soda lakes and from soda soil in Siberia and Kenya. The 16S rRNA gene sequences of strains AN 1, AN 2, and AN 4 are deposited in the GenBank database.

The mol% G + C of the DNA is: 62.0 (T_m).

Type strain: AN 1, LMD 97.163.

GenBank accession number (16S rRNA): AF 069956.

The type strain is stored in the culture collection of the Department of Microbiologie, University of Technology, Delft, The Netherlands.

3. **Nitrobacter hamburgensis** Bock, Sundermeyer-Klinger and Stackebrandt 2001, 1[VP] (Effective publication: Bock, Sundermeyer-Klinger and Stackebrandt 1983, 283.)
ham′ bur.gen.sis. M.L. adj. *hamburgensis* pertaining to the city of Hamburg, Federal Republic of Germany, where the organism was first isolated.

Morphology and ultrastructure are as described for the genus. Carboxysomes are present. Motile by a subpolar to lateral flagellum. Grows poorly lithoautotrophically but well mixotrophically. Optimal growth rates are obtained in a mixotrophic medium containing nitrite, pyruvate, yeast extract and peptone. One strain could grow only in the presence of organic material. Both nitrite and organic compounds are metabolized during mixotrophic growth. Growth by dissimilatory nitrate reduction is possible, but the cells are sensitive to oxygen when changing from anoxic to oxic conditions. Isolated from soils in Hamburg (Germany), Yucatan (Mexico) and Corse (France).

The mol% G + C of the DNA is: 61.6 (T_m).

Type strain: X 14.

GenBank accession number (16S rRNA): L11663.

The type strain is stored in the culture collection of the Institute of General Botany, Department of Microbiology, University of Hamburg, FRG.

4. **Nitrobacter vulgaris** Bock, Koops, Möller and Rudert 2001, 1[VP] (Effective publication: Bock, Koops, Möller and Rudert 1990, 109.)
vul.ga′ ris. L. adj. *vulgaris* common.

The morphology and ultrastructure are as described for the genus. Carboxysomes are present. Most strains show diphasic growth, oxidizing nitrite first and then organic material. Lithoautotrophic growth is often slower than chemoorganotrophic growth. Cells of strain ‘Z’ double in number in 140 h during lithoautotrophic growth and in 25 h during mixotrophic growth. Either nitrate or oxygen can serve as electron acceptor during heterotrophic growth with acetate or pyruvate as electron donor. Cells produce extracellular polymers as biofilm and form microcolonies. In contrast to the other strains of this genus, cells of *N.*

vulgaris are insensitive to oxygen stress. Only one membrane-bound *c*-type cytochrome of 32 kDa is present, in contrast to *N. winogradskyi* and *N. hamburgensis*, which also possess a 30 kDa *c*-type cytochrome. Strains have been isolated from soils, groundwater, fresh and brackish water, sewage and a termite heap. *N. vulgaris* is the most abundant species of *Nitrobacter* in concrete and natural building stone.

The mol% G + C of the DNA is: 59.4 (T_m).

Type strain: Z.

Type strain is stored in the culture collection of the Institute of General Botany, Department of Microbiology, University of Hamburg, FRG.

Genus VII. **Oligotropha** *Meyer, Stackebrandt and Auling 1994, 182*[VP] *(Effective publication: Meyer, Stackebrandt and Auling 1993, 391)*

ORTWIN O. MEYER

O.li.go.tro'pha. Gr. n. *oligos* little, scanty; *tropha* nourishing, living on few substrates; M.L. fem. n. *Oligotropha* utilizer of few substrates.

Rod-shaped cells, slightly curved, 0.4–0.7 × 1.0–3.0 μm. **Motility variable**; when present, it is by means of **one subpolar flagellum** (Meyer and Schlegel, 1978). Star-shaped aggregates (rosettes)—held together by polar pili and excreted slime—are formed to a certain extent, especially in the post exponential and stationary growth phases. Gram negative. Colonies are white or cream colored, and no carotenoid pigment is produced. Colony formation on agar plates is slow (one to four weeks, depending on the medium). Aerobic, having a respiratory type of metabolism, with oxygen as the terminal electron acceptor; however, some strains can denitrify. **Facultatively chemolithoautotrophic.** Chemoorganoheterotrophic substrates are usually restricted to the salts of some organic acids such as pyruvate, although some strains can also utilize sugars and amino acids. Dinitrogen is not fixed. Not phototrophic. Not methanotrophic. Isolated from wastewater of sewage treatment settling ponds and from soil.

The mol% G + C of the DNA is: 62.5–63.1.

Type species: **Oligotropha carboxidovorans** (Meyer and Schlegel 1978) Meyer, Stackebrandt and Auling 1994, 182 (Effective publication: Meyer, Stackebrandt and Auling 1993, 391) (*"Pseudomonas carboxydovorans"* Meyer and Schlegel 1978, 42; *"Hydrogenomonas carboxydovorans"* Kistner 1954, 186.)

FURTHER DESCRIPTIVE INFORMATION

Cells of *Oligotropha* lack intracytoplasmic membranes or chlorosomes, and thus electron micrographs of the cytoplasm are in accord with the absence of phototrophic or methanotrophic metabolic capabilities (Meyer and Rohde, 1984; Rohde et al., 1984). For electron micrographs of the flagella, see Meyer and Schlegel (1978), Meyer and Rohde (1984), and Rohde et al. (1984). The flagellar fine structure (Aragno et al., 1977) and the cell wall (Walther-Mauruschat et al., 1977) are of type I.

Under heterotrophic conditions (e.g., on the mineral medium of Meyer and Schlegel (1983) supplemented with 0.1% nutrient broth and 0.1% pyruvate), colonies first become visible after about 1 week of incubation. Under chemolithoautotrophic conditions (e.g., the mineral medium of Meyer and Schlegel (1983) in a gas atmosphere of 50% CO, 5% CO_2 and 45% air, or of 50% H_2, 10% CO_2 and 40% air), colonies first become visible after a month or more of incubation. Colony sizes may vary, depending on whether a colony has been developed from a single bacterium or a number of aggregated cells.

Submerged growth in shaken liquid cultures is usually much faster than on solid media. Growth of strain OM5 with CO in submerged culture (e.g., in 30–l fermentors at 30°C) in the mineral medium of Meyer and Schlegel (1983) supplied with the indicated trace elements TS2 and a gas mixture of 20% CO and 80% air at a flow rate of 2 l/min occurs at generation times of 20 h. Under these conditions, exponential growth proceeds to an OD436 of 7 and a yield of 1 g wet weight/l. Cultivation of the bacteria with H_2 requires essentially the same conditions as with CO, except that a gas mixture of 5% CO_2, 20% H_2, and 75% air is employed. Under these conditions, the generation time is 15 h, and exponential growth proceeds to an OD_{436} of 7 and a yield of 1 g wet weight/l. Because *O. carboxidovorans* OM5 employs a membrane-bound heterodimeric NiFe-hydrogenase for the chemolithoautotrophic utilization of H_2 (Santiago and Meyer, 1997), Ni must be supplied for chemolithoautotrophic growth with H_2.

The metabolism is generally aerobic and facultatively chemolithoautrophic (Meyer and Schlegel, 1983). The respiratory metabolism is in accord with the presence of cytochromes (Cypionka and Meyer, 1983b). One strain can reduce nitrate to nitrite (Frunzke and Meyer, 1990). Obligate chemolithoautotrophic strains are not known. So far, only mesophilic strains have been characterized. Chemoorganoheterotrophic substrates utilized under aerobic conditions include the salts of pyruvate, formate, glyoxylate, lactate, ascorbate, acetate, malate, fumarate, oxoglutarate, and oxalate (Meyer et al., 1993). Vitamins are not required. Sugars and amino acids are not used by the strains OM3, OM4, and OM5 of *O. carboxidovorans*, whereas strain OM2 utilizes most sugars and amino acids. Suitable nitrogen sources of all strains are urea, ammonia, nitrate, and nitrite. Nitrate is not assimilated by strain OM5 when CO is the substrate.

The aerobic chemolithoautotrophic utilization of CO by *O. carboxidovorans* OM5 follows this equation: $O_2 + 2.19\ CO \rightarrow 1.83\ CO_2 + 0.36$ cell carbon (Meyer and Schlegel, 1978, 1983). The bacteria oxidize CO for the generation of energy ($5\ CO + 2.5\ O_2 \rightarrow 5\ CO_2$) and of reducing equivalents ($2\ CO + H_2O \rightarrow 2\ CO_2 + 2 \times 2\ [H]$). CO_2 derives from the oxidation of CO and is assimilated in the Calvin-Benson-Bassham-cycle ($CO_2 + 2 \times 2\ [H] \rightarrow [CH_2O] + H_2O$). The sum of these equations ($7\ CO + 2.5\ O_2 + H_2O \rightarrow 6\ CO_2 + [CH_2O]$) is in accordance with the actually observed stoichiometry of CO oxidation and indicates that 86% of the CO is oxidized for energy generation and 14% of the CO carbon is assimilated.

Carbon monoxide oxidation in *O. carboxidovorans* OM5 is catalyzed by the heterohexameric metalloenzyme CO dehydrogenase ($CO + H_2O \rightarrow CO_2 + 2\ H^+ + 2\ e^-$) that is associated with the inner aspect of the cytoplasmic membrane (Meyer and Rohde, 1984; Rohde et al., 1984; Meyer et al., 2000). CO dehydrogenases are very much conserved in all aerobic CO oxidizing bacteria (Schübel et al., 1995; Santiago et al., 1999), and the CO dehydrogenases from the strains OM5, OM4, OM3, and OM2 of

O. carboxidovorans are very similar as indicated by a close immunological relationship, same molecular masses, same subunit structure, same types and number of cofactors, indistinguishable electron acceptor specificity, and co-migration upon non-denaturing or SDS-PAGE (Cypionka et al., 1980; Meyer and Rohde, 1984; Hugendieck and Meyer, 1992). The CO dehydrogenase from *O. carboxidovorans* is a 277-kDa Mo- and Cu-containing iron-sulfur flavoprotein (Meyer et al., 2000); therefore, growth with CO has a special requirement for Mo and Cu. The enzyme contains the cofactor molybdopterin cytosine dinucleotide. CO dehydrogenase has been crystallized in different states and structurally characterized (Gremer et al., 2000; Meyer et al., 2000; Dobbek, et al., 2002). The bimetallic [$CuSMoO_2$] active site of the enzyme has also been studied by x-ray spectroscopy (Gnida et al., 2003). The subunit structure of CO dehydrogenase is $(LMS)_2$, and it consists of a dimer of LMS heterotrimers. Each heterotrimer is composed of a 17.8-kDa iron-sulfur protein (S, 166 amino acid residues), which carries two types of [2Fe-2S] clusters, a 30.2-kDa flavoprotein (M, 288 amino acid residues), which contains a noncovalently bound FAD cofactor, and a 88.7-kDa molybdoprotein (L, amino acid 809 residues), which harbors a [$CuSMoO_2$] cluster in the active site of the enzyme.

The CO dehydrogenase structural genes *coxMSL* are an integral part of an elaborate CO oxidizing system (Santiago et al., 1999), which itself is part of an extended chemolithoautrophy module covering 39% of the entire sequence of the 133.056-kb plasmid pHCG3 of *O. carboxidovorans* OM5 Fuhrmann et al., 2003. The respiratory chain of *O. carboxidovorans*, particularly the terminal cytochrome oxidase, is insensitive to CO (Cypionka and Meyer, 1983a).

H_2 oxidation by *O. carboxidovorans* strain OM5 is catalyzed by a membrane-bound hydrogenase [$H_2 \rightarrow 2\ H^+ + 2\ e^-$], which has been solubilized, isolated, and characterized (Santiago and Meyer, 1997). It belongs to the class I of hydrogenases and is a heterodimeric 101,692-Da NiFe-protein composed of the polypeptides HoxL and HoxS. The hydrogenase structural genes *hoxLS* are part of the chemolithoautotrophy module on pHCG3. HoxL comprises 604 amino acid residues and has a molecular mass of 67,163 Da. Pre-HoxS comprises 360 amino acid residues and is synthesized as a precursor protein that is cleaved after alanine at position 45, thus producing a mature HoxS of 33,767 Da. The leader sequence corresponds to the signal peptide of small subunits of hydrogenases. The hydropathy plots of HoxL and HoxS indicate the absence of transmembrane helices. Total DNA of species of *Oligotropha* did not hybridize with a *nifH* probe, indicating the absence of genes coding for the conventional, molybdenum-containing nitrogenase (Auling et al., 1988). In addition, growth with N_2 as a sole nitrogen source could not be demonstrated.

Megaplasmids have been identified in the strains OM5 (pHCG3: 133 kb) OM4 (pHCG5-a: 158 kb; pHCG5-b: 128 kb), and OM2 (pHCG4: 128 kb) of *O. carboxidovorans* (Kraut and Meyer, 1988). *O. carboxidovorans* strain OM3 does not carry a plasmid. *O. carboxidovorans* OM5 harbors the low copy number 133,058 bp circular DNA plasmid pHCG3, which has been sequenced and is required for the chemolithoautotrophic utilization of CO, H_2, and CO_2 by the bacterium. The calculated G + C content of the plasmid is 60.55 mol%. Loss of the plasmid is associated with loss of the ability to grow with CO or H_2 or to assimilate CO_2. The complete nucleotide sequence of the plasmid pHCG3 was obtained. Sequence analysis indicated 128 open reading frames. Of these, 95 are putative structural genes. The most striking feature is the occurrence of the four gene clusters *cox*, *cbb*, *hox*, and *tra/trb*, which have functions in the utilization of CO, CO_2 or H_2, and the conjugal transfer of the plasmid, respectively. The clusters *cox*, *cbb*, and *hox* form a 51.2-kb chemolithoautotrophy module, containing 12 *cox* genes (14.54 kb), 13 *cbb* genes (13.33 kb), and 20 *hox* genes (23.35 kb). The 24.58-kb *tra/trb* cluster is separated from the chemolithoautotrophy module by two regions of 25.4- and 29.6-kb with miscellaneous or so far unknown functions. The *tra/trb* cluster carries 10 *tra* genes and 10 *trb* genes, in an arrangement very similar to the Ti-plasmid conjugal transfer system of *Agrobacterium tumefaciens*. The 25.4- and 29.6-kb regions with other functions carry a number of single genes coding for the replication and stabilization of the megaplasmid. Among these are an *oriV* coding for the replication proteins RepA, B, and C, two ORFs coding for transposase A, and a single ORF encoding transposase B. The plasmid pHCG3 also contains the insertion sequence SC1190 of *Sulfolobus solfataricus*, a gene function involved in the biosynthesis of acylated homoserine lactones, which participate in quorum sensing, and *rspD* and *rspE*, which function in rhizobiocine secretion. Most interestingly, the megaplasmid pHCG3 of *O. carboxidovorans* carries numerous genes with highest homologies to *Bradyrhizobium japonicum*, *Nitrobacter vulgaris*, *Agrobacterium tumefaciens*, *Rhizobium leguminosarum*, *Rhizobium rhizogenes*, *Rhodobacter capsulatus*, and *Rhodobacter sphaeroides*, which might be taken as an indication of horizontal gene transfer among the members of the α2 and the α3 subclasses of the *Alphaproteobacteria* (Fig. BXII.α.185).

As are all carboxidotrophic bacteria, the members of *Oligotropha* are cosmopolites inhabiting all sorts of environments, including sewage, water, and soil (Meyer and Schlegel, 1978, 1983). Natural enrichment can be found in the covering soil of smoldering charcoal piles (Meyer et al., 1991; Meyer, 1997).

Enrichment and Isolation Procedures

Enrichment and isolation of pure cultures of *Oligotropha* and other aerobic carbon monoxide oxidizing microorganisms from natural habitats apply conditions selective for the ability to proliferate in a mineral medium with CO as a sole energy source and CO_2 as a sole carbon source under respiratory conditions with O_2 as the terminal electron acceptor. The CO present is counterselective for most contaminating microorganisms that cannot utilize CO. Alternatively, enrichments may be carried out under anoxic conditions in the presence of a suitable electron acceptor. Typically, enrichments are done in liquid batch cultures employing a mineral medium (e.g., that of Meyer and Schlegel, 1983, plus the indicated trace elements) incubated in desiccators supplied with a gas atmosphere composed of 5% CO_2, 10% O_2, and 85% CO (alternatively 5% CO_2, 45% CO, and 50% air). The concentrations of CO and O_2 can be varied to modify the selective conditions. About 1 g of environmental sample is suspended in 15 ml of sterile mineral medium contained in 100 ml Erlenmeyer flasks. The flasks are placed in desiccators and the appropriate gas atmosphere is established by evacuation and refilling. After about 1 month with or without shaking at 30°C in the dark, subcultures are made (10% inoculum). Further subcultures are prepared about every 2 weeks (5% inoculum). Aliquots of the suspensions are streaked on agar plates made of mineral medium supplied with nutrient broth and pyruvate (0.1% of each) and solidified with 1.4% agar. The plates are incubated in desiccators at 30°C under the same CO-containing atmosphere used for enrichment. The very fast growing colonies are generally CO-tolerant contaminants. The slow growing colonies appearing after

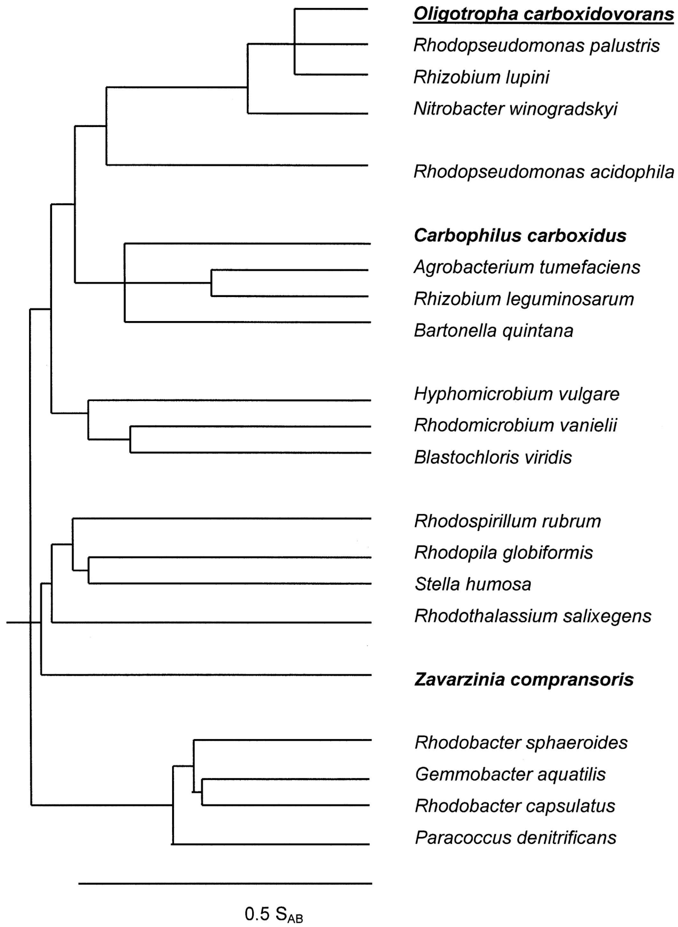

FIGURE BXII.α.185. Position of *Oligotropha carboxidovorans* strain OM5^T (DSM 1227, ATCC 49405) relative to other carboxidotrophic bacteria (*Carbophilus carboxidus* DSM 1086^T, *Zavarzinia compransoris* DSM 1231^T) in the phylogenetic tree of the *Alphaproteobacteria*. For a list of similarity coefficients refer to Table 6 of Auling et al. (1988). Modified from Auling et al. (1988). Refer to Meyer et al. (1993) for the transfer and amended descriptions of *"Pseudomonas carboxydovorans"* OM5^T to *Oligotropha*, gen. nov., as *Oligotropha carboxidovorans*, comb. nov., of "*Alcaligenes carboxydus*" DSM 1086^T to *Carbophilus*, gen. nov., as *Carbophilus carboxidus*, comb. nov., and of *"Pseudomonas compransoris"* DSM 1231^T to *Zavarzinia*, gen. nov., as *Zavarzinia compransoris*, comb. nov. Note that *O. carboxidovorans*, *Bradyrhizobium japonicum* strain 110spc4 (Lorite et al., 2000), *Carbophilus carboxidus*, and *Zavarzinia compransoris* are carboxidotrophic, i.e., they contain the molybdo- and copper-enzyme CO dehydrogenase and are capable of chemolithoautotrophic growth with CO as a sole energy and CO_2 as a carbon source under aerobic conditions.

1 week are purified by streaking. Because *Oligotropha* can form stellate aggregations, a pure culture will yield colonies of different diameter and dissimilar appearance. However, the microscopic observation of a single morphological type of cell in small and large colonies along with the formation of aggregates can be taken as evidence that a culture is axenic. Purity of a culture can be further confirmed by determining the viable cell numbers on different media (e.g., plates made up with the salts of pyruvate, lactate, acetate, succinate, or with nutrient broth, with sugars, or with mineral medium in the presence of 5% CO_2, 10% O_2, and 85% CO or 5% CO_2, 10% O_2, and 85% H_2). Pure cultures should reveal either identical colony numbers or no colonies at all. Because of the slow growth on CO or H_2 on solid media, the use of low agar concentrations (1.2–1.4%) is advisable.

Differentiation of the genus *Oligotropha* from other genera

Within the *Alphaproteobacteria*, the ability to form CO dehydrogenase and to utilize CO under aerobic chemolithoautotrophic conditions is known from individual strains of the genera *Oligotropha*, *Bradyrhizobium*, *Carbophilus*, and *Zavarzinia*. The genus *Oligotropha* is differentiated from *Bradyrhizobium* by the inability to nodulate leguminous plants, the absence of nitrogenase, and the inability to fix N_2. In addition, the variety of carbon sources utilized by the *Bradyrhizobium* species includes a much wider range than those utilized by *Oligotropha*. The genus *Carbophilus* is placed by 16S rRNA cataloging in an individual subline of descent within the α2 subclass of the *Alphaproteobacteria* (Fig. BXII.α.185). In contrast to *Oligotropha carboxidovorans*, *Carbophilus carboxidus* carries up to five peritrichous flagella, is unable to grow at the expense of H_2 plus CO_2 under aerobic chemolithoautotrophic conditions, and utilizes a broad spectrum of organic compounds, particularly sugars, as source of carbon and energy. In addition, *Carbophilus* and *Oligotropha* can be differentiated based on their sensitivity to different kinds of antibiotics and profiles of fatty acids and polyamines (see Table 1 of Meyer et al., 1993). The genus *Zavarzinia* has an isolated phylogenetic position intermediate between the α1 and α2 subclasses of the *Alphaproteobacteria* (Fig. BXII.α.185). *Zavarzinia compransoris* can be differentiated from *Oligotropha* by a very long polar flagellum, the requirement of thiamine as a growth factor, a higher G + C content of the DNA, different sensitivity to antibiotics, and different profiles of fatty acids and polyamines (see Table 1 of Meyer et al., 1993).

Taxonomic Comments

On the basis of 16S rRNA cataloging, the presence of signature oligonucleotides in their 16S rRNA catalogues [see Table 5 of Auling et al. (1988)], and the presence of ubiquinone Q-10 as the major quinone (see Table 3 of Auling et al., 1988), *sym*-homospermidine as the major polyamine (see Table 4 of Auling et al., 1988), and *cis*-vaccinic acid as the major fatty acid (see Table 3 of Auling et al., 1988), *O. carboxidovorans* has been allocated to the class *Alphaproteobacteria* in the phylum *Proteobacteria* (Fig. BXII.α.185). For a dendrogram of relationship, derived from the S_{AB} values by average linkage clustering, refer to Auling et al. (1988). The phylogenetic position of *O. carboxidovorans* indicates a high relationship to certain members of the *Alphaproteobacteria*, such as *Rhodopseudomonas palustris*, *Bradyrhizobium japonicum*, *Rhizobium lupini*, *Nitrobacter winogradskyi*, and *N. hamburgensis*.

The type species was formerly known as *"Pseudomonas carboxydovorans"* (Meyer and Schlegel, 1978) and was a re-isolate of *"Hydrogenomonas carboxydovorans"* (Kistner, 1953, 1954), which was lost or lost its properties (see discussion in Meyer and Schlegel, 1978).

Although they have been placed in a separate genus, the strains of *O. carboxidovorans* are phylogenetically related to the dinitrogen fixers *Bradyrhizobium japonicum* and *Rhodopseudomonas palustris* (Fig. BXII.α.185). Indeed, *B. japonicum* strain 110spc4 has been demonstrated to grow with CO chemolithoautotrophically and to contain a CO dehydrogenase that is very closely related to the corresponding enzyme from *O. carboxidovorans* strain OM5 (Lorite et al., 2000). However, *O. carboxidovorans* does not fix N_2 and no hybridization with a *nifH* gene probe points to the absence of a conventional nitrogenase.

DNA base ratios of total DNA from *O. carboxidovorans* strains OM5 (62.8 mol% G + C), OM4 (62.6 mol% G + C), OM3 (62.6 mol% G + C), and OM2 (63.1) based on T_m and analysis of the base content by reverse-phase HPLC are narrow (Auling et al., 1988).

So far, only a single species has been identified. The isolates designated OM2, OM3, OM4, and OM5 have all grouped together as strains of the species *Oligotropha carboxidovorans*.

List of species of the genus Oligotropha

1. **Oligotropha carboxidovorans** (Meyer and Schlegel 1978) Meyer, Stackebrandt and Auling 1994, 182[VP] (Effective publication: Meyer, Stackebrandt and Auling 1993, 391) (*"Pseudomonas carboxydovorans"* Meyer and Schlegel 1978, 42; *"Hydrogenomonas carboxydovorans"* Kistner 1954, 186.)
car.box.i.do'vo.rans. L. n. *carbo* charcoal, carbon; Gr. adj. *oxys* sour, acid; L. v. *voro* devour; M.L. part. adj. *carboxidovorans* carbon-acid devouring; named for its ability to use CO as a sole carbon and energy source.

The description is as given for the genus. The strains OM4 and OM5 of *O. carboxidovorans* were isolated from wastewater of the settling pond of the municipal sewage treatment plant of the city of Göttingen (Germany). The strains OM2 and OM3 were isolated from soil.
The mol% G + C of the DNA is: 62.8 (T_m).
Type strain: OM5, ATCC 49405, DSM 1227.

Genus VIII. Rhodoblastus *Imhoff 2001, 1865*[VP]

JOHANNES F. IMHOFF

Rho.do.blas'tus. Gr. n. *rhodon* the rose; Gr. n. *blastos* bud shoot; M.L. masc. n. *Rhodoblastus* the budding rose.

Cells are rod shaped, motile by means of flagella; show polar growth, budding, and asymmetric cell division. Gram negative and belong to the *Alphaproteobacteria*. Internal photosynthetic membranes appear as lamellae underlying and parallel to the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids. Straight-chain monounsaturated $C_{18:1}$, $C_{16:1}$, and saturated $C_{16:0}$ are the major cellular fatty acids. Contain ubiquinones, rhodoquinones, and menaquinones with 10 isoprene units (Q-10, MK-10, and RQ-10).

Preferred mode of growth is photoheterotrophically under anoxic conditions in the light. Photoautotrophic growth may be possible under anoxic conditions with hydrogen as electron donor. Chemotrophic growth occurs under microoxic to oxic conditions, but with some substrates also anaerobically by fermentation. Growth factors are not required by the type species. **Mesophilic freshwater bacteria with preference for acidic pH.**

Habitat: slightly acidic freshwater ponds.

The mol% G + C of the DNA is: 62.2–66.8.

Type species: **Rhodoblastus acidophilus** (*Rhodopseudomonas acidophila* Pfennig 1969a, 601) Imhoff 2001, 1865.

FURTHER DESCRIPTIVE INFORMATION

During growth on methanol, *Rhodoblastus acidophilus* assimilates its cell carbon via the ribulosebisphosphate cycle and carboxylation reactions of C_3 fatty acids. There was no evidence of the operation of a reduced C_1 fixation sequence (Sahm et al., 1976). A slow fermentative metabolism may be a property of most *Rhodopseudomonas* species. Gürgün et al. (1976) quantitatively demonstrated the formation from pyruvate of CO_2, formate, acetate, diacetyl, acetoin, and butandiol by *Rhodoblastus acidophilus*. Photoautotrophic growth with hydrogen has been found in *Rhodopseudomonas palustris* in *Rhodoblastus acidophilus* (Pfennig, 1969a). *Rhodoblastus acidophilus* also grows chemoautotrophically with hydrogen and utilizes methanol and formate under these conditions if the oxygen tension is kept at a low level (Siefert and Pfennig, 1979).

In contrast to *Rhodopseudomonas palustris*, sulfate is assimilated by *Rhodoblastus acidophilus* via the adenosine-5′-phosphosulfate pathway (Imhoff, 1982). Nitrogenase has been found in all species investigated (Madigan et al., 1984). Ammonia assimilation proceeds via glutamine synthetase and glutamate synthase in *Rhodoblastus acidophilus* (NADH-linked) (Brown and Herbert, 1977; Herbert et al., 1978); glutamate dehydrogenase is lacking.

ENRICHMENT AND ISOLATION PROCEDURES

Standard procedures are used for the isolation of purple nonsulfur bacteria (PNSB). A mineral medium that is suitable for most PNSB is also applicable for the cultivation of *Rhodoblastus* species (Imhoff, 1988; Imhoff and Trüper, 1992; for this medium, see the footnote in the chapter describing the genus *Rhodospirillum*). For selective enrichments, the preference for low pH values is used for cultures of *Rhodoblastus acidophilus*. A succinate-mineral medium without growth factors with an initial pH of 5.2 is highly selective for *Rhodoblastus acidophilus* (and also *Rhodomicrobium vannielii*) (Pfennig, 1969a).

MAINTENANCE PROCEDURES

Cultures of *Rhodoblastus* can be preserved in liquid nitrogen, by lyophilization, or at −80°C in a mechanical freezer.

DIFFERENTIATION OF THE GENUS *RHODOBLASTUS* FROM OTHER GENERA

Differential characteristics of the genera and species of *Rhodoblastus*, *Rhodopseudomonas*, *Rhodobium*, *Rhodoplanes*, *Blastochloris*, and *Rhodomicrobium* and are shown in Tables 3 (pp. 125–126) and 4 (p. 127) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. Their phylogenetic relationships are shown in Fig. 2 (p. 128) of that chapter. The properties of *Rhodoblastus* are compared to those of *Rhodopseudomonas* species in Tables BXII.α.156 and BXII.α.157.

TAXONOMIC COMMENTS

Rhodoblastus acidophilus contains glucosamine (not 2,3-diamino-2,3-dideoxyhexose) in the lipid A (Tegtmeyer et al., 1985). This is in contrast to *Rhodopseudomonas palustris* and to *Blastochloris* species (also formerly assigned to *Rhodopseudomonas*).

List of species of the genus Rhodoblastus

1. **Rhodoblastus acidophilus** (*Rhodopseudomonas acidophila* Pfennig 1969a, 601[AL]) Imhoff 2001, 1865[VP]
a.ci.do′phi.lus. L. adj. *acidus* sour; M.L. neut. n. *acidum* an acid; Gr. adj. *philos* loving; M.L. masc. adj. *acidophilus* acid-loving.

Cells are rod shaped to elongate-ovoid, slightly curved, 1.0–1.3 × 2.0–5.0 μm, motile by polar flagella, and Gram negative. Daughter cells originate by polar growth as sessile buds at the pole opposite that bearing the flagella; there is no tube or filament between mother and daughter cells (Fig. BXII.α.186). When the daughter cell reaches the size of the mother cell, cell division is completed by constriction. In the next cycle, both cells form buds at the poles of the former cell division. Under certain conditions, rosettes and clusters are formed that are similar to those of the type species. In media lacking calcium ions, cells are immotile. Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. Color of anaerobic liquid cultures is purple-red to orange-brown. Cells grown under oxic conditions are colorless to light pink or orange. Absorption spectra of living cells show maxima at 375, 460, 490, 525, 590, 805, 855, and 890 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esteri-

fied with phytol) and carotenoids of the spirilloxanthin series with glucosides of rhodopin and rhodopinal. The latter are characteristic of this species.

Photoheterotrophic growth with a number of organic carbon sources is the preferred growth mode. Photoautotrophic growth is possible with hydrogen as electron donor; sulfide and thiosulfate cannot be used. Cells grow under microoxic to oxic conditions in the dark, with hydrogen as electron donor autotrophically. The organic carbon sources used are acetate, propionate, butyrate, lactate, pyruvate, fumarate, malate, succinate, valerate, formate, methanol, and ethanol. Not used are caprylate, pelargonate, glycerol, benzoate, sugars, sugar alcohols, glutamate, and other amino acids. Sulfate can be used as sole sulfur source. Ammonia, dinitrogen, and some amino acids are used as nitrogen source. Growth factors are not required; yeast extract, or other complex nutrients do not increase the growth rate.

Mesophilic freshwater bacterium with optimal growth at 25–30°C and pH 5.5–6.0.

Ubiquinones and menaquinones with 10 isoprene units (Q-10 and MK-10) are present.

The mol% G + C of the DNA is: 62.2–66.8 (Bd).

Deposited strain: Pfennig 7050, ATCC 25092, DSM 137.

GenBank accession number (16S rRNA): M34128.

Genus IX. **Rhodopseudomonas** *Czurda and Maresch 1937, 119[AL] emend. Imhoff, Trüper and Pfennig 1984, 341*

JOHANNES F. IMHOFF

Rho.do.pseu.do.mo'nas. Gr. n. *rhodon* the rose; M.L. fem. n. *Pseudomonas* a bacterial genus; M.L. fem. n. *Rhodopseudomonas* the red *Pseudomonas*.

Cells are rod-shaped, motile by means of polar or subpolar flagella; show polar growth, budding and asymmetric cell division. Gram-negative and belong to the *Alphaproteobacteria*. Internal photosynthetic membranes appear as lamellae underlying and parallel to the cytoplasmic membrane. Photosynthetic pigments are **bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series**. **Straight-chain monounsaturated $C_{18:1}$ is the major component of cellular fatty acids. Contains ubiquinones with 10 isoprene units (Q-10).**

Preferred mode of growth is photoheterotrophic under anoxic conditions in the light. **Photoautotrophic growth may be possible under anoxic conditions with hydrogen, thiosulfate, or sulfide** as electron donor. **Chemotrophic growth under microoxic to oxic conditions** is also possible. Growth factors may be required.

Mesophilic freshwater bacteria with preference for neutral pH.

The mol% G + C of the DNA is: 64.8–66.3.

Type species: **Rhodopseudomonas palustris** (Molisch 1907) van Niel 1944, 89 (*"Rhodobacillus palustris"* Molisch 1907, 14.)

Further descriptive information

Rhodopseudomonas species are characterized by asymmetric cells during cell division. Most characteristic is the formation of prosthecae and rosette-like cell aggregates.

A reductive and oxygen-inhibited degradation of benzoate has been demonstrated in *R. palustris* (Dutton and Evans, 1969, 1978; Gibson and Harwood, 1995). Citrate may be used by some strains of *Rhodopseudomonas palustris.* During fermentation, pyruvate is quantitatively transformed into CO_2, formate, acetate, lactate, butyrate, and acetoin by *R. palustris* (Gürgün et al., 1976). Photoautotrophic growth with hydrogen occurs in *R. palustris* (Klemme, 1968).

Sulfate can serve as sole sulfur source and is assimilated via the 3′-phosphoadenosine-5′-phosphosulfate (Imhoff, 1982). *R. palustris* is able to use reduced sulfur compounds as photosynthetic electron donors. Sulfide is oxidized by *R. palustris* to elemental sulfur (Hansen, 1974), and thiosulfate to sulfate (Rolls and Lindstrom, 1967).

In *R. palustris* (Zumft and Castillo, 1978) nitrogenase shows a "switch-off" effect by ammonia and some organic nitrogen compounds. This effect is reversible. Ammonia assimilation proceeds via glutamine synthetase and glutamate synthase in *Rhodopseudomonas palustris* (NADH-linked) (Brown and Herbert, 1977; Herbert et al., 1978). A glutamate dehydrogenase is present. Besides ammonia, *R. palustris* uses a great number of nitrogen sources: nitrate, dimethylamine, trimethylamine, azaguanine, L-histidine, L-glutamate, L-aspartate, L-arginine, L-cysteine, L-methionine, DL-lysine, DL-alanine, DL-leucine, casein hydrolysate (Malofeeva and Laush, 1976), guanine, uric acid, xanthine (Aretz et al., 1978), cytidine, and cytosine (Kaspari, 1979). Most strains of *R. palustris* are not able to use nitrate as a nitrogen source (Klemme, 1979). Three isolates, however, are capable of dissimilatory nitrate reduction and growth under anoxic dark conditions with nitrate as terminal electron acceptor (Klemme et al., 1980).

Rhodopseudomonas palustris and *Nitrobacter winogradskyi* show a high degree of 16S rDNA sequence similarity (Seewaldt et al., 1982), and the lipid A structure of the lipopolysaccharide of *Nitrobacter* species contains the unusual 2,3-diamino-2,3-deoxy-D-glucose that is characteristic for *Rhodopseudomonas palustris* (Mayer et al., 1983, 1984). This sugar has also been found in *Blastochloris viridis* (see Weckesser et al., 1979), *Blastochloris sulfoviridis* (Ahamed et al., 1982), *Pseudomonas diminuta*, and *Pseudomonas vesicularis* (Mayer et al., 1983).

Enrichment and Isolation Procedures

Rhodopseudomonas palustris is a very common species of purple nonsulfur bacteria (PNSB) in nature, and many enrichments select for *R. palustris.* Benzoate is a carbon source particularly for enrichment of this species. Standard procedures for other PNSB can be used for isolation of *Rhodopseudomonas* species. A mineral medium that is suitable for most PNSB can be applied for isolation and cultivation of *Rhodopseudomonas* species (Imhoff, 1988; Imhoff and Trüper, 1992; see chapter Genus *Rhodospirillum* for this medium).

Maintenance Procedures

Cultures of *Rhodopseudomonas* species are well preserved in liquid nitrogen, by lyophilization or at -80°C in a mechanical freezer.

Differentiation of the genus *Rhodopseudomonas* from other genera

Differential characteristics of the genera and species of *Rhodopseudomonas*, *Rhodobium*, *Rhodoplanes*, *Blastochloris*, *Rhodoblastus*, and *Rhodomicrobium* are shown in Tables 3 and 4 of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria." (pp. 125–127, Volume 2, Part A). Their phylogenetic relationships are shown in Fig. 2 (p. 128) of that same chapter.

Taxonomic Comments

After the removal of PNSB that contained vesicular internal photosynthetic membranes and those that were *Betaproteobacteria* from the genus *Rhodopseudomonas* (Imhoff et al., 1984), those that remained had lamellar internal membrane structures and a budding mode of growth and reproduction. Even after the removal of bacteria now recognized as species of *Rhodopila*, *Rhodobacter*, *Rhodovulum*, and *Rubrivivax*, the genus *Rhodopseudomonas* still represented a heterogeneous assemblage of species (Imhoff et al., 1984). Based on 16S rDNA sequence data (Kawasaki et al., 1993b), isolation and description of new species, and additional data, *Rhodopseudomonas rosea* was transferred to *Rhodoplanes roseus* (Hiraishi and Ueda, 1994b), *Rhodopseudomonas marina* to the new genus *Rhodobium* as *Rhodobium marinum*, and *R. viridis* and *R. sulfoviridis* to the genus *Blastochloris* as *Blastochloris viridis* and *Blastochloris sulfoviridis* (Hiraishi, 1997). *Rhodopseudomonas acidophila* was transferred to *Rhodoblastus acidophilus* (Imhoff, 2001).

Rhodopseudomonas blastica has many chemotaxonomic properties in common with bacteria in the informal group "alpha-3 proteobacteria", *Rhodobacter*, *Rhodovulum*, and *Paracoccus denitrificans.* Its 16S rDNA sequence is most similar to and clusters with the *Rhodobacter* species. Therefore, it was transferred to this genus and is now known as *Rhodobacter blasticus* (Kawasaki et al., 1993b).

Hiraishi et al. (1992b) considered *Rhodopseudomonas rutila* as identical to *R. palustris* and the species name as a later subjective synonym of *R. palustris*, although it has been described as a separate species (Akiba et al., 1983). In the original species description *R. palustris* was not included as a reference organism and properties of the new isolates were reinvestigated later (Hiraishi et al., 1992b). These authors established identity between the type strains of *R. palustris* and *R. rutila.* In particular, in regard to the utilization of acetate, propionate, benzoate, fructose, sulfide, and thiosulfate, Hiraishi et al. (1992b) disagreed with Akiba et al. (1983) and found conformity with the properties of six *R. palustris* strains. The former authors also found that *Rhodopseudomonas rutila* requires *p*-aminobenzoic acid as a growth factor. Both bacteria were identical in quinone, lipid and fatty acid composition and 16S rDNA sequence (accession number of the 16S rDNA sequence of strain ATCC 33872, the former type of *R. rutila* at EMBL is D14435). DNA–DNA similarity between *R. rutila* and *R. palustris* strains was between 80–90%.

In addition to *R. palustris*, three species of *Rhodopseudomonas* are known. *Rhodopseudomonas rhenobacensis* is a recently described bacterium notably reducing nitrate (Hougardy et al., 2000). *Rhodopseudomonas julia* is an acidic sulfur spring isolate with the distinct ability to grow photoautotrophically (Kompantseva, 1989a). *"Rhodopseudomonas cryptolactis"* was also isolated from a hot spring and is characterized by a lack of autotrophic growth and a quite restricted substrate spectrum (Stadtwalddemchick et al., 1990). This bacterium has not been validly published.

Differentiation of the species of the genus *Rhodopseudomonas*

Characters that differentiate the species of the genus *Rhodopseudomonas* from each other and from *Rhodoblastus acidophilus* are given in Tables BXII.α.156 and BXII.α.157 of the chapter on *Rhodoblastus.*

List of species of the genus Rhodopseudomonas

1. **Rhodopseudomonas palustris** (Molisch 1907) van Niel 1944, 89[AL] (*"Rhodobacillus palustris"* Molisch 1907, 14.)
pa.lus′tris. L. fem. adj. *palustris* marshy, swampy.

Individual cells are rod-shaped to ovoid, occasionally slightly curved, 0.6–0.9 × 1.2–2.0 μm, motile by means of subpolar flagella, and reproduce by budding. The mother cell produces a slender prostheca 1.5–2.0 times the length of the original cell at the pole opposite to that bearing the flagella. The end of the prostheca swells, and the daughter cell grows, producing a dumbbell-shaped organism (Fig. BXII.α.187). Asymmetric division then takes place. Young individual cells are highly motile. The formation of rosettes and clusters in which the individual cells are attached to each other at their flagellated poles are characteristic in older cultures. In certain complex media, individual cells become up to 10 μm long and irregular in shape. Internal photosynthetic membranes appear as lamellae underlying and parallel to the cytoplasmic membrane; no lamellae are present in the prostheca. Color of cell suspensions is red to brownish-red. Living cells show absorption maxima at 375, 468, 493, 520–545, 589, 802, and 860–875 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the normal spirilloxanthin series.

Photoautotrophic growth occurs with hydrogen, sulfide, and thiosulfate as electron donors in the presence of small amounts of yeast extract. Photoheterotrophic growth is possible with various organic substrates. Chemotrophic growth occurs in the dark under microoxic to oxic conditions. With some substrates fermentation takes place under anoxic conditions. Sulfate can be used as sole sulfur source. The nitrogen source may be ammonia, dinitrogen, some amino acids, or for a few strains, nitrate.

Growth factors required are *p*-aminobenzoate and, for some strains, biotin; yeast extract stimulates growth considerably.

Ubiquinones with 10 isoprene units (Q-10) are present.

Mesophilic freshwater bacteria with optimal growth at 30–37°C and pH 6.9 (pH range: 5.5–8.5).

The mol% G + C of the DNA is: 64.8–66.3 (Bd).

Type strain: ATH 2.1.6, ATCC 17001, DSM 123.

GenBank accession number (16S rRNA): D12700, D25312, L11664.

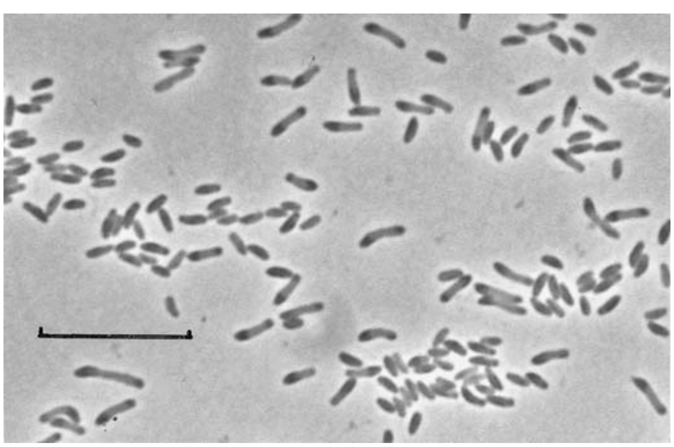

FIGURE BXII.α.187. *Rhodopseudomonas palustris* strain 1850 grown in succinate-yeast extract medium. The budding type of reproduction can be recognized in a number of cells. Phase-contrast micrograph. Bar = 10 μm. (Courtesy of N. Pfennig.)

2. **Rhodopseudomonas julia** Kompantseva 1993, 188[VP] (Effective publication: Kompantseva 1989a, 258.)
ju.li.a. L. fem. adj. *julia* discovered and described in July.

Cells are straight or slightly curved rods, 1–1.5 × 2.5 μm. Formation of rosettes is characteristic. Propagation by budding; the bud is sessile. Motile by means of polar flagella. Photosynthetic membrane systems appear as concentric lamellae. Color of cell suspensions is pink to purple. The absorption spectra of living cell suspensions may have maxima at 380, 590, 803, and 850 nm (indicative of bacteriochlorophyll *a*) and at 490, 516, and 550 nm (indicating the presence of carotenoids of the normal spirilloxanthin series).

Facultative photoorganoheterotrophs. Can also grow chemoorganotrophically under microaerobic conditions and photolithoautotrophically, oxidizing H_2S or S^0 to sulfate. The intermediate product of H_2S oxidation is elemental sulfur, which is deposited both outside and inside the cells. Ammonia and Casamino acids, but not nitrate, are utilized as nitrogen sources; H_2S, S^0, cysteine, and glutathione, but not sulfate, serve as sulfur sources. No vitamins are required. Hydrogen donors and carbon sources: fatty acids to valerate, hydroxy acids of the tricarboxylic and acid cycle, formate, pyruvate, aspartate, glycerol, glucose, gluconate, mannitol, sorbitol, fructose, yeast extract, and Casamino acids. Substrates not utilized: arginine, benzoate, glutamate, malonate, tartrate, citrate, and alcohols. Storage material: poly-β-hydroxybutyrate. Catalase activity is present.

Optimal growth conditions: pH 6.0–6.5, 25–35°C, light intensity more than 2000 lux.

Habitat: slightly and moderately acid sulfide springs having a high content of elemental sulfur.

The mol% G + C of the DNA is: 63.5 ± 1 (method not available in the literature).

Type strain: KR-11-67, ATCC 52215, DSM 11549.

GenBank accession number (16S rRNA): AB087720.

3. **Rhodopseudomonas rhenobacensis** Hougardy, Tindall, Klemme 2000, 991[VP]
rhe.no.ba.cen′sis. M.L. adj. *rhenobacensis* pertaining to Rheinbach, a small German town.

Cells are rods, 0.4–0.6 × 1.5–2 μm. Multiply by budding and form characteristic rosette-like aggregates. Motile by means of polar flagella. Photosynthetic membrane system appears as lamellae. Color of cell suspensions is red. The absorption spectra of living cell suspensions show maxima at 376, 591, 805, and 878 nm (bacteriochlorophyll *a*) and at 471, 503, and 540 nm (carotenoids).

Facultative photoorganoheterotrophs. Also grow chemoorganotrophically under aerobic conditions. Nitrate is reduced to nitrite, which accumulates in the medium. Hydrogen donors and carbon sources: formate, acetate, pyruvate, lactate, malate, succinate, fumarate, tartrate, gluconate, ethanol, and butyrate (plus carbonate). Substrates not utilized: citrate, benzoate, glucose, fructose, methanol, propionate, arginine, and glutamate. Gelatin is not hydrolyzed. Ammonia, glutamate dinitrogen, and yeast extract serve as nitrogen sources. *p*-Aminobenzoic acid required as growth factor.

Optimal pH 5.5 (range: 5.0–8.0). NaCl is not required and completely inhibits growth at 1%.

Habitat: freshwater lake sediment.

The mol% G + C of the DNA is: 65.4 (HPLC).

Type strain: Rb, DSM 12706.

GenBank accession number (16S rRNA): AJ132402.

4. **"Rhodopseudomonas cryptolactis"**

cryp.to' lac.tis. Gr. adj. *cryptos* hidden; L. fem. n. *lactes* milk; M.L. fem. adj. *cryptolactis* hidden of milk.

Cells are rod-shaped, approximately 1.0 × 4 μm, motile by means of flagella, and reproduce by budding. The formation of rosettes is observed. Internal photosynthetic membranes appear as lamellae underlying the cytoplasmic membrane. Color of cell suspensions is red. Absorption maxima of living cells at 590, 800, and 857 nm is indicative of the presence of bacteriochlorophyll *a*.

Photoheterotrophic growth occurs with pyruvate, acetate, malate, succinate, and lactate (only in the presence of bicarbonate). Hydrogen and sulfide are not used as electron donors. Chemoheterotrophic growth occurs in the dark under oxic conditions. Ammonia, dinitrogen, urea, and L-glutamine are used as nitrogen source. Growth factors required are vitamin B_{12}, niacin, and *p*-aminobenzoate.

Mesophilic freshwater bacterium with optimal growth at 40°C (range: 35–46°C), and pH 6.8–7.2 (pH range: 6.4–8.5).

Habitat: thermopolis Hot Spring, Wyoming, USA.

The mol% G + C of the DNA is: 68.8.

Deposited strain: ATCC 49414.

Family VIII. **Hyphomicrobiaceae** Babudieri 1950, 589

George M. Garrity, Julia A. Bell and Timothy Lilburn

Hy.pho.mi.cro.bi.a' ce.ae. M.L. neut. n. *Hyphomicrobium* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Hyphomicrobiaceae* the *Hyphomicrobium* family.

The family *Hyphomicrobiaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Hyphomicrobium* (type genus), *Ancalomicrobium*, *Ancylobacter*, *Angulomicrobium*, *Aquabacter*, *Azorhizobium*, *Blastochloris*, *Devosia*, *Dichotomicrobium*, *Filomicrobium*, *Gemmiger*, *Labrys*, *Methylorhabdus*, *Pedomicrobium*, *Prosthecomicrobium*, *Rhodomicrobium*, *Rhodoplanes*, *Seliberia*, *Starkeya*, and *Xanthobacter*.

The family is morphologically, metabolically, and ecologically diverse. Many members form hyphae or prosthecae; a number reproduce by budding. Includes organisms that are photosynthetic, facultatively methylotrophic, facultatively chemolithoautotrophic, and chemoheterotrophic.

Type genus: **Hyphomicrobium** Stutzer and Hartleb 1898, 76.

Genus I. **Hyphomicrobium** *Stutzer and Hartleb 1898, 76*[AL]

Christian Gliesche, Andreas Fesefeldt and Peter Hirsch

Hy.pho.mi.cro' bi.um. Gr. *hyphe* thread; Gr. adj. *micros* small; Gr. masc. n. *bios* life; M.L. neut. n. *Hyphomicrobium* thread-producing microbe.

Cells 0.3–1.2 × 1–3 μm; rod-shaped with pointed ends, or **oval, egg-, or bean-shaped**; produce **monopolar or bipolar filamentous outgrowths** (hyphae or prosthecae) of varying length and 0.2–0.3 μm in diameter. Hyphae are not septate, but hyphal cytoplasmic membranes show conspicuous constrictions. **Hyphae may be truly branched**; secondary branches are rare. Cells stain with carbol fuchsin, but stain weakly with aqueous aniline dyes. Gram negative and non-acid-fast. Do not form spores.

Multiplication: **daughter cell formation by a budding process** at one hyphal tip at a time (Figs. BXII.α.188 and BXII.α.189); mature buds become **motile swarmers** that break off and may attach to surfaces or other cells to form clumps or **rosettes**. Motility is lost soon after swarmer cell liberation and/or attachment. Older cultures may lack motile swarmer cells. **Poly-β-hydroxybutyrate is stored by most cells, usually at a distinct cell pole**.

Colonies on solid media are small, even after prolonged incubation; they are **brownish** in transmitted light and **bright beige or colorless** in reflected light. Colony surface is shiny or granular, folded or smooth. Older colonies often display concentric rings and change color to darker brown or bright yellow-orange.

Chemoorganotrophic, aerobic. Carbon dioxide is required for growth. **Oligocarbophilic**, i.e., growth can occur on mineral salts media without carbon sources added to the medium, possibly instead resulting from the presence of volatile carbon and energy sources. Growth may be stimulated by soil extract if the pH remains near neutral. **Good growth with 0.1–0.2% (w/v) of one-carbon compounds, such as methanol, methylamine, or even chloromethane**. NH_4^+ is a good nitrogen source, but organic nitrogen compounds (some amino acids) may also be utilized. No nitrification. Widely distributed in soils and aquatic habitats. Mesophilic. Optimal pH: above 7.0, except for one species with a lower optimal pH.

The mol% G + C of the DNA is: 59–65 (T_m).

Type species: **Hyphomicrobium vulgare** Stutzer and Hartleb 1898, 76.

FIGURE BXII.α.188. *Hyphomicrobium facile* IFAM B-522. Mother cell with hyphae and young bud. Bar = 1.0 μm.

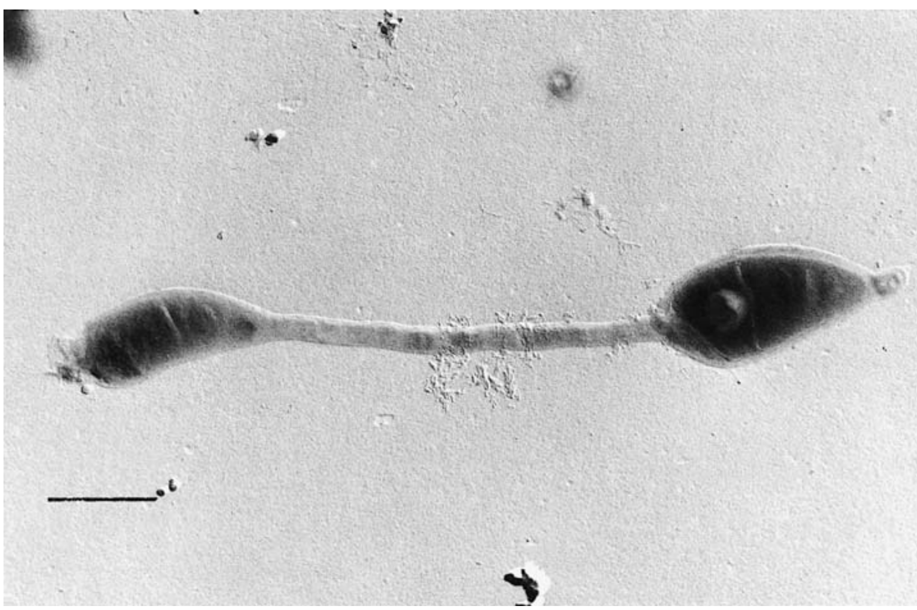

FIGURE BXII.α.189. *Hyphomicrobium facile* subsp. *ureaphilum* IFAM CO-582. Mother cell, hyphae, and mature bud. The mother cell contains a storage granule (poly-β-hydroxybutyrate). Shadow-cast. Bar = 1 μm.

Further descriptive information

Phylogeny and probes Analysis of 5S rDNA (Stackebrandt et al., 1988a; Boulygina et al., 1993), 16S rRNA (Stackebrandt et al., 1988a), and 16S rDNA (Stackebrandt et al., 1988a; Tsuji et al., 1990; Tuhela et al., 1997; Rainey et al., 1998; Borodina et al., 2000; De Marco et al., 2000; Layton et al., 2000; McDonald et al., 2001), determination of 16S rRNA cistron similarities (Moore 1977; Roggentin and Hirsch 1989), membrane fatty acids and quinones (Urakami and Komagata 1979, 1986b, 1987a, b; Sittig and Hirsch, 1992) have confirmed the membership of hyphomicrobia in the Class *Alphaproteobacteria* (Order *Rhizobiales*). The coherency of the genus is supported by phage typing (Gliesche et al., 1988), low-molecular-mass RNA patterns (Höfle, 1990), and enzyme electrophoresis patterns (Urakami and Komagata,

1981). However, 16S rRNA cataloguing (Stackebrandt et al., 1988a) and 16S rDNA sequencing (Rainey et al., 1998; Borodina et al., 2000; Layton et al., 2000) show the genus *Filomicrobium* to branch within the radiation of *Hyphomicrobium*. Furthermore, 16S rRNA cistron similarities (Roggentin and Hirsch, 1989) and 16S rDNA sequences (Cox and Sly, 1997; Layton et al., 2000) confirm a close relationship of hyphomicrobia to the genus *Pedomicrobium*.

Based on data on morphological and physiological characteristics, 5S rRNA sequences, fatty acid and lipid composition of their membranes, and sensitivity to antibiotics, an evolutionary pathway from *Caulobacter* to *Hyphomicrobium* has been proposed by Nikitin et al. (1990). However, this phylogenetic view is not supported by 16S rDNA sequence analysis (Rainey et al., 1998; Sly et al., 1999; Layton et al., 2000).

The intrageneric structure based on 16S rDNA sequences shows two clusters (Rainey et al., 1998). Cluster I contains the neotype species of *H. vulgare*, as well as *H. aestuarii*, *H. hollandicum*, and *H. zavarzinii*. Cluster II comprises *H. facile*, *H. denitrificans*, *H. methylovorum*, and *H. chloromethanicum* (McDonald et al., 2001). 16S rDNA signature nucleotides that define clusters I and II of *Hyphomicrobium* species are given by Rainey et al. (1998). A detailed phylogenetic investigation of the 16S rDNA of hyphomicrobia isolated from a sewage treatment plant and its receiving lake (Holm et al., 1996) has revealed a significantly greater diversity and resulted in the creation of additional clusters, III and IV. Of these, cluster III comprises 16 strains (B 376, P 251, P 262, P 139, P 165, P 482, B 47, P 425, P 148, P 37, A 676, IFAM 1460, P 645, B 455, A 739, and A 679). Cluster IV consists of *Hyphomicrobium* sp. 502 and *Filomicrobium fusiforme* (Rainey and Stackebrandt, unpublished data). A dendrogram showing the phylogenetic position of the genera *Hyphomicrobium* and *Filomicrobium* among the closest relatives in the *Alphaproteobacteria* is given in Fig. BXII.α.190. This intrageneric structure is supported by a phylogenetic analysis of a fragment of the gene coding for the α-subunit of methanol dehydrogenase (*mxaF*). Fig. BXII.α.191 shows a dendrogram of hyphomicrobia based on published sequences of this gene fragment. A comparative sequence analysis of this *mxaF* gene fragment, including 150 strains, indicates a coherent evolution of this essential metabolic gene and the 16S rRNA gene in hyphomicrobia. The dendrogram based on the *mxaF* nucleic acid sequence has a finer resolution and results in the five clusters A to E, which correspond exactly to the 16S rDNA-based subdivision (*mxaF* clusters B and C are identical to the 16S cluster II) (Fesefeldt, 1998). Furthermore, genomic DNA of *Filomicrobium fusiforme* DSM 5304^T gives a strong hybridization signal with a fragment (position 1009–1553, according to *Paracoccus denitrificans* PD1207) of the *mxaF* gene of *Hyphomicrobium* sp. P 502 (*mxaF* cluster E) (Fesefeldt, 1998). This observation supports the close relationship between both genera and indicates that *Filomicrobium* retains parts of the methanol dehydrogenase gene cluster.

The distinctiveness of *Hyphomicrobium* species has been demonstrated by DNA–DNA hybridizations (Moore and Hirsch, 1972; Urakami et al., 1985; Gebers et al., 1986; Doronina et al., 1996b; McDonald et al., 2001); low-molecular-mass RNA patterns (Höfle, 1990); 16S rRNA cistron similarities (Roggentin and Hirsch, 1989); membrane fatty acids, phospholipids, and quinones (Sittig and Hirsch, 1992); and differences of more than 1.2% in 16S rDNA sequences for the closely related species (Rainey et al., 1998). Unfortunately, molecular analyses have not yet been conducted for undescribed strains for which species status has been discussed based on phenotypic analysis (Vedenina et al., 1991; Holm et al., 1996).

Probes for hyphomicrobia have been developed specifically for different taxonomic levels: (1) species-specific (Hfa-1 for *H. facile* [Fesefeldt et al., 1997] and Hvu-1 for *H. vulgare* [Gliesche et al., 1997]); (2) cluster-specific (S-S-HyphoCI-648-a-A-20 for *Hyphomicrobium* Cluster I and S-S-HyphoCII-654-a-A-18 for *Hyphomicrobium* Cluster II [Layton et al., 2000]); and (3) genus-specific (S-G-Hypho-1241-a-A-19 for *Hyphomicrobium* spp. [Layton et al., 2000]). Probe Hvu1034 (Neef et al., 1996) has exhibited an uncertain specificity (Neef and Fesefeldt, unpublished data).

Cell morphology The cell morphology may vary with growth conditions. In media with low nutrient concentrations, hyphae may elongate up to 300 μm. The degree of branching depends on the type and concentration of carbon source present. Some strains have helically twisted hyphae. Stirring laboratory cultures may result in increased intercalary bud formation in the hyphae. The number and attachment sites of flagella vary among the nine described species. Most hyphomicrobia that utilize C_1 compounds have 1–3 subpolar flagella, which are easily shed.

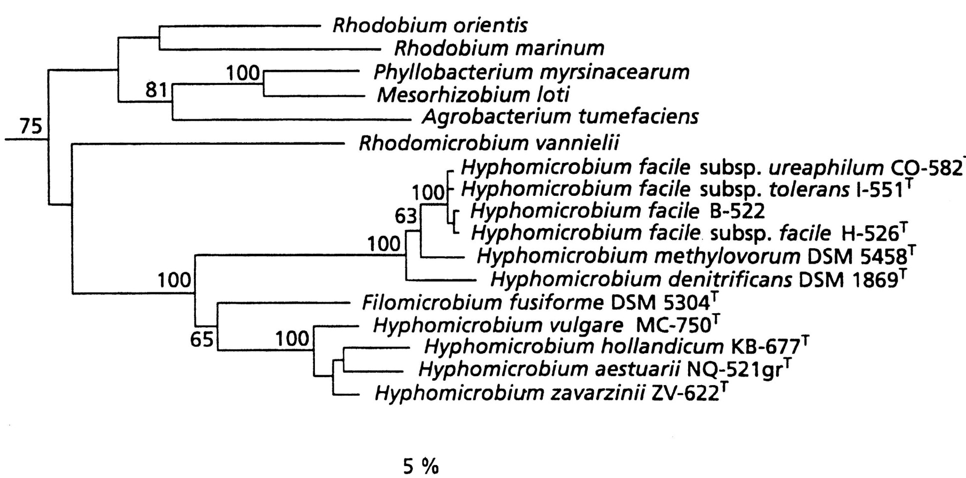

FIGURE BXII.α.190. Dendrogram based on 16S rDNA sequences, showing the phylogenetic position of the genera *Hyphomicrobium* and *Filomicrobium* among the closest relatives in the *Alphaproteobacteria* after Rainey et al. (1998).

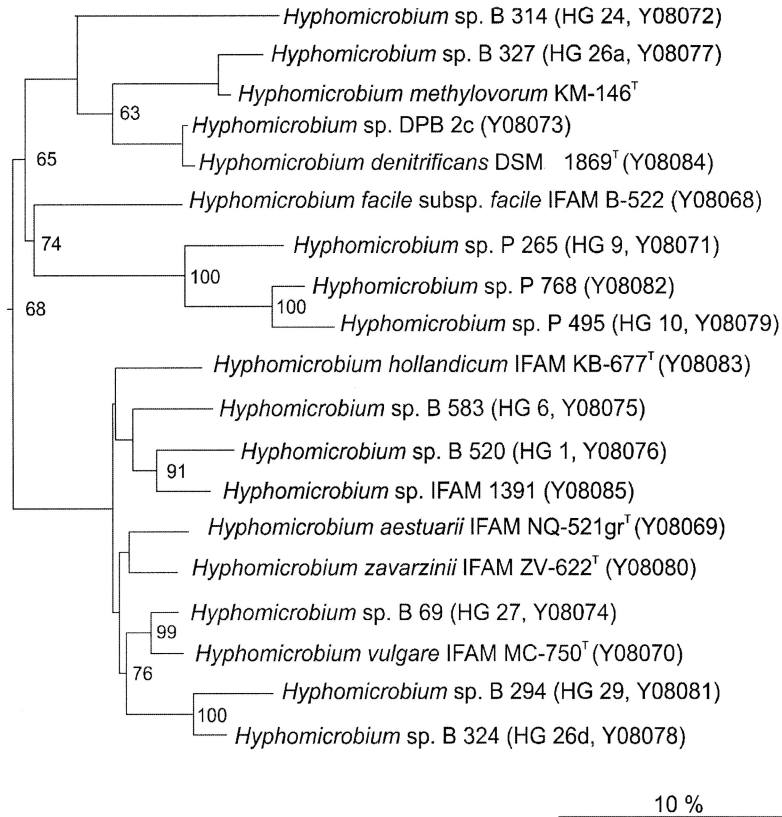

FIGURE BXII.α.191. Phylogenetic relationship constructed for partial *mxaF* genes of selected *Hyphomicrobium* strains (based on the nucleotide sequence position 1009–1553 of *Paracoccus denitrificans* PD 1207). The dendrogram was generated by phylogenetic-distance analysis with a neighbor-joining algorithm. The bootstrap values indicate the percentage of 100 replicate trees supporting the branching order. Values below 50 were omitted. DNA–DNA-hybridization group and accession numbers are given in brackets. Bar = 10 mutations per 100 sequence positions.

Cell wall and membrane compositions Cell walls of one strain (IFAM B-522) have been analyzed and found to contain α,ε-diaminopimelic acid, as well as the other normal components of most Gram-negative walls (Jones and Hirsch, 1968). Mother cells have less D-alanine and, therefore, a less highly cross-linked murein than do hyphae or swarmer cells (Roggentin, 1980; Roggentin and Hirsch, 1982). Fine structural studies of a few isolates have shown intracytoplasmic membrane systems, which develop in older cells under certain growth conditions (Conti and Hirsch, 1965). The major cellular fatty acid in hyphomicrobia is straight-chain unsaturated $C_{18:1}$ (Urakami and Komagata, 1987b). Unusually long-chain hydroxy fatty acids with 24 and 26 carbon atoms have been found in some *Hyphomicrobium* strains (Sittig and Hirsch, 1992). All strains investigated so far contain ubiquinone Q-9 and a small amount of squalene, whereas Hopan-22(29)-ene and Hopan-22(29)-ol are present in only some strains (Urakami and Komagata, 1986b). 2-*o*-methyl-D-mannose has been reported to occur as a component of the extracellular acidic polysaccharide hyphomican in *Hyphomicrobium* sp. JTS-811. Hyphomicran consists of D-glucose, D-mannose, 2-*o*-methyl-D-mannose, and pyruvic acid residues in relative proportions of 2:1:1:1 (Kanamaru et al., 1982a, b).

Colonial or cultural characteristics Liquid media may either become turbid or remain clear upon growth of hyphomicrobia, depending on the strain. In the latter case, growth occurs as a surface pellicle or ring on the glass walls near the medium surface. Attachment to glass walls may be inhibited by light in some strains (Hirsch and Conti, 1964b). Surface pellicles, when shaken, fall to the bottom of the vessel, especially in older cultures. Colonies on solid media remain quite small, even after long incubation. Some pellicle-forming strains have colonies of variable sizes.

The life cycle of *Hyphomicrobium* species is complicated. It has been studied with special emphasis on the budding process (Kingma-Boltjes, 1936; Mevius, 1953) and on bud nucleation and the possibility of obtaining synchronous swarmer cells (Moore and Hirsch, 1973a; Matzen and Hirsch, 1982a). Up to 12 consecutive buds are formed on one hyphal tip, and the size of swarmer cells produced increases with mother-cell age. Synchronous swarmer cells of nearly identical size have been produced by Matzen and Hirsch (1982a) from chemostat cultures transferred to a glass wool-packed column and washed with fresh medium for several hours. Silver ions (5 ng/ml) increase the time required for growth initiation (Giangiordano and Klein, 1994). Motile swarmer cells of *Hyphomicrobium* sp. W1-1B display a positive chemotactic response toward methylamine, dimethylamine, and trimethylamine, but not toward methanol or arginine (Tuhela et al., 1998).

Metabolism and metabolic pathways All species described so far are methylotrophs; the highest growth yields are obtained with methanol or methylamine as the carbon and energy source. Most strains are also stimulated by a variety of other carbon

sources; however, growth rates and yields are usually substantially lower than with the C_1 compounds (Matzen and Hirsch, 1982b). The uptake of methylamine occurs via a single inducible transport system, irrespective of whether methylamine is used as the carbon and energy source or only as the nitrogen source. Cells grown on other carbon and nitrogen sources do not possess this transport system, but it can be induced by methylamine within 45–50 min. Methylamine uptake is inhibited by azide, cyanide, *N*-ethylmaleimide, and carbonyl cyanide-*m*-chlorophenyl-hydrazone (Brooke and Attwood, 1984). Specialized *Hyphomicrobium* strains can use a variety of other specific C_1-compounds (Table BXII.α.158).

Hyphomicrobia do not possess an active pyruvate dehydrogenase complex. This makes it impossible to convert pyruvate into acetyl-CoA and to generate energy from carbon compounds containing three or more carbon atoms (Harder et al., 1975).

Some strains are able to grow with C_2-compounds, such as ethanol and acetate, or with the C_4-compound β-hydroxybutyrate. In these strains, the activities of the following enzymes have been measured in cell-free extracts: ethanol dehydrogenase, acetaldehyde dehydrogenase, acetothiokinase, 3-hydroxybutyrate dehydrogenase, and β-ketothiolase. It has been suggested that when cells are grown on ethanol, acetate, or 3-hydroxybutyrate, acetyl-CoA and energy are formed and reducing power is generated mainly by the tricarboxylic acid cycle, while carbon was assimilated via the glyoxylate cycle, with phosphoenolpyruvate carboxykinase functioning as the main gluconeogenetic enzyme (Attwood and Harder, 1974). A mutant lacking methanol dehydrogenase activity has been grown in a medium containing both methylamine and ethanol and does not show diauxic growth. When the concentration of methylamine in the medium falls to 9 $\pm$ 0.8 mM, ethanol is utilized and the two substrates are then metabolized simultaneously until the supply of methylamine is exhausted (Brooke and Attwood, 1983).

Methanol is oxidized by a periplasmic methanol dehydrogenase, which contains pyrroloquinoline-quinone (PQQ) as the redox cofactor (Duine and Frank, 1980a) and transfers the electrons to cytochrome c_L (Dijkstra et al., 1989). Methylamine is metabolized via *N*-methyl-glutamate using an *N*-methyl-glutamate dehydrogenase (Loginova et al., 1976; Meiberg and Harder, 1978). Di- and trimethylamine dehydrogenases are located in the cytoplasm (Kasprzak and Steenkamp, 1983, 1984). Hyphomicrobia contain tetrahydrofolate (H_4F)-linked, as well as tetrahydromethanopterin (H_4MPT)-linked, C_1-metabolites. Some interconverting enzymes have been determined (Marison and Attwood, 1982; Vorholt et al., 1999). Molecular analysis has indicated that the chloromethane utilization pathway in *H. chloromethanicum* is similar to the corrinoid-dependent methyl transfer system in *Methylobacterium chloromethanicum* (McAnulla et al., 2001).

The roles of some other NADP-dependent (plus unknown factor) or dye-linked (form)-aldehyde dehydrogenases, some of them with high activity and specificity, remain to be elucidated (Marison and Attwood, 1980; Köhler and Schwartz, 1982; Köhler et al., 1985; Poels and Duine, 1989; Klein et al., 1994; Kesseler and Schwartz, 1995).

The dichloromethane-utilizing *Hyphomicrobium* sp. DM2 possesses a type A dichloromethane dehalogenase (Schmid-Appert et al., 1997).

Hyphomicrobia use the serine pathway for carbon assimilation from reduced C_1-compounds. However, there has been controversy concerning the occurrence of isocitrate lyase in the genus *Hyphomicrobium*. Specific strains possess the icl^+ variant (Bellion and Spain, 1976; Uebayasi et al., 1985; Yoshida et al., 1995a; Doronina et al., 1996b; Tanaka et al., 1997a). On the other hand, Attwood and Harder (1977), Doronina (1985), and Doronina et al. (1996b) have had evidence for the icl^- variant of the serine pathway in certain strains. Recent observations have confirmed the distribution of unstable isocitrate lyase activities in the genus *Hyphomicrobium*, and the general operation of the icl^+ serine pathway has been suggested (Izumi et al., 1996).

Enzymes for the assimilatory pathways of either C_1- or C_2-compounds are regulated coordinately, but separately from the dissimilatory pathway enzymes associated with these compounds (Brooke and Attwood, 1985).

When the nitrogen source is ammonium sulfate or methylamine and the supply is in excess, NADPH-dependent glutamate dehydrogenase is used for the assimilation of nitrogen. In contrast, with a limited nitrogen supply, the cells express high levels of glutamine synthetase and NADH-dependent glutamine:2-oxoglutamate aminotransferase activity, while the activity of glutamate dehydrogenase is lower. When nitrate is the nitrogen source, the glutamine synthetase/glutamine oxoglutamate aminotransferase pathway is used, irrespective of the nitrogen concentration (Brooke et al., 1987). Some strains are able to use allantoin as a nitrogen source (van der Drift et al., 1981). The activity of NH_4^+-assimilating enzymes is regulated by the C/N ratio in the growth medium (Gräzer-Lampart et al., 1986; Duchars and Attwood, 1989).

Nitrate is reduced anaerobically by some strains; for these organisms, a special enrichment technique using KNO_3 and methanol has been described by Attwood and Harder (1972) and Sperl and Hoare (1971). A fundamental study of the *Hyphomicrobium* denitrifying capacity shows (Timmermans and van Haute, 1983) that these bacteria grow well anaerobically and with identical rates in the presence of methanol and either NO_3^- or NO_2^-. However, denitrification enzymes are present only to a limited extent (Sperl and Hoare, 1971; Vedenina et al., 1991; Kloos et al., 1995; Fesefeldt et al., 1998a, b) or are not expressed (Lebedinskii and Vedenina, 1981). Some strains have the ability to grow with methanol and nitrous oxide as the terminal electron acceptor (Lebedinskii, 1981). *Hyphomicrobium* sp. X can grow anaerobically on di- or trimethylamine in the presence of nitrate (Meiberg and Harder, 1978; Meiberg et al., 1980). *Hyphomicrobium* sp. DM2 has recently been shown to grow with dichloromethane in the absence of oxygen, using nitrate as a terminal electron acceptor (Kohler-Staub et al., 1995). White et al., (1987) have described a *Hyphomicrobium* strain that grows anaerobically on methylsulfate as a carbon and energy source at the expense of nitrate. Electron transport from methanol to nitrate has been described by Lebedinskii and Vedenina (1987).

Cells of *Hyphomicrobium* spp. VS and EG oxidize sulfide to thiosulfate very actively (Suylen et al., 1986; Pol et al., 1994). Yield data and ATP synthesis indicate that further oxidation of thiosulfate is possible (Suylen et al., 1986; Vedenina and Sorokin, 1992). *Hyphomicrobium* sp. 53-49 shows autotrophic growth with $H_2/CO_2/O_2$ and NH_4^+ (Uebayasi et al., 1981, 1984, 1985). Metabolism of monomethyl sulfate remains uncertain. ^{13}C-NMR data are consistent with the hydroxylation of monomethyl sulfate via a monooxygenation mechanism and subsequent spontaneous hydrolysis of the methanediol monosulfate intermediate (Higgins et al., 1996).

Vitamin B_{12} stimulates growth of some species, especially their swarmer cells (Matzen and Hirsch, 1982b), but there is no absolute vitamin requirement in batch cultures. Most strains grow

TABLE BXII.α.158. Growth substrates used by specific undescribed *Hyphomicrobium* strains as sole carbon and energy source

Substrate	*Hyphomicrobium* species or strain
Acetate, 0.2% (w/w)[a]	MS 72, MS 75; MS 219, MS 223, MS 246, TMPO 1/8, TMPO 1/9, TMPO 1/10, DMMP 1/6, DMMP 1/9, DMMP 1/10, DMMP 1/11, DMMP 1/15, TMPO 2/3, TMPO 2/6, TMPO 2/9, TMPO 2/10, TMPO 2/13, DMPO/HW1-5

[q]Used with very low growth rates.

in the presence of 2.5% NaCl, but they also develop at low salt concentrations, approaching that of distilled water. Milk is coagulated by one strain. H_2S evolution and gelatin liquefaction have also been observed in this organism. Some isolates of *Hyphomicrobium* grow at 4–6°C; others can multiply at 45°C (Hirsch, unpublished observations).

Genetics and bacteriophages Genome sizes of three species ranged from 2.13–2.62 × 10^9 Da (Moore and Hirsch, 1973b; Kölbel-Boelke et al., 1985).

In addition to amino acid auxotrophs, mutants have been found that are specifically defective in methanol oxidation, resistant against antibiotics, or nonmotile and/or morphologically altered (Wieczorek and Hirsch, 1979; Marison and Attwood, 1982; Gliesche and Eckhardt, 1991; Gliesche and Hirsch, 1992). Transposon mutagenesis has been established for *H. facile* IFAM B-522 using transposon Tn5 and its derivatives, Tn7, Tn10, and Tn501 (Gliesche and Hirsch, 1992).

Broad host range IncP-1 plasmids (RP1, RP4, RP4::Mu*cts*, R68, R68.45, pMO60, pLUB21, pLUB113) have been successfully

transferred by interspecific matings to *H. facile* IFAM B-522 and *H. denitrificans* DSM 1869^T (Dijkhuizen et al., 1984; Gliesche and Hirsch, 1992). Mermod et al. (1986) have reported the transfer of plasmid pNM185 (a pKT231 derivative) into *H. denitrificans* NCIB11706.

Chromosome mobilization has been demonstrated with the conjugative IncP-1 plasmids RP1, R68.45, and pMO60 into *H. facile* (Gliesche and Hirsch, 1992). Using the IncP helper pRK2013 plasmid, pLA2917 has been introduced into *Hyphomicrobium* species by triparental matings. However, pLA2917 is always found integrated into the chromosome (Gliesche, 1997). Genes *aceE*, *aceF*, and *lpd* from *Escherichia coli* K12 JC6310, which code for the pyruvate dehydrogenase complex, have been expressed in *H. denitrificans* DSM 1869^T, with RP4′*pdh*1 resulting in growth and denitrification with pyruvate as the sole carbon source (Dijkhuizen et al., 1984).

An efficient system for electroporation of *H. facile* IFAM H-526^T and *H. denitrificans* DSM 1869^T has been developed with vectors based on the broad-host-range plasmid pBBR1 (Gliesche, 1997).

The occurrence of genes coding for denitrification and nitrogen fixation enzymes has been shown by Southern or dot blot hybridization with gene probes specific for nitrate reductase (*narG*), cytochrome c,d_1-containing nitrite reductase (*nirS*), Cu-containing nitrite reductase (*nirK*), nitrous oxide reductase (*nosZ*), and nitrogenase reductase (*nifH*). In hyphomicrobia, the Cu-containing nitrite reductase appears to be more common than the cytochrome c,d_1-containing nitrite reductase (Suzuki et al., 1993; Kloos et al., 1995; Tuhela et al., 1997; Fesefeldt et al., 1998a, b). Southern blot hybridizations have indicated the presence of genes coding for methanesulfonic acid monooxygenase (*msn*) in a methanesulfonate-degrading *Hyphomicrobium* strain (De Marco et al., 2000).

DNA sequence data exist for genes coding for the 5S rDNA (Stackebrandt et al., 1988a; Boulygina et al., 1993), 16S rDNA (Stackebrandt et al., 1988a; Tsuji et al., 1990; Tuhela et al., 1997; Rainey et al., 1998; Borodina et al., 2000; De Marco et al., 2000; Layton et al., 2000; McDonald et al., 2001; Stein et al., 2001), methanol dehydrogenase (*mxaF*; Fesefeldt and Gliesche, 1997; McDonald and Murrell, 1997a; Tanaka et al., 1997b), dimethylamine dehydrogenase (*dmd*; Yang et al., 1995a), methyltransferase gene cluster (*cmu*; McAnulla et al., 2001), Cu-containing nitrite reductase (*nirK*; Braker et al., 1998), isocitrate lyase (Tanaka et al., 1997a), serine–glyoxylate aminotransferase (Hagishita et al., 1996a), serine hydroxymethyltransferase (Miyata et al., 1993), hydroxypyruvate reductase (Yoshida et al., 1994), dichloromethane dehalogenase (*dcmA*; Vuilleumier et al., 1997), methenyl tetrahydromethanopterin cyclohydrolase (*mch*; Vorholt et al., 1999), and unknown gene fragments involved in methanol oxidation (Fesefeldt et al., 1997; Gliesche et al., 1997). Specific PCR primer systems have been described for the amplification of these genes from pure cultures or environmental samples (Miyata et al., 1993; Yoshida et al., 1994; Yang et al., 1995a; Hagishita et al., 1996a; Fesefeldt and Gliesche, 1997; McDonald and Murrell, 1997a Tanaka et al., 1997a; Vuilleumier et al., 1997; Braker et al., 1998; Vorholt et al., 1999; McAnulla et al., 2001). An identification system for environmental *Hyphomicrobium* isolates, based on denaturing gradient gel electrophoresis of a fragment of the *mxaF* gene, has been described by Fesefeldt and Gliesche (1997).

Partial amino acid sequences exist for the enzymes dimethylamine dehydrogenase and trimethylamine dehydrogenase (Kasprzak et al., 1983). In *Hyphomicrobium* sp. DM2 and GJ21, the *dcm* region (dichloromethane utilization genes) is associated with the insertion sequences IS1354 (only in DM2), IS1355, and IS1357. Furthermore, multiple copies of these insertion sequences have been found outside the *dcm* region. The high degree of sequence conservation observed within the genomic region responsible for dichloromethane utilization in other aerobic methylotrophic bacteria and the occurrence of clusters of insertion sequences in the vicinity of the *dcm* genes suggest that a transposon is involved in the horizontal transfer of these genes among methylotrophic bacteria (Schmid-Appert et al., 1997).

Ribosomal RNA cistron homologies among *Hyphomicrobium* strains have been investigated by Moore (1977). Low molecular weight RNA profiles have been used for genotypic identification of several *Hyphomicrobium* species (Höfle, 1990). The 16S–23S rRNA internal transcribed spacer region has been investigated by Scheinert et al. (1996). Poly(A) sequences at the 3′-terminus have been observed in the RNA of *H. facile* (Schultz et al., 1978).

Lytic bacteriophages have been isolated for several strains of *Hyphomicrobium* (Voelz et al., 1971; Kaplan et al., 1976; Yelton et al., 1979; Gliesche et al., 1988; Preissner et al., 1988). The presence of temperate bacteriophages and bacteriocins in *Hyphomicrobium* strains has also been demonstrated (Gliesche et al., 1988; Holm, 1991). *Hyphomicrobium facile* IFAM B-522 (RP4) is not sensitive toward the donor-specific (IncP) phages PRD1 and GU5 (Gliesche and Hirsch, 1992).

Serological relationships among some hyphomicrobial isolates have been studied by Powell et al. (1980).

Pathogenicity Twelve strains have been tested for pathogenicity against mice or guinea pigs; all are avirulent (Famureva et al., 1983).

Ecology and use in biotechnology *Hyphomicrobium* species could be isolated from all soil samples tested so far; they are present in nearly all water samples as well (Hirsch and Conti, 1964a; Hirsch and Rheinheimer, 1968). In freshwater habitats, they are especially prevalent in the neuston layer, on submerged surfaces, and in the upper sediment layer, even under anaerobic conditions. Hyphomicrobia also come from temporary puddles, sewage treatment plants, and the surface of indoor flower-pots (Hirsch, 1974a).

An association of hyphomicrobia with methanotrophs is capable of denitrifying with methanol; growth is possible under high CH_4 and low O_2 conditions (Wilkinson et al., 1974; Amaral et al., 1995). On the other hand, co-immobilized mixtures of *Hyphomicrobium* sp. and methanogenic bacteria are very efficient in simultaneous denitrification and methanogenesis (Lin and Chen, 1995; Zellner et al., 1995).

Using the most-probable-number technique with methanol as the sole carbon source, hyphomicrobia have been enumerated as 0.2% (= 10^6 g^{-1} dry weight hyphomicrobia) of the total bacteria determined by acridine-orange direct counts in a clay loam soil (Aa and Olsen, 1996). With the same method, Fesefeldt et al. (1997) have found 2×10^4 g^{-1} dry weight hyphomicrobia in a garden soil (0.7% of colony-forming units of methylotrophic bacteria). The *H. facile* population amounted to 30% of total hyphomicrobia in this soil.

The existence of denitrifying hyphomicrobia is of special interest because of the necessity to remove nitrate at drinking water treatment plants (Liessens et al., 1993) and sewage treatment plants (Schmider and Ottow, 1986; Nyberg et al., 1992; Lee and Welander, 1996; Lemmer et al., 1997). Coenoses consisting of a

Hyphomicrobium sp. and a *Paracoccus* sp. are quite efficient in the removal of both methanol and nitrate (Claus and Kutzner, 1985; Vedenina and Govorukhina, 1988; Neef et al., 1996). Investigation of the community structure in sewage treatment plants has revealed a very high abundance and diversity of hyphomicrobia (Holm et al., 1996). A domestic wastewater treatment plant has been found to contain up to 2×10^4 hyphomicrobia ml^{-1} in the influent, 9×10^4–6×10^5 in activated sludge, 1–4×10^3 in the effluent, and 2–12 hyphomicrobia ml^{-1} in the receiving lake. DNA–DNA hybridizations have classified the isolates into 30 groups (Holm et al., 1996), which can be assigned to Clusters I to IV based on 16S rDNA sequences (Rainey and Stackebrandt, unpublished data). The population of denitrifying *Hyphomicrobium* DNA–DNA-hybridization group HG 27 amounts to approximately 30% of the total facultatively anaerobic hyphomicrobia found in this activated sludge (Gliesche and Fesefeldt, 1998). When Layton et al. (2000) extracted DNA from an industrial wastewater from a treatment plant, they found 16S rDNA sequences from representatives of *Hyphomicrobium* clusters I and II. *Hyphomicrobium* 16S rRNA comprised approximately 5% of the 16S rRNA in the activated sludge of this treatment plant.

16S rDNA genes related to *Hyphomicrobium* spp. have been amplified from total community DNA extracted from a water sample of the northern portion of Green Bay (40 m depth) (Stein et al., 2001).

Hyphomicrobia have also been used for the removal of odorous, volatile sulfur compounds, such as hydrogen sulfide, methanethiol, dimethylsulfide (Zhang et al., 1991; Cho et al., 1992; Pol et al., 1994; Smet et al., 1996), and dichloromethane (Diks et al., 1994a, b) from air and gases. Specific *Hyphomicrobium* strains and enzymes have been applied in biosensors for the detection of methanol (Argall and Smith, 1993), methylsulfates (Schär and Ghisalba, 1985; Ghisalba et al., 1986), trimethylamine (Large and McDougal, 1975; Wong and Gill, 1987), dihalomethanes (Gälli and Leisinger 1985; Henrysson and Mattiasson, 1993), L-serine, and glyoxylate (Yoshida et al., 1993). A coenosis consisting of *Hyphomicrobium* sp. DM2 and *Rhodococcus rhodochrous* OFS has efficiently degraded dichloromethane, 2-propanol, and methanol in a gas lift loop bioreactor (Vanderberg-Twary et al., 1997).

Hyphomicrobium methylovorum has been used for the production of L-serine (Yamada et al., 1986; Izumi et al., 1993).

Other studies *Hyphomicrobium* species have been investigated for fatty acids (Auran and Schmidt, 1972; Ikemoto et al., 1978a; Eckhardt et al., 1979; Urakami and Komagata, 1979, 1987a, b; Vedenina et al., 1991; Sittig and Hirsch, 1992), phospholipids (Goldfine and Hagen, 1968; Guckert et al., 1991; Sittig and Hirsch, 1992; Batrakov and Nikitin, 1996), hopanoids (Rohmer et al., 1984), ubiquinones (Köhler and Schwartz, 1981; Urakami and Komagata, 1981, 1986b; Sittig and Hirsch, 1992), cytochromes (Large et al., 1979; Köhler and Schwartz, 1983; Dijkstra et al., 1988a, b, 1989; Frank and Duine, 1990a), pyrroloquinoline quinone (Duine et al., 1980, 1981, 1990; De Beer et al., 1983; Houck et al., 1989), and poly-β-hydroxybutyrate (Jacobsen, 1975). The following enzymes have been purified and characterized in more detail: methanol dehydrogenase (Duine et al., 1978; Duine and Frank, 1979, 1980a, b ; Schär et al., 1985; Miyazaki et al., 1987a; Frank et al., 1988; Frank and Duine, 1990b; Geerlof et al., 1994b), dimethylamine dehydrogenase (Kasprzak and Steenkamp, 1984; Meiberg and Harder, 1979; Steenkamp 1979; Steenkamp and Beinert, 1982a, b), trimethylamine dehydrogenase (Steenkamp 1979; Steenkamp and Beinert, 1982a, b; Kasprzak et al., 1983), dye-linked aldehyde dehydrogenase (Marison and Attwood, 1980; Köhler and Schwartz, 1982), dye-linked formaldehyde dehydrogenase (Klein et al., 1994), NAD-linked, GSH- and factor-independent aldehyde dehydrogenase (Poels and Duine, 1989; Duine, 1990), $NADP^+$-dependent glutamate dehydrogenase (Duchars and Attwood, 1987), glutamine synthetase (Duchars and Attwood, 1991), hydroxypyruvate reductase (Goldberg et al., 1992, 1994; Yoshida et al., 1994; Hagishita et al., 1996b; Izumi et al., 1996), serine–glyoxylate aminotransferase (Hagishita et al., 1996a, b; Izumi et al., 1996), glycerate kinase (Hill and Attwood, 1974; Yoshida et al., 1992; Izumi et al., 1996), phosphoenolpyruvate carboxylase (Yoshida et al.,1995b; Izumi et al., 1996), methyl mercaptan oxidase (Suylen et al., 1987), dichloromethane dehalogenase (Kohler-Staub and Leisinger, 1985; Kohler-Staub et al., 1986; Leisinger and Kohler-Staub, 1990), dimethyl sulfoxide reductase (Hatton et al., 1994), phosphoglycerate mutase (Hill and Attwood, 1976a, b), serine hydroxymethyltransferase (Miyazaki et al., 1986, 1987b, c, d), and copper-containing nitrite reductase (Suzuki et al., 1993).

Enrichment and Isolation Procedures

A variety of enrichment techniques has been proposed. In all cases, growth of hyphomicrobia is slow; they may be overgrown in the presence of other heterotrophic bacteria. Most enrichment cultures for nitrifying bacteria contain hyphomicrobia in large numbers (Stutzer and Hartleb, 1898; Hirsch and Rheinheimer, 1968; Hirsch, 1970). Under oligotrophic conditions and after prolonged incubation, hyphomicrobia usually outcompete other bacteria. A slow, but successful method consists of keeping a natural water sample at room temperature in the dark for several weeks or months. Eventually, hyphomicrobia become part of the dominant microflora, even in the presence of amoebae. Another method prescribes the addition to a natural water sample or soil suspension of methylamine hydrochloride at 3.38 g/l and/or incubation in an atmosphere of methanol (Hirsch, 1970). Such an enrichment should be monitored frequently in order to determine the optimal time for subculturing. Inoculation of a natural sample into mineral salts medium 337, containing 0.1–0.2% (w/v) of a C_1-compound, and dark incubation at 20–25°C for a few weeks usually yields hyphomicrobia in large numbers (Hirsch and Conti, 1965). Improvements of medium 337[1] that result in faster growth and higher yields have been reported by Matzen and Hirsch (1982b). Several modifications of medium 377-B (Matzen and Hirsch, 1982b) have been developed for specific genetic and physiological applications and for the isolation of a greater *Hyphomicrobium* diversity from natural habitats (Table BXII.α.159).

Isolation of rosette-forming and denitrifying hyphomicrobia from aquatic sediments has been achieved by inoculating sediment samples into a mineral salts medium containing 5 g/l KNO_3 and up to 0.5% (v/v) of methanol; incubation is anaerobic at room temperature (Attwood and Harder, 1972). It must be stressed, however, that all of these methods will yield different *Hyphomicrobium* species. The application of an oligotrophic medium containing low concentrations of peptone, yeast extract, and glucose ("PYG"; Staley, 1968) has often yielded morphologically *Hyphomicrobium*-like bacteria. Such isolates usually do not

1. Composition of medium 337: KH_2PO_4, 1.36 g; Na_2HPO_4, 2.13 g; $MgSO_4 \cdot 7H_2O$, 0.3 g; $(NH_4)_2SO_4$, 0.5 g; $CaCl_2 \cdot 2H_2O$, 1.99 mg; $FeSO_4 \cdot 7H_2O$, 1.0 mg; $MnSO_4 \cdot H_2O$, 0.35 mg; $Na_2MoO_4 \cdot 2H_2O$, 0.5 mg; vitamin B_{12} (if needed), 2.5 μg; distilled water, to 1000 ml; pH, 7.2.

TABLE BXII.α.159. Growth media for specific applications with hyphomicrobia

Medium	Characteristics and composition	Application
337[a]	Mineral salts medium (carbon source: methylamine or methanol)	Enrichment, isolation, and cultivation of hyphomicrobia
337a[b]	Modification of medium 337 with 3.38 g/l methylamine and reduction of the trace elements	Enrichment, isolation, and cultivation of hyphomicrobia
337-MA[c]	337a with 3.38 g/l methylamine	Enrichment, isolation, and cultivation of hyphomicrobia
337-M[c]	337a with 0.5% (v/v) methanol	Enrichment, isolation, and cultivation of hyphomicrobia
337-B[c]	337a with 2.5 g/l vitamin B_{12}, 0.3 g/l L-lysine and 5.0 g/l Na-gluconate (C-source: 3.38 g/l methylamine–HCl or 0.5% (v/v) methanol)	Optimized medium for *Hyphomicrobium facile*
337-B1[d]	337-B with 3.38/l methylamine–HCl, but without vitamin B_{12}, L-lysine, or gluconate	Standard minimal medium for the cultivation of all hyphomicrobia growing on methylamine
337-B2[d]	337-B1 with 0.2% (w/v) Bacto nutrient broth and 0.2% (w/v) Casamino acids	Isolation of auxotrophic mutants
337-B3[d]	337-B1 and 0.075% (w/v) Bacto nutrient broth and 0.075% (w/v) Casamino acids	Interspecific matings
337-B4[e]	337-B1 and 2.5 g/l vitamin B_{12}	Cultivation of vitamin B_{12}-dependent hyphomicrobia
337-B5[e]	337-B4 and 0.25 g/l peptone, 20 ml/l HBM and 10 ml/l vitamin solution No. 6[f]	Enrichment, isolation, and cultivation of specific hyphomicrobia from sewage
337-B6[g]	337-B5 and 0.075% (w/v) Bacto nutrient broth and 0.075% (w/v) Casamino acids	Interspecific matings with hyphomicrobia with optimal growth on medium 337-B5
337-B7[h]	337-B5 with 5 mM $NaNO_3$ and 0.5% (v/v) methanol instead of methylamine	Determination of the denitrification activity
337-B8[i]	337-B1 with 0.5% (v/v) methanol instead of methylamine	Standard minimal medium for the cultivation of all hyphomicrobia growing on methanol
337-B9[j]	337-B8 with 0.5% (w/v) KNO_3	Enrichment, isolation, and cultivation of denitrifying hyphomicrobia
337-B10[k]	337-B5 with 0.5% (v/v) methanol instead of methylamine–HCl	Cultivation of specific hyphomicrobia from sewage
337-B11[k]	337-B5 with 5 mM KNO_3 and 0.5% (v/v) methanol instead of methylamine–HCl	Cultivation of denitrifying hyphomicrobia with optimal growth on medium 337-B5
DST[l]	Mineral salts, trace elements, 1% (w/v) Difco agar, and an atmosphere of 1% (v/v) CH_3Cl	Enrichment and cultivation of hyphomicrobia that utilize chloromethane

[l]Data from Doronina et al. (1996b).

grow on C_1 compounds and are often pigmented; they comprise a different group of generic rank (see *Hirschia* spp.; Schlesner et al., 1990).

Hyphomicrobia growing on chloromethane can be enriched for with the addition of 1% (w/v) CH_3Cl to a mineral salts medium. Subsequently, this can be plated on the same medium solidified with 1% Difco agar and containing 0.01% (w/v) bromothymol blue to indicate the release of HCl (Doronina et al., 1996b).

Once hyphomicrobia occur or predominate in liquid enrichments, they can be isolated and purified by repeatedly streaking enrichments on mineral salts medium "337" and incubating the plates in the dark at 20–25°C. To avoid excessive drying of the plates, they should be placed in plastic bags, or thicker layers of agar should be used. Concerning the purification procedure, it should be remembered that pellicle-forming strains (e.g., NQ-521Gr) usually produce colonies of quite different size. Subculturing small or large colonies results again in growth of both types.

Hyphomicrobium colonies are often tough and coherent; before spreading on plates, they should be ground up properly. Typical colonies of hyphomicrobia appear dark brown in transmitted light, often with folds and concentric rings. Under reflected light, the colonies of many strains are shiny and bright beige or even colorless.

Maintenance Procedures

Most hyphomicrobia can be kept well at 4–5°C when growing on slants. Subculturing every 5–6 months is sufficient. Lyophilization in skim milk is the optimal method for maintenance of most cultures. Suspension in phosphate buffer and sterile glycerol, followed by immediate vortexing and cooling down to −25°C, is another technique; such preparations may be kept for several years in the freezing compartment of a refrigerator. For subculturing, the glycerol suspension is streaked directly onto agar plates. Warming up of the glycerol suspension should be avoided, since rapid death of the cells results. Doronina and Trotsenko (1992) have successfully stored hyphomicrobia that grew with chloromethane by deep-freezing these on Whatman paper without cryoprotectants at −40°C to −80°C.

Procedures for Testing Special Characters

Cell shape and morphogenesis An agar slide culture is prepared with medium "337" and 1.8% Bacto Noble agar (Hirsch, unpublished). The sterile agar medium is spread thinly over sterile glass slides and allowed to solidify. Using sterile coverslips, agar is then cut off to leave two agar squares side-by-side and separated only by a small ditch. One of the squares is inoculated with a thin *Hyphomicrobium* suspension; the other square receives a small droplet of 0.5% methanol. Both squares are covered together with one large coverslip, and the edges can be sealed with a Vaseline–paraffin mixture. Spreading of methanol to the inoculated square should be avoided, since direct contact at this concentration is toxic for the bacteria. Growth and morphogenesis can then be followed over a period of up to 48 h or more.

Cell size measurements Only living cells, preferentially those in agar slide cultures, are used for size measurements. Phase-contrast light micrographs are prepared and enlarged 10 times; sizes are measured on these enlargements from at least 50–100 cells, since considerable size variations exist in asynchronous *Hyphomicrobium* cultures.

Growth on carbon sources Medium 337 is used as a base, and sterile-filtered carbon sources are added at 0.1–0.2% (w/v). Most hyphomicrobia are oligocarbophilic, i.e., they grow (although slowly) at the expense of contaminants in the laboratory air. It is mandatory, therefore, to have control plates inoculated, which do not contain the carbon source to be tested; growth on these controls has to be considered. Growth on plates can be scored after 1, 2, and 4 weeks. Furthermore, oligotrophic growth makes it necessary to subculture at least two additional times with the same carbon source to ensure that the growth observed is due to the substrate offered and not to substrate carried over with the inoculum. Liquid carbon utilization tests can be scored by measuring optical density at 650 nm (OD_{650}) if cells grow turbidly. However, dramatic changes of cell size and morphology can result from some carbon sources, and light microscopy is required to ascertain that this is not the case. Protein determinations are applied widely as a better method for growth estimation (Matzen and Hirsch, 1982b). In all such experiments, it is crucial to have very homogeneous suspensions in the initial inoculation procedure.

Growth stimulation by vitamins Growth of some hyphomicrobia is markedly stimulated by vitamin B_{12}, especially in chemostat cultures where the population consists mainly of very young cells. Obviously, nutrient requirements can change with cell age. Static asynchronous cultures contain large numbers of older mother cells and do not require B_{12} addition for growth. It has been found, however, that application of a vitamin mixture (Vitamin Solution no. 6; van Ert and Staley, 1971) leads to less stimulation than does the application of B_{12} alone (Matzen and Hirsch, 1982b).

Growth inhibition by visible light Hyphomicrobia that form surface pellicles rather than turbidity are markedly inhibited by light (Hirsch and Conti, 1964b). Experiments to determine the influence of light on *Hyphomicrobium* growth can be carried out with sunlight illumination of agar plates or liquid cultures. Care must be taken to ensure temperature constancy and to avoid water condensation and/or drying of the plates. In the case of liquid cultures, the light inhibition can be detected by the failure of swarmer cells to attach to glass walls on the illuminated side.

DNA extraction procedures Lysis of hyphomicrobia is often difficult; a variety of techniques has been described for DNA extraction (Gebers et al., 1985). For the "cell mill A" method, 1–2 g of bacterial wet weight are suspended in 20 ml of saline–EDTA supplemented with 1 mg proteinase K. Then, 50 g glass beads (0.1 mm diameter) are added, and the precooled mixture is shaken for 5–10 s in an MSK cell homogenizer (Braun, Melsungen, Germany). Cell lysis is completed by adding 20 mg sodium dodecyl sulfate ml^{-1} to the suspension. For DNA extraction, $NaClO_4$ and chloroform–isoamyl alcohol are added, and the suspension is shaken for 15 min at 100 rpm. Centrifugation at 1350 × g for 20 min results in separation of the emulsion into two layers. The nucleic acids can be precipitated from the aqueous phase. This is followed by a 45 min ribonuclease treatment and by a 2 h treatment with proteinase K (200 µg/ml) at 37°C. Then, 1 volume of phenol is added (saturated with 1 × SSC [0.15 M NaCl + 0.015 M Na_3-citrate], pH 7) and 0.1 volume of chloroform–isoamyl alcohol is added and the preparation agitated for 10 min at 100 rpm. Centrifugation at 27,000 × g for 20 min results in the separation of the emulsion into three layers, the upper one of which is used for the precipitation of DNA by ethanol. In some cases, a similar method described by Gebers et al. (1981b) and called the "enzyme A" method yields better results.

Extraction of genomic DNA for PCR

Procedure I of Gliesche et al. (1997) Late-exponential-phase cultures (500 ml; 400–500 mg wet weight) are harvested by centrifugation (8000 × g, 45 min, 4°C), resuspended in 1.0 ml double-distilled water with 4.0 ml acetone (4°C), and incubated for 30 min at 0°C. The pellet (4000 × g, 10 min) is dried and resuspended in 4.0 ml buffer 1 (50 mM EDTA, 30 mM Tris, and 5 mM NaCl). Then, 1.0 ml of a lysozyme solution (20 mg lysozyme ml^{-1} TE [10 mM Tris-HCl, 1 mM EDTA, pH 8.0]) is added and the mixture incubated for 45 min at 37°C. Cells are lysed by the addition of 1.0 ml SDS (10% w/v) and 130 µl of proteinase K solution (20 mg/ml phosphate buffer [0.1 M K_2HPO_4, 0.1 M KH_2PO_4, pH 6.25]), followed by incubation at 56°C for 3 h. After lysis, 275 µl of 5 M NaCl (final concentration 1%, w/v) are added and the suspension gently mixed and incubated for 1 h at 0°C. The cell debris is then pelleted for 30 min at 24,000 × g. High molecular weight genomic DNA is precipitated from the aqueous phase with 0.7–1 volume of isopropanol (20 min, 24,000 × g, 4°C) and air-dried (37°C, 20 min). The resulting pellet is resuspended in 4.0 ml TE. After gently shaking in a water bath (30°C, overnight), 60 µl of RNase A (10 mg/ml in TE) are added, and the suspension incubated for 45 min at 37°C. The lysate is extracted two to three times (6500 × g, 15 min, 4°C) with phenol (saturated with SSC [0.15 M NaCl +0.015 M trisodium citrate, pH 7.5]), phenol/chloroform (until the interface is clear), and chloroform/isoamyl alcohol (24:1). DNA is precipitated from the aqueous phase with 1/10 volume of 3 M sodium acetate (pH 5.2; final concentration of 0.3 M), and three volumes of 96% ethanol (0°C, 30 min–4 h). The pellet (6000 × g, 30 min, 4°C) is washed once with 10 ml ethanol (70%), dried briefly in air at room temperature, and resuspended in 300–500 µl TE by gentle shaking.

Procedure II of Fesefeldt and Gliesche (1997) Cells from 200 ml late exponential phase *Hyphomicrobium* cultures are harvested by centrifugation (8000 × g, 45 min, 4°C). 100 mg cells (wet weight) are resuspended in 300 µl of 1 × SSC. This cell suspension,

together with 200 mg glass beads (0.10–0.11 mm diameter; Braun, Melsungen) and 60 µl of a 10% (v/v) SDS are filled into 2.0 ml microtubes with screw cap closures (Sarstedt, Germany) and shaken at 2000 rpm on a rotary shaker 3300 (Eppendorf, Hamburg) for 5 (IFAM P-645) or 15 min. Then, 1.0 ml phenol (65°C; saturated with SSC) is added. After 2 min of gentle shaking by hand, the cell debris and glass beads are pelleted for 30 min at 14,000 rpm and 4°C (Centrifuge 5415C, Eppendorf). The aqueous phase (300–400 µl) is transferred to a fresh microtube. Purification and precipitation of nucleic acids are performed as described in procedure I. The nucleic acids are resuspended in 200 µl TE by gentle shaking. After adding 10 µl RNase A (50,000 U/ml in TE), the suspension is incubated for 30 min at 37°C. From this, DNA is purified and precipitated as in procedure I and resuspended in 100 µl TE by gentle shaking.

Isolation of plasmid DNA (Gliesche, 1997) Late exponential phase cultures (200 ml; 100–200 mg wet weight) are harvested by centrifugation (8000 × g, 45 min, 4°C), resuspended in 0.3 ml double distilled water with 1.5 ml acetone (4°C), and incubated for 15 min at 0°C. The pellet (10,000 × g, 10 min) is dried with air (5 min), resuspended in 300 µl buffer A (50 mM EDTA, 30 mM Tris, and 5 mM NaCl) and 45 µl of a lysozyme solution (20 mg/ml TE), and incubated for 45 min at 37°C. Then 60 µl of Proteinase K solution (20 mg/ml phosphate buffer [0.1 M K_2HPO_4, 0.1 M KH_2PO_4, pH 6.25]) are added, followed by incubation at 55°C for 2 h. Cells are harvested (10,000 × g, 10 min, 4°C) and resuspended in buffer 1 (QIAGEN, Germany). Plasmid DNA is isolated and purified with the QIAGEN Plasmid Maxi Kit, according to the manufacturer's instructions.

Differentiation of the genus *Hyphomicrobium* from other genera

All *Hyphomicrobium* species described so far grow with C_1 compounds, especially methanol, although methanol was not mentioned in the initial description of the type species, *H. vulgare*, which grows well on formate (Stutzer and Hartleb, 1898). C_1 compounds do not support growth of any of the other morphologically similar genera listed in Table BXII.α.160. Cell shape, arrangement of the bud on the hyphal tip, and the tapering of prosthecae are the best differential characters for this group of budding bacteria. It should be pointed out, however, that the cell shape can vary with the carbon source, growth temperature, nutrient concentration, etc.

Natural samples may sometimes contain organisms that superficially resemble *Hyphomicrobium* species. There are bacteria, such as *Achromatium oxaliferum* from acid bog lakes, which undergo constrictive division, and the "umbilical cord" which holds the two daughter cells of this species together may be mistaken for a thin hyphae (Hirsch, 1974a). Fell (1966) has described *Sterigmatomyces* species, which are yeasts that have a surprising resemblance to hyphomicrobia, except that the cells are much larger and usually carry true vacuoles, as eucaryotes do.

Taxonomic Comments

The genus *Hyphomicrobium*—considered monospecific until recently—has been defined mainly by morphological characters and by its conspicuous life cycle. Consequently, many authors have named their isolates *H. vulgare* because they saw mother cells, hyphae, and motile swarmer cells (Kingma-Boltjes, 1936; Mevius, 1953; Zavarzin, 1960; Hirsch and Conti, 1964a; Shishkina and Trotsenko, 1974; Lebedinskii, 1981). Often, the authors have noted substantial morphological differences among their isolates (Hirsch and Conti, 1964a; Lebedinskii, 1981), and thus it has become increasingly clear that *H. vulgare* is apparently composed of several different species. A detailed study has been conducted on the taxonomy of some 80 C_1-utilizing hyphomicrobia (Hirsch, unpublished data). A computer analysis of these strains carried out by R. Colwell has revealed eight different groups, separated by similarity values of 50–65%. This must be taken as an indication of the need to separate these isolates on a higher level than that of species. A confirmation of these results comes from DNA–DNA hybridization data obtained with 19 *Hyphomicrobium* strains (Table BXII.α.161; Gebers et al., 1986). Those strains that fall within the eight computer-selected groups show high homology (86–100%), but the homology between members of different groups is, in most cases, below 10%. The differences among the *Hyphomicrobium* species shown in Tables BXII.α.162, BXII.α.163, and BXII.α.164 concern morphological, physiological, and ecological characteristics.

A large number of *Hyphomicrobium*-like bacteria that form hyphae and buds from mother cells and cannot usually grow with C_1 compounds can be found in culture collections. These require at least low concentrations of peptone, yeast extract, etc. In some cases, such organisms have been called "*Hyphomonas*", but information is still lacking on the properties of such strains. Mol% G + C values of these "organic hyphomicrobia" may be lower than those of the C_1 hyphomicrobia (Gebers et al., 1985).

Hyphomicrobium neptunium Leifson 1964 has been isolated from seawater and does not resemble C_1-utilizing hyphomicrobia, other than with respect to morphology and life cycle. Recently, this organism has been compared with *Hyphomonas* species (Moore and Hirsch, 1972; Hirsch, 1974a, b ; Weiner et al., 1985), and Moore et al. (1984) has subsequently transferred *H. neptunium* to the genus *Hyphomonas*.

A bacterium isolated from seawater by Weisrock and Johnson (1966) and supposedly resembling hyphomicrobia has been described as *Hyphomicrobium indicum*. It has already been pointed out by Hirsch (1974a, b) that there exist substantial differences between this facultatively anaerobic organism and the type species, *Hyphomicrobium vulgare*. *H. indicum* forms acid from sugars, is indole, nitrate, and H_2S positive, and deaminates phenylalanine. It is psychrotrophic, requires 50–100% seawater, and lacks true budding and hyphal branching. The mol% G + C of the DNA from *Hyphomicrobium indicum* is 40, in contrast to all other, true hyphomicrobia, which have a range of 59–65. This bacterium should no longer be included in the genus *Hyphomicrobium*.

A budding bacterium labeled *"Hyphomicrobium variabile"* is available from culture collections; it is a patent strain, and further information on its properties is lacking.

The definition of the genus *Hyphomicrobium* has been hampered seriously by the lack of a type culture; *H. vulgare*, as described by Stutzer and Hartleb (1898), no longer exists. A search for a neotype culture has been difficult, since not all of the tests described in the 1898 publication can be used only partly or checked at the present time. Among the 80 C_1-utilizing hyphomicrobia mentioned above, strain IFAM MC-750 has been found to have properties essentially identical to those of *H. vulgare*. This strain also shows a high similarity to the hypothetical median organism of the 80 hyphomicrobia (Colwell and Hirsch, unpublished data). It has been proposed, therefore, to accept this strain as the neotype culture for the genus *Hyphomicrobium* (Hirsch, 1989). DNA–DNA hybridization studies of 19 hyphomicrobia indicate at least weak relationships between IFAM MC-750 (Institut

DIFFERENTIATION OF THE SPECIES OF THE GENUS *HYPHOMICROBIUM*

The differential characteristics of the species of *Hyphomicrobium* are given in Table BXII.α.162, morphological characteristics of the species are listed in Table BXII.α.163, and physiological properties are listed in Table BXII.α.164.

List of species of the genus Hyphomicrobium

1. **Hyphomicrobium vulgare** Stutzer and Hartleb 1898, 76[AL]
vul.ga′ re. L. neut. adj. *vulgare* common.

The following description is based on characteristics given by Stutzer and Hartleb (1898) and those of the neotype strain, IFAM MC-750. Mother cells are oval, pear-, or drop-shaped, 0.5–1.2 × 1–3 μm, with prosthecae (hyphae) of varying lengths and rather constant diameter (0.2–0.3 μm; up to 0.4 μm when stained). In liquids, growth occurs as turbidity or rarely as pellicle and turbidity; cells do not form rosettes. Swarmer cells have one to three subpolar flagella. Colonies remain small, even after long incubation; they are colorless or beige, and brownish in transmitted light. Colony surface shiny but granular, the edge is wavy.

Chemoorganotrophic, aerobic, oligocarbophilic. Grow well with methanol, methylamine·HCl, formate, acetate, *n*-butyrate, isovalerate, propionate, lactate (except for IFAM MC-750), isobutanol, glycerol, L-arabinose, D-mannose, D-melibiose, raffinose, dextrin, amygdalin, esculin, D-glucosamine, *N*-acetylglucosamine, dilute human urine, succinate, or asparagine. Growth is slow, but stimulated by pyruvate, α-oxoglutarate, β-hydroxybutyrate, oxalate, galacturonate, chitin, lactose, or D-maltose. Most amino acids are inhibi-

[a]Symbols: −, 90% or more of strains are negative; +, 90% or more of strains are positive; nd, not determined; (+), growth stimulation weak but significant.

[b]Strains: *H. vulgare* Stutzer and Hartleb 1898; *H. vulgare* IFAM MC-750; *H. aestuarii* IFAM NQ-521Gr; *H. chloromethanicum* CM2; *H. coagulans* 10-2; *H. denitrificans* TK 0415; *H. facile* subsp. *facile* IFAM H-526; *H. facile* subsp. *tolerans* IFAM I-551; *H. facile* subsp. *ureaphilum* IFAM CO-582; *H. hollandicum* IFAM KB-677; *H. methylovorum* KM-146; *H. zavarzinii* IFAM ZV-622.

[c]Anaerobic growth with KNO_3, but nitrate reduction was considered to be negative.

[d]Data from Kölbel-Boelke et al. (1985).

tory. The type strain grew well with propionate, isobutyrate, valerate, and mannitol. It did not grow with fructose or sucrose.

Nitrogen sources utilized (in order of growth stimulation) are: NH_4^+, NO_3^-, NO_2^-, and ureate. Do not use urea or fix N_2, although slow oligonitrophilic growth has been observed. Do not nitrify. Anaerobic growth occurs in the presence of NO_3^-, but NO_2^- has not been detected. Slow growth on sheep blood agar.

Strain IFAM MC-750 is inhibited by 30 μg disks of kanamycin, neomycin, and novobiocin and by 10 μg of streptomycin. It tolerates 5.5% NaCl, but growth is retarded at this concentration. The pH optimum is between 6.5 and 7.5; the temperature range for growth is 15–37°C. IFAM MC-750 is catalase and cytochrome oxidase positive, sheep's blood is hemolyzed (α-hemolysis), and most cells form poly-β-hydroxybutyrate as a storage product. MC-750 is not pathogenic for mice and guinea pigs.

The genome size is 2.13×10^9 Da (Kölbel-Boelke et al., 1985).

Habitat: soil. The neotype strain came from construction soil.

The mol% G + C of the DNA is: 61.4 (T_m) (Gebers et al., 1986) or 61.1 (HPLC) (Urakami et al., 1995b).

GenBank accession number (16S rRNA): Y14302.

Additional Remarks: IFAM MC-750 (ATCC 27500) is recommended as the neotype strain; the original type strain no longer exists.

2. **Hyphomicrobium aestuarii** Hirsch 1989b, 495[VP] (Effective publication: Hirsch 1989, 1901)
ae.stu.a′ri.i. L. n. *aestuarium* estuary; M.L. gen. n. *aestuarii* of the estuary.

Mother cells bean-shaped, often with short hyphae; the terminal bud on a hypha is also bean shaped, but is turned at a 90° angle from the mother cell. Mother cells 0.6 ×

1.6 µm (range: 0.5–1.0 × 0.6–5.0 µm). Older hyphae branched. Swarmers with 1–3 subpolar flagella. Cells do not form rosettes, but clump easily and grow in liquids as surface pellicles; shaking precipitates the pellicle. Growth also occurs on the glass surface near the top of the vessel. Attachment of swarmer cells to the glass walls is inhibited by light. Colonies on solid media are brownish, strongly and irregularly folded; surface often has concentric rings. Colony cells very cohesive.

Chemoorganotrophic, aerobic, oligocarbophilic. Grow well with methanol, methylamine·HCl, formate, formamide, dilute human urine, acetate, pyruvate, malate, ethanol, and acetamide. Growth is stimulated, but slow, with *n*-butyrate, isovalerate, lactate, α-oxoglutarate, succinate, crotonate, β-hydroxybutyrate, oxalate, glucuronate, ethanol, *n*-propanol, isobutanol, formaldehyde, glycerol, chitin, and Bacto peptone. Also stimulatory (as C sources) are: D,L-aspartate, L-asparagine, and *N*-acetylglucosamine.

Nitrogen sources utilized for growth: NH_4^+, NO_3^-, and urea; the organisms are oligonitrophilic. Slow growth on Bacto peptone with methylamine·HCl added and on sheep blood agar, but there is no hemolysis.

Inhibited by 30 µg each of kanamycin, neomycin, tetracycline, and erythromycin and by 10 µg of streptomycin (all administered on disks). Grow well in the presence of 3.5% NaCl and faintly with 5.5% NaCl. Temperature range: 5–45°C. Optimal pH: 6.5–7.5. Inhibited by visible light. With methanol and KNO_3, there is anaerobic growth and gas formation; grow anaerobically with methylamine in the presence of thioglycolate. Cytochrome oxidase and catalase positive, gelatin is not liquefied. Not pathogenic for mice or guinea pigs.

Habitat: isolated from brackish water of the Elbe River estuary near Cuxhaven, Germany (Mevius, 1953) and from harbor water of Woods Hole, Massachusetts (Hirsch and Rheinheimer, 1968). Originally present in enrichments of nitrifiers.

The genome size is 2.62×10^9 Da (Kölbel-Boelke et al., 1985).

The mol% G + C of the DNA is: 64.1 (T_m) (Gebers et al., 1986) or 65.5–66.1 (HPLC) (Urakami et al., 1995b; Urakami and Komagata 1987b).

Type strain: ATCC 27483, IFAM NQ-521Gr.

Additional Remarks: Additional strains include IFAM MEV-533, IFAM MEV-533Gr (ATCC 27488), IFAM WH-563, IFAM EA-617, IFAM EN-616, IFAM NQ-521, and IFAM NQ-528. With the exception of strain IFAM WH-563, all of these strains are descendants of isolate “B”, which was originally obtained by Mevius (1953).

3. **Hyphomicrobium chloromethanicum** McDonald, Doronina, Trotsenko, McAnulla and Murrell 2001, 121^{VP}
chlo.ro.me.tha' ni.cum. Gr. adj. *chloros* green, referring to the chlorine radical; M.L. adj. *methanicus* methane (utilizing); N.L. neut. n. *chloromethanicum* chloromethane (utilizing).

Monoprosthecate rods, budding on the prosthecal (hyphal) tips. Cells 0.5–0.6 × 1.3–1.8 µm, nonpigmented, may store poly-β-hydroxybutyrate. Daughter cells are motile. Growth is aerobic. Cells are restricted facultative methylotrophs, capable of growth on one-carbon compounds, such as chloromethane, methanol, or methylamine as sole sources of carbon and energy. The chloromethane-degrading enzymes are inducible. Growth occurs also on ethanol. The type strain, CM2^T, also oxidizes, but does not grow on, bromomethane or iodomethane. Do not grow autotrophically, but growth occurs on mineral salts medium or mineral agar (pH 7.2) with 1% (v/v) CH_3Cl as gas; pyruvate–dehydrogenase activity is negative. C_1 compound assimilation is via the serine pathway (icl$^+$); NH_4^+ assimilation is via the glutamate cycle. Nitrate is not reduced; oxidase and catalase activity is positive. Vitamins are not required. Storage of viable cells on Whatman paper in sealed flasks or ampules kept at −40 to −80°C (Doronina and Trotsenko, 1992).

The temperature optimum for growth is 28–30°C. The pH optimum for growth is 6.5–7.5. The major fatty acid is $C_{18:1}$ and the major quinone is Q-9.

H. chloromethanicum shares high 16S rRNA gene sequence similarity with *H. facile* subsp. *facile* (97.1%), *H. denitrificans* (96.3%), and *H. methylovorum* (96.0%). The DNA–DNA similarity with *H. zavarzinii* ZV-622^T has been found to be 29.4%.

Habitat: strain CM2 was isolated from polluted soil at the Nizhekamsk petrochemical factory, Tatarstan, Russia. Strain CM29 came from soil of the Alushta dendropark, Crimea, Ukraine.

The mol% G + C of the DNA is: 60 (T_m).

Type strain: CM2, NCIMB 13687, VKMB-2176.

GenBank accession number (16S rRNA): AF198623.

Additional Remarks: CM29 is identical to CM2.

4. **Hyphomicrobium coagulans** (ex Takada 1975) Hirsch 1989b, 495^{VP} (Effective publication: Hirsch 1989, 1903.)
co.a' gu.lans. L. part. adj. *coagulans* curdling, coagulating.

Mother cells ovoid or pear-shaped, 0.6–1.2 × 1.2–2.0 µm. Hyphae polar or bipolar, branched in older cultures. Swarmer cells motile with 1–3 polar flagella. In liquid media, growth occurs as turbidity or pellicle. Growth on solid media may become yellow.

Chemoorganotrophic, aerobic. Good growth on methanol, methylamine, and ethanol. Other carbon sources utilized are: *n*-propanol, *n*-butanol, isobutanol, benzyl alcohol, furfuryl alcohol, trimethylene glycol, formate, and citrate. Carbon sources not utilized: acetate, lactate, formaldehyde, and glycerate. Growth is stimulated by glucose, sucrose, and lactose. Methane is utilized as a carbon source.

Acid is formed (without gas) from glucose, lactose, glycerol, methyl-α-glucoside, sucrose, maltose, salicin, arabinose, galactose, mannitol, inulin, xylose, and soluble starch. Gelatin is liquefied, peptone is utilized, and milk is slowly coagulated, but not peptonized. Casein is not hydrolyzed, indole is not produced. H_2S-positive; methyl red test and Voges–Proskauer tests are positive. Nitrate reduction negative.

Nitrogen sources utilized are: Casamino acids, polypeptone, aspartate, KNO_3, and NH_4^+.

Optimal pH: ~6.0; range: 5.7–8.0. Temperature optimum: 35°C.

Habitat: rice field soil of Hirakata, Osaka, Japan.

The mol% G + C of the DNA is: not reported.

Type strain: Takada 10-2.

5. **Hyphomicrobium denitrificans** Urakami, Sasaki, Suzuki and Komagata 1995b, 531^{VP}
de.ni.tri' fi.cans. M.L. part. adj. *denitrificans* denitrifying.

Mother cells are rod-shaped, oval, egg-shaped or bean-shaped, often with pointed ends, 0.3–0.6 μm × 1.0–3.0 μm, with mono- or bipolar hyphae of varying lengths that are 0.3–0.4 μm in diameter. Swarmer cells motile, often attaching to surfaces or to other cells and forming clumps. Granules of poly-β-hydroxybutyrate accumulate in the cells.

Colonies on methanol-containing agar are shiny, smooth, raised, entire, white, and 1–2 mm after 3–6 d at 30°C. Chemoorganotrophic, aerobic, not fermentative. Good growth on methanol, mono-, di-, and trimethylamine, pectin, and acetate. Methanol is utilized by the serine pathway via activated formaldehyde incorporation.

Some strains utilize formate and ethanol. The following compounds are not utilized: L-arabinose, D-xylose, D-glucose, D-mannose, galactose, maltose, sucrose, lactose, trehalose, D-sorbitol, D-mannitol, inositol, glycerol, soluble starch, propionic acid, isobutyric acid, *n*-valeric acid, lactic acid, succinic acid, oxalic acid, and methane. Vitamins and amino acids are not required for growth. No growth on nutrient broth or peptone broth.

Nitrogen sources utilized: ammonia, nitrate, and urea. Nitrate is reduced to nitrite; nitrate reduction is strong. Methyl red, Voges–Proskauer, gelatin, and starch hydrolysis are negative. Indole, H_2S and ammonia are not produced. Oxidase, urease, and catalase positive. Acid is not produced from sugars oxidatively or fermentatively.

Optimal pH range for good growth: pH 6.0–8.0. Good growth at 30°C. No growth in nutrient broth, peptone broth, or in media with 3% sodium chloride.

The cellular fatty acids include large amounts of straight-chain, unsaturated $C_{18:1}$ acid. The hydroxy fatty acids include large amounts of $C_{14:0\ 3OH}$ and $C_{16:0\ 3OH}$ hydroxy acids. The major ubiquinone is Q-9.

Habitat: soil.

The mol% G + C of the DNA is: 60.4 (HPLC) (Urakami et al., 1995b) or 60.5 (HPLC) (Urakami and Komagata, 1987b).

Type strain: Attwood and Harder strain X, DSM 1869, NCIB 11706, TK 0145.

GenBank accession number (16S rRNA): Y14308.

6. **Hyphomicrobium facile** Hirsch 1989b, 495^{VP} (Effective publication: Hirsch 1989, 1902.)
fa' ci.le. L. adj. *facile* ready, quick.

The three subspecies of *Hyphomicrobium facile* are described below.

The mol% G + C of the DNA is: 59.5–61.2

Type strain: see subspecies list below.

GenBank accession number (16S rRNA): see subspecies list below.

a. **Hyphomicrobium facile** *subsp.* **facile** Hirsch 1989b, 495^{VP} (Effective publication: Hirsch 1989, 1902.)

Mother cells pear- or drop-shaped, 0.95 × 2.0 μm (range: 0.6–1.5 × 0.9–6.0 μm); on some media, hyphae are richly branched and often formed bipolarly. Swarmer cells have 1–3 subpolar flagella, which are easily shed. Grow in liquid media as turbidity; colonies on solid media are light brownish to beige, with a smooth and shiny surface and entire edges. Vigorous stirring of liquid cultures results in intercalary bud formation in hyphae. Chemoorganotrophic, aerobic. Grow well with methanol, methylamine·HCl, *N*-acetylglucosamine, and gelatin (strain IFAM B-522). Growth is significantly stimulated by formate, acetate, lactate, α-oxoglutarate, succinate, β-hydroxybutyrate, oxalate, glucuronate, ethanol, glycerol, amygdalin, chitin, and poly-β-hydroxybutyrate. Oligocarbophilic. Growth is also stimulated significantly by DL-leucine, DL-lysine, and DL-phenylalanine. There is no growth in dilute human urine.

Nitrogen sources utilized: NH_4^+, NO_3^-, urea, and (slow) Bacto peptone. Slow growth oligonitrophilically. There is faint growth, but no hemolysis, on sheep blood agar. Inhibited by 30 μg each of kanamycin, neomycin, tetracycline, and erythromycin and by 10 μg streptomycin. Slow growth in the presence of 3.5% NaCl. Temperature range: 5–37°C. Optimal pH: 6.5–7.0. Light does not inhibit growth. Grow anaerobically with methylamine·HCl and thioglycolate; denitrification-negative; catalase and cytochrome oxidase positive. Gelatin is not liquefied, and poly-β-hydroxybutyrate is formed as a storage product. Lysine decarboxylase negative.

Not pathogenic for mice or guinea pigs.

The genome size is 2.35 × 10^9 Da (strain IFAM B-522).

Habitat: soil.

The mol% G + C of the DNA is: 59.5–61.2 (T_m, HPLC) (Gebers et al., 1986; Urakami et al., 1985, 1995b).

Type strain: ATCC 27485, IFAM H-526.

GenBank accession number (16S rRNA): Y14309.

Additional Remarks: Additional strains include IFAM D-524, E-525, G-527, K-529, L-530, and B-522 (ATCC 27484).

b. **Hyphomicrobium facile** *subsp.* **tolerans** Hirsch 1989b, 495^{VP} (Effective publication: Hirsch 1989, 1902.)
to' le.rans. L. part. adj. *tolerans* tolerating; pertaining to the tolerance of high CO concentrations.

Morphology and cell sizes as in *H. facile* subsp. *facile.* Colonies on solid media are light brown to beige, smooth and shiny, with entire edges. Grow in liquids as turbidity.

Chemoorganotrophic, aerobic, oligocarbophilic. Good growth on methanol, methylamine·HCl, formate, *n*-butyrate, isovalerate, glycerol, and *N*-acetylglucosamine. Slow growth, but significant stimulation, by pyruvate, crotonate, β-hydroxybutyrate, isobutanol, formaldehyde, Bacto peptone, and ureate. Nitrogen source utilized: NH_4^+. Slow growth, but not hemolysis, on sheep blood agar. Inhibited by 30 μg each of kanamycin, neomycin, tetracycline, and erythromycin and by 10 μg of streptomycin. Growth in the presence of 2.5% NaCl has been observed; growth is faint with 5.5% NaCl. Temperature range: 15–45°C. Optimal pH: 6.5–7.5. Not inhibited by visible light. Do not denitrify, but growth occurs with methylamine·HCl anaerobically with thioglycolate. Catalase and cytochrome oxidase positive. Tolerate up to 90% (v/v) of CO in the atmosphere. Gelatin is not liquefied; poly-β-hydroxybutyrate is formed. Not pathogenic for mice or guinea pigs.

Habitat: soil.

The mol% G + C of the DNA is: is 59.4–60.5 (T_m, HPLC); (Urakami et al., 1985; Gebers et al., 1986; Urakami and Komagata, 1987b).

Type strain: ATCC 27489, IFAM I-551.
GenBank accession number (16S rRNA): Y14311.
Additional Remarks: Additional strains include IFAM O-545, P-546, Q-547, R-549, M-552, CO-553, CO-557, and CO-558 (ATCC 27491).

c. **Hyphomicrobium facile** *subsp.* **ureaphilum** Hirsch 1989b, 495[VP] (Effective publication: Hirsch 1989, 1902.)
u.re.a.phi' lum. Gr. n. *urum* urine; Gr. adj. *philus* loving; M.L. adj. *ureaphilum* loving urea.

Cell sizes and morphology are very similar to IFAM I-551 (Fig. BXII.α.189). Mother cell width 1.1 μm (range: 1.0–1.25 μm). Grow as turbidity in liquid media. Colonies on solid media brownish to beige, smooth, shiny, with entire edges. Physiological properties as for *H. facile* subsp. *tolerans* IFAM I-551, except for the following: growth is stimulated significantly by α-oxoglutarate, but not by crotonate; growth is stimulated by ethanol, but not by Bacto peptone, urea, and ureate as carbon sources. Urea is utilized as a nitrogen source in the presence of methanol. Temperature range: 25–37°C; there is weak growth at 15°C and 45°C. Grow weakly on sheep blood agar with α-hemolysis. Poly-β-hydroxybutyrate may be formed.

Habitat: soil.
The mol% G + C of the DNA is: 60.5 (T_m, HPLC) (Urakami et al., 1995b; Gebers et al., 1986).
Type strain: ATCC 27492, IFAM CO-582.
GenBank accession number (16S rRNA): Y14310.
Additional Remarks: Additional strains include IFAM CO-573, CO-574, CO-587, CO-611, CO-613, CO-614, CO-610, and CO-645.

7. **Hyphomicrobium hollandicum** Hirsch 1989b, 495[VP] (Effective publication: Hirsch 1989, 1902.)
hol.lan' di.cum. M.L. neut. adj. *hollandicum* pertaining to the isolation from the Netherlands.

Mother cells oval or pear-shaped, 0.70 × 1.66 μm (range: 0.6–0.8 × 1.5-3.5 μm). Older hyphae branched. Swarmer cells subpolarly flagellated. Growth in liquid media as pellicle or turbidity; cells may tend to clump. Colonies on solid media are brownish in transparent light and beige in reflected light, with entire edges and shiny surface. Chemoorganotrophic, aerobic, oligocarbophilic. Grow well with methanol, methylamine·HCl, formate, glycerol, cellobiose, raffinose, dextrin, amygdalin, esculin, *N*-acetylglucosamine, and ureate. Growth is stimulated with isovalerate, pyruvate, lactate, succinate, oxalate, isobutanol, formaldehyde, L-sorbose, D-maltose, chitin, DL-aspartate, D-glucosamine, and dilute urine.

Nitrogen sources utilized: NH_4^+, NO_2^-, NO_3^-. The bacteria grow slowly without an added nitrogen source, i.e., oligonitrophilically. Strain IFAM KB-677 is inhibited by 30 μg each of kanamycin, neomycin, and tetracycline. There is no growth in the presence of 2.5% NaCl. Temperature range: 25–37°C. Optimal pH: >7.5. Strain KB-677 is slightly inhibited by visible light. Catalase and cytochrome oxidase positive, gelatin liquefaction and hemolysis negative. Poly-β-hydroxybutyric acid is formed as a storage product. Not pathogenic for mice or guinea pigs.

The genome size is 2.43 × 10^9 Da (Kölbel-Boelke et al., 1985).

Habitat: strain IFAM KB-677 was obtained from T.Y. Kingma-Boltjes, who isolated it from sewage.
The mol% G + C of the DNA is: 62.4 (T_m) (Gebers et al., 1986) or 62.9 (HPLC) (Urakami et al., 1995b).
Type strain: ATCC 27498, IFAM KB-677.
GenBank accession number (16S rRNA): Y14303.
Additional Remarks: Strain IFAM MC-651 (ATCC 27 497) is related and was isolated from soil by M. Macpherson-Kraviec.

8. **Hyphomicrobium methylovorum** Izumi, Takizawa, Tani and Yamada 1983, 439[VP] (Effective publication: Izumi, Takizawa, Tani and Yamada 1982, 373.)
me.thy.lo.vo' rum. M.L. n. *methyl* the methyl radical; L. v. *voro* devour; M.L. n. *methylovorum* methyl devourer.

Mother cells oval, 0.3–0.65 × 0.5–2.0 μm, with monopolar or bipolar hyphae. Swarmer cells motile with a single lateral flagellum. On solid media, colonies white to faintly yellow, circular, convex, smooth, and glistening.

Chemoorganotrophic, aerobic, aminopeptidase positive. Carbon sources utilized for growth: methanol, methylamine, dimethylamine, and trimethylamine. Poor growth on formate and formamide. Compounds not utilized are: methane, formaldehyde, ethanol, *n*-propanol, glycerol, D-glucose, D-fructose, D-lactose, D-arabinose, sucrose, trehalose, melibiose, cellobiose, mannitol, inositol, dextrin, starch, acetate, pyruvate, lactate, succinate, oxalate, glycolate, glyoxylate, citrate, fumarate, malate, tartrate, glycine, and serine.

Nitrogen sources utilized: NH_4^+ and L-glutamine; poor growth on peptone, Casamino acids, L-cysteine, and L-aspartate. Nitrogen compounds not utilized: nitrate, urea, yeast extract, meat extract, glycine, and L-serine. Nitrate reduction, Voges–Proskauer, indole, H_2S, starch hydrolysis, citrate, and urease are all negative. Catalase positive. Temperature range for growth: 14–33°C. Optimal temperature: around 28°C. Optimal pH: around 7.0. Vitamins are not required.

Habitat: soil.
The mol% G + C of the DNA is: 60.6 (T_m) (Urakami et al., 1985) or 58.5 (HPLC) (Urakami et al., 1995b).
Type strain: DSM 5458, IFO 1480, KM-146.
GenBank accession number (16S rRNA): Y14307.

9. **Hyphomicrobium zavarzinii** Hirsch 1989b, 495[VP] (Effective publication: Hirsch 1989, 1903.)
za.var.zin' i.i. M.L. gen. n. *zavarzinii* of Zavarzin, named for G.A. Zavarzin, the Russian microbiologist who isolated these bacteria.

Mother cells drop- or pear-shaped, somewhat slender, with hyphae that rarely branch. Mother cells 0.63 × 1.8 μm (range: 0.5–0.9 × 0.7–2.5 μm). Swarmer cells with 1–3 subpolar flagella. In liquid media under most growth conditions, rosettes are formed, since mother cells produce a polar holdfast. Growth in liquids initially as turbidity and later as a pellicle, with precipitation on the bottom. Colonies on solid media are colorless to light brownish or beige, smooth and shiny, with entire edges.

Chemoorganotrophic, aerobic, oligocarbophilic. Good growth with the following carbon sources: methanol, methylamine·HCl, formate, *n*-butyrate, isovalerate, crotonate, β-hydroxybutyrate, ethanol, *n*-propanol, isobutanol, and glyc-

erol. Growth is stimulated significantly by acetate, *n*-valerate, α-oxoglutarate, galacturonate, formaldehyde, D-glucose, D-mannose, D-melibiose, amygdalin, esculin, chitin, Bacto peptone, DL-lysine, DL-aspartate, and dilute human urine. Nitrogen sources utilized are: NH_4^+, NO_2^-, NO_3^-, and (poorly) Bacto peptone. There is slow growth in the absence of added nitrogen sources (oligonitrophily). Poor growth on sheep blood agar with α-hemolysis. The following antibiotics inhibit growth at 30 μg (per disc): kanamycin, neomycin, and tetracycline. Streptomycin at 10 μg is also inhibitory. There is growth in the presence of 3.5% NaCl. Temperature range: 15–37°C. Optimal pH: 6.5–7.5. Visible light inhibits growth slightly.

Grow anaerobically with nitrate and gas formation (with methanol as the carbon source). With methylamine·HCl and thioglycolate, there is little growth. Catalase and cytochrome oxidase are positive; gelatin liquefaction is negative. Poly-β-hydroxybutyrate is a storage product.

Not pathogenic for mice or guinea pigs.

Genome size: 2.73×10^9 Da (strain ZV-580; Kölbel-Boelke et al., 1985).

Habitat: peaty and moist soil near Moscow, Russia.

The mol% G + C of the DNA is: 61.8–64.8 (Bd, T_m, HPLC) (Mandel et al., 1972; Gebers et al., 1986; Urakami and Komagata, 1987b; Urakami et al., 1995b).

Type strain: ATCC 27496, IFAM ZV-622.

GenBank accession number (16S rRNA): Y14305.

Additional Remarks: Additional strains include IFAM ZV-580, ZV-620, MY-619, MC-625, MC-629, MC-630, and MC-627.

Genus II. **Ancalomicrobium** *Staley 1968, 1940*[AL]

CHERYL JENKINS, PATRICIA M. STANLEY AND JAMES T. STALEY

An.ca' lo.mi.cro' bi.um. Gr. masc. n. *ancalos* arm; Gr. adj. *micros* small; Gr. masc. n. *bios* life; M.L. neut. n. *Ancalomicrobium* arm (-producing) microorganism.

Unicellular bacterium with conical cells ~1.0 μm in diameter. **Two to eight or more prosthecae** produced per cell. Prosthecae are cylindrical without crossbands and taper gradually from cell to a distal diameter of ~0.2 μm and a length of 2–5 μm when fully differentiated. Prosthecae may be bifurcated. **Budding bacterium**. Buds are formed directly from mother cell, never from prosthecae. Cells occur singly or in pairs prior to division; rarely form aggregates.

Gram negative. Flagella and holdfasts not produced. **Gas vacuoles** are formed by all strains investigated.

Facultatively anaerobic. Chemoheterotrophic. Use sugars anaerobically and aerobically. Ferments sugars by **mixed acid fermentation**. Some organic acids are used aerobically, but not fermented. Ammonium can be used as sole nitrogen source. Vitamins are required. Oxidase and catalase positive. Temperature range for type strain: 9–39°C. Optimal pH: 7.0, pH range 6.3–7.5. Found in freshwaters and pulp mill oxidation lagoons.

Type genus: **Ancalomicrobium adetum** Staley 1968, 1940.

FURTHER DESCRIPTIVE INFORMATION

A. adetum lives in freshwater habitats, including lakes and eutrophic habitats, such as ponds, rivers and pulp mill oxidation lagoons (Staley, 1971; Stanley et al., 1979; Staley et al., 1980).

The most distinctive feature of the genus is its cellular morphology. The size, shape, and location of the prominent prosthecae, combined with a lack of cell motility, are unique features of this genus. Under normal growth conditions, in which a low concentration of nutrients is supplied, the prosthecae attain a length of 2–5 μm (Fig. BXII.α.192). Shorter prosthecae, as formed by members of the genus *Prosthecomicrobium*, are not produced by *Ancalomicrobium*; however, aberrant cell morphology can be observed under *in vitro* cultivation conditions in the presence of high concentrations of nutrients.

Buds begin as small protuberances on a non-appendaged area of the "mother cell". The buds enlarge and differentiate, and new prosthecae are formed so that the daughter cell is a pseudo-mirror image of the mother cell at the time of cell separation. The mother cell retains its original prostheca, and each new bud is produced at the same location on the mother cell. The daughter buds are produced essentially *de novo* during the budding process (Staley, 1973b; Staley et al., 1981) as shown in Fig. BXII.α.193.

Gas vacuoles are produced by all strains studied. Gas vesicles may be produced in some cells under aerobic conditions with sugars as a carbon source; however, they are only observed during the stationary growth phase. In contrast, all strains studied produce gas vacuoles prodigiously during anaerobic growth at low temperatures (<18°C) (A. Van Neerven and J.T. Staley, unpublished observations). Gas vacuoles are also produced under microaerophilic conditions on organic acids, including acetic, pyruvic and succinic acids (R.L. Irgens and J.T. Staley, unpublished observations).

A variety of sugars, sugar alcohols, and organic acids can be used as carbon sources for aerobic growth. These include D-arabinose, L-arabinose, D-ribose, D-glucose, D-fructose, D-mannose, D-galactose, D-xylose, L-fucose, L-rhamnose, D-melibiose, maltose, lactose, cellobiose, trehalose, *N*-acetylglucosamine, acetate, pyruvate malate, glycerol, inositol, and mannitol. Agar is digested slowly.

Some carbon sources, including some sugars and sugar alcohols, are used anaerobically by fermentation. Sugars are fermented by a mixed acid fermentation (Van Neerven and Staley, 1988). Glucose is fermented to acetic acid, ethanol, lactic acid, formic acid, succinic acid, hydrogen gas, and carbon dioxide. These are the same products that *Escherichia coli* produces under the same conditions for growth.

Ammonium salts are used as a sole source of nitrogen. Pantothenic acid is required for growth, and biotin, thiamine, folic

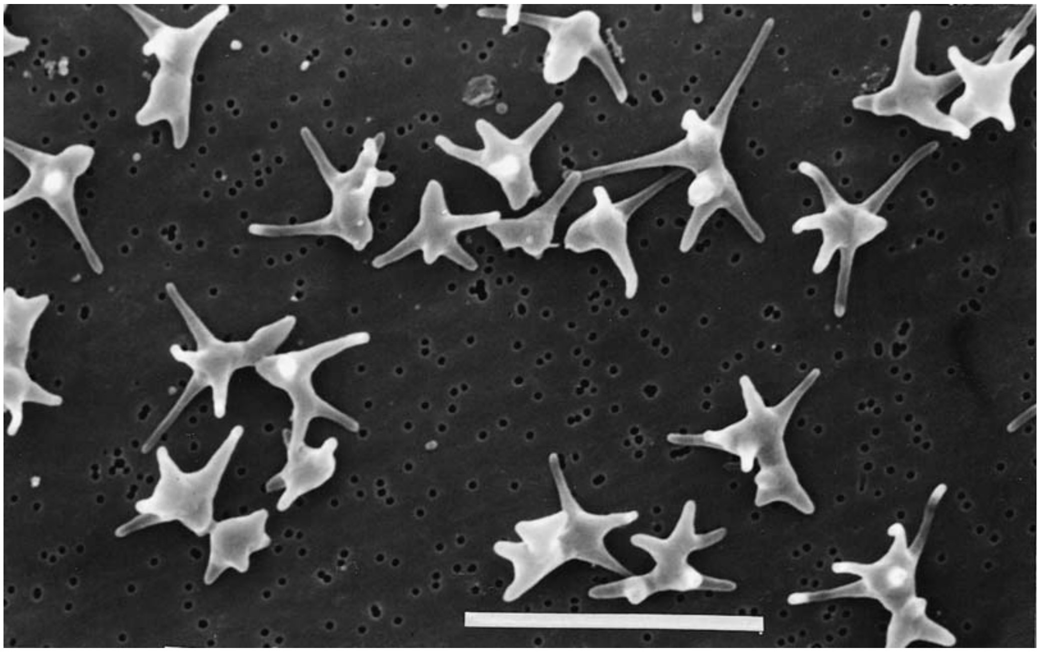

FIGURE BXII.α.192. *Ancalomicrobium adetum.* Scanning electron micrograph. Bar = 5.0 μm. (Courtesy of A.R.W. van Neerven.)

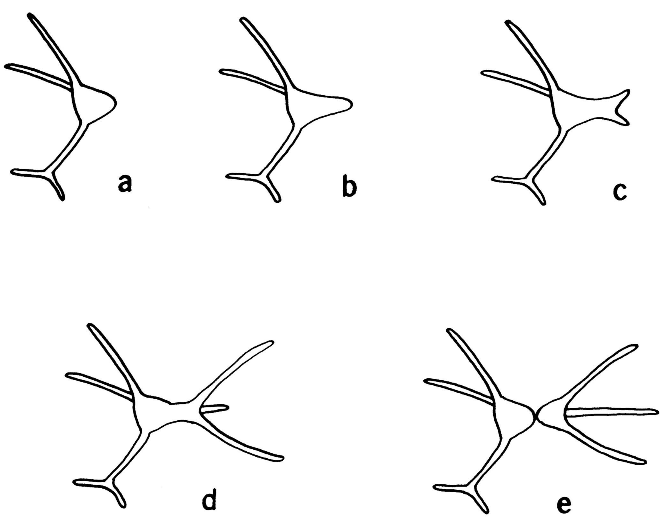

FIGURE BXII.α.193. A diagram of *Ancalomicrobium adetum*, illustrating the life cycle of this budding bacterium. The mother cell has three appendages, one of which is bifurcated (*a*). Bud formation occurs at the apex of the conical cell (*b*). The bud begins to differentiate (*c* and *d*) and ultimately separates from the mother cell (*e*). Following division, the mother cell, whose appearance after reproduction remains essentially identical to its initial appearance in *a*, will produce another daughter cell from the same location. This process will be repeated again and again, as long as conditions are favorable for growth. (Reproduced with permission from J.T. Staley, Journal of Bacteriology *95:* 1921–1942, 1968, ©American Society for Microbiology.)

acid, and nicotinamide are stimulatory for growth of the type strain.

The type strain grows on a minimal, defined medium containing ammonium salts, phosphate, a modified Hutner's salts solution, and vitamins (see *Bergey's Manual of Systematic Bacteriology*, first edition). Better growth is obtained in complex media, such as modified medium B (MMB; Staley, 1968), which contains yeast extract, in addition to the constituents provided in the defined medium. The highest yields have been obtained in a richer complex medium (R.L. Irgens, personal communication; Staley, 1989).

The minimal temperature for growth of the type strain is between 6 and 9°C, whereas the maximum lies between 39 and 43°C. The optimal pH for growth is between 6.9 and 7.3; however, growth has been observed at all pH values tested, ranging from 6.3 to 7.5.

Enrichment and Isolation Procedures

Selective isolation procedures have not yet been developed. However, the addition of peptone to a final concentration of 0.01% may be used to enrich for these bacteria.

Enrichment cultures of 100 ml are normally used. Graduated 150-ml beakers containing 10 mg of peptone are covered with aluminum foil and autoclaved. Natural water samples are collected aseptically, and 100 ml aliquots are added to the beaker. Enrichment cultures are incubated at room temperature without shaking. Cultures should be examined periodically for the appearance of multiply appendaged prosthecate bacteria. Wet mounts should be prepared for phase microscopic observation, from the time the cultures become turbid (usually 4–7 days), until 2–3 weeks have elapsed. Whereas *Caulobacter* species are frequently observed attached to debris in the surface film of the enrichment, these planktonic multiply-appendaged forms are rarely encountered there. They are usually found moving with the currents in the wet mount and are most often seen in areas where free-floating forms have accumulated near debris or air bubbles. When multiply-appendaged forms comprise a significant portion of the enrichment culture (~1%), attempts should be made to isolate them by streaking onto MMB plates (see Staley,

1989). Alternatively, 10^{-3}–10^{-5} dilutions of the enrichment culture can be spread-plated onto MMB agar. Plates should be incubated at room temperature for 1–2 weeks before examination. Individual colonies are selected for examination by wet mount. When positive colonies are found, they are restreaked for purification.

Maintenance Procedures

A. adetum can be maintained for at least 1 month on MMB slants that have been refrigerated. Long-term preservation is effected by lyophilization of cultures grown on complex media.

Differentiation of the genus *Ancalomicrobium* from other genera

The striking morphology of members of the genus *Ancalomicrobium* allows them to be readily distinguished from nonappendaged bacteria and from most of the other prosthecate bacteria. However, some of the multiply-appendaged bacteria may appear similar. The genus *Stella* can be differentiated from *Ancalomicrobium* because all of its appendages lie in one plane. The most morphologically similar genus is *Prosthecomicrobium*. Some cells of *P. hirschii*, in particular, appear identical to *A. adetum*, although short-appendaged cells are also produced by *P. hirschii*. In addition, all *P. hirschii* strains are motile, while *A. adetum* is nonflagellated. Furthermore, *Ancalomicrobium* strains produce gas vacuoles, while *P. hirschii* does not. More significantly, these two groups are physiologically distinct. All species of *Prosthecomicrobium* are obligately aerobic, whereas *Ancalomicrobium* strains are fermentative, facultative anaerobes. Table BXII.α.165 summarizes the important differential characteristics that distinguish these two genera.

Taxonomic Comments

DNA–DNA hybridization studies have shown that *Ancalomicrobium* strains and *Prosthecomicrobium* strains form separate taxonomic groups (Moore and Staley, 1976). This finding is consistent with the current taxonomy of these two genera. According to 16S rRNA analyses, both *Ancalomicrobium* and *Prosthecomicrobium* species are members of the *Alphaproteobacteria*; however, based on sequence data from at least three strains, *Ancalomicrobium* has been shown to form a distinct genus (See Fig. BXII.α.194).

Although further taxonomic work on this genus is desirable, the difficulty encountered in obtaining isolates has hindered taxonomic investigations of the genus. However, since the initial isolation of the type strain, a number of strains have been isolated from pulp mill oxidation lagoons (A. Van Neerven and J.T. Staley, unpublished studies).

It is noteworthy that *A. adetum* is currently the only fermentative, heterotrophic, budding, and prosthecate bacterium in pure culture. Of special note in this regard is the discovery that *A. adetum* is a mixed acid fermenter whose fermentation products are identical to those of *E. coli* (Van Neerven and Staley, 1988). Furthermore, the phosphoenolpyruvate–sugar phosphotransferase system of this organism has been compared to that of certain enteric bacteria (Saier and Staley, 1977). The most interesting discovery from this investigation is that enzymatic cross-reactivity has been detected between the membrane-associated enzyme II complexes of *A. adetum* and the soluble enzyme I components of the enteric bacterium *Salmonella typhimurium*. It is noteworthy that *A. adetum* is a member of the *Alphaproteobacteria*, whereas the enteric bacteria are members of the *Gammaproteobacteria*.

TABLE BXII.α.165. Differentiation of *Ancalomicrobium* from *Prosthecomicrobium*[a]

Characteristic	*Ancalomicrobium*	*Prosthecomicrobium*
Short prosthecae (i.e., <2.0 μm when fully developed)	−	+
Long prosthecae (i.e., 2–5 μm when fully developed)	+	D[b]
Gas vesicles	+	D
Glucose fermentation	+	−

[a]Symbols: −, no strains/species positive; +, all strains/species positive; D, varies depending on species.

[b]Some species of *Prosthecomicrobium*, such as *P. hirschii* and *P. pneumaticum*, produce longer prosthecae as well as shorter ones.

List of species of the genus Ancalomicrobium

1. **Ancalomicrobium adetum** Staley 1968, 1940[VP]
a′de.tum. M.L. adj. *adetum* arm or appendage.

The characteristics are as described for the genus. Occur in freshwater.

The mol% G + C of the DNA is: 70.4 (Bd)
Type strain: ATCC 23632, DSM 4722.

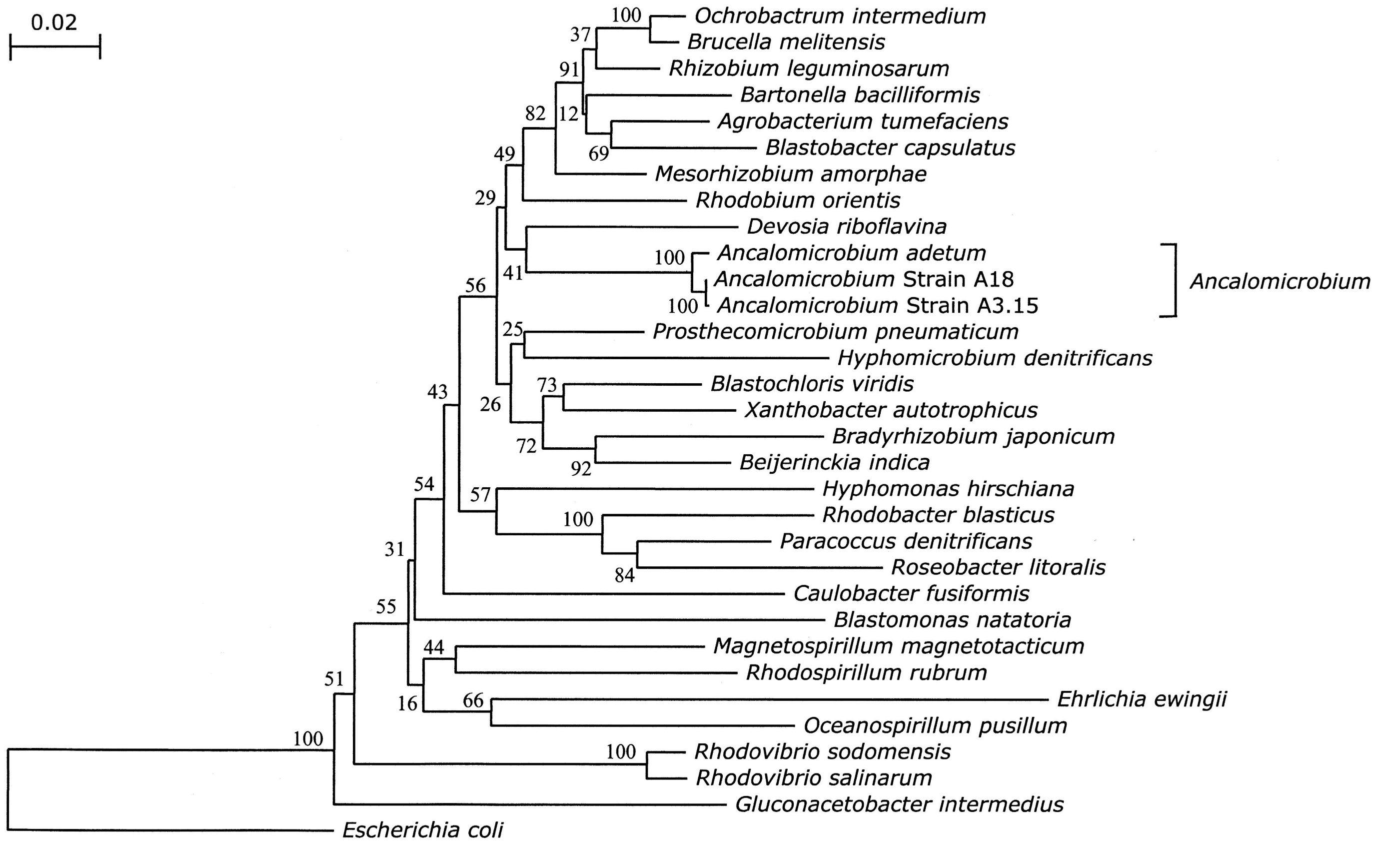

FIGURE BXII.α.194. Phylogenetic tree based on 16S rRNA sequences showing the position of *Ancalomicrobium* within the *Alphaproteobacteria*. The type strain of *Ancalomicrobium*, *A. adetum*, and two additional organisms isolated from pulp mill oxidation lagoons, strains A18 and A3.15, form a distinct genus. These strains form a separate lineage from other prosthecate bacteria, such as *Prosthecomicrobium* and *Hyphomicrobium*. The tree was constructed using Kimura distances and the neighbor-joining algorithm with 100 bootstrap replicates within the program Treecon. The distance scale indicates 0.02 substitutions per site.

Genus III. **Ancylobacter** *Raj 1983, 397[VP]*

JAMES T. STALEY, CHERYL JENKINS AND ALLAN E. KONOPKA

An' cy.lo.bac' ter. Gr. adj. *ankylos* sharply curved; Gr. n. *bakterion* rod; M.L. masc. n. *Ancylobacter* a curved rod.

Curved rods, 0.3–1.0 × 1.0–3.0 µm. **Rings** (0.9–3.0 µm outer diameter) occasionally formed prior to cell separation. Coiled, helical, and filamentous forms are not produced. Cells are encapsulated. Resting stages not known. **Some strains produce gas vacuoles.** Gram negative. **Generally nonmotile**, but motility occurs in one gas vacuolate strain by means of a single polar flagellum. **Obligately aerobic**, possessing a strictly respiratory type of metabolism, with oxygen as the terminal electron acceptor. Optimal temperature, 22–37°C. Colonies are translucent to opaque and white to cream colored. Pellicles are produced in liquid media. **Oxidase positive.** Catalase positive. Chemoorganotrophic, using a variety of sugars or salts of organic acids as carbon sources. Chemolithotrophic growth has been reported on molecular hydrogen. Strains that have been tested can use methanol and formate (**facultatively methylotrophic**). Occur in soil and freshwater environments.

The mol% G + C of the DNA is: 66–69 (Bd).

Type species: **Ancylobacter aquaticus** (Ørskov 1928) Raj 1983, 297 (*Microcyclus aquaticus* Ørskov 1928, 128.)

FURTHER DESCRIPTIVE INFORMATION

Cells of *Ancylobacter aquaticus* typically appear as curved rods (Figs. BXII.α.195 and BXII.α.196). Ring-like forms occur when the ends of a curved cell overlap prior to cell separation; this occurs infrequently under normal growth conditions. Pleomorphic forms have been reported under certain cultural conditions. For example, older cultures of the type strain contain swollen cells and other involution forms (Raj, 1970, 1977).

A number of gas-vacuolated strains of *Ancylobacter aquaticus* have been isolated (Nikitin, 1971; Van Ert and Staley, 1971; Konopka et al., 1977). These appear to be very similar to the type strain, so no new species have been proposed to accommodate them. We consider the type strain of *A. aquaticus* to be avacuolate, despite a claim to the contrary (Raj, 1977). In addition to a lack of convincing microscopic evidence for vacuoles in this strain in our laboratory, we have found that antiserum prepared against gas vacuoles is incapable of causing precipitation in lysates of the type strain, whereas precipitation does occur with the lysates of all gas-vacuolated strains.

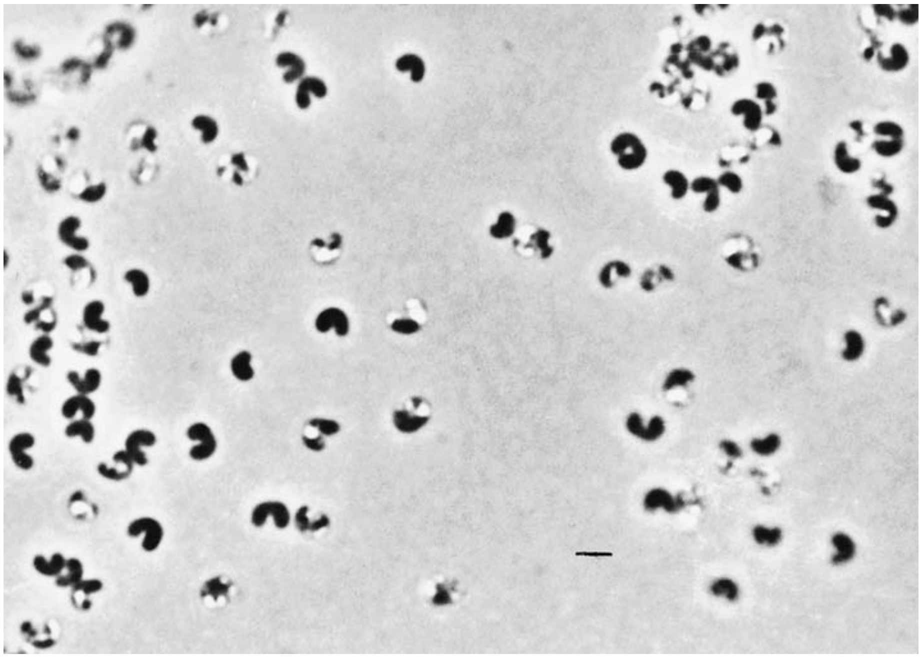

FIGURE BXII.α.195. A phase-contrast photomicrograph showing numerous cells of *Ancylobacter aquaticus*. The refractile intracellular areas of some cells are gas vacuoles. Bar = 2.0 μm.

FIGURE BXII.α.196. An electron micrograph of a cell of a gas-vacuolated strain of *Ancylobacter aquaticus*. Individual gas vesicles can be seen. Bar = 1.0 μm. (Courtesy of Dr. J.C. Lara.)

Cells are encapsulated.

Motility has not been detected in *Ancylobacter*, except in the case of one of the gas-vacuolated strains of *A. aquaticus* (Konopka et al., 1976). In this strain (strain M6), the cells possess single polar flagellum. The occurrence of flagella is best seen in cells cultivated at higher growth temperatures, i.e., above 20°C, a condition that precludes extensive gas vacuole formation. The strain forms numerous gas vacuoles when cultivated at 20°C, but flagella are rarely formed at this temperature.

The maximum temperature at which growth occurs is usually

37°C, although one strain can grow at 43°C. The minimum temperature for growth is 5°C.

Colonies of *Ancylobacter aquaticus* are nonpigmented to cream colored, circular, and convex, with an entire margin. In gas-vacuolated strains, the colonies appear in gradations from translucent (if few vacuoles are formed) to opaque, chalky white (if vacuoles are abundant).

Acid is produced from a variety of carbon sources when the medium of Hugh and Leifson (1953) is incubated aerobically (Raj, 1970; Van Ert and Staley, 1971; Larkin et al., 1977). All strains of *Ancylobacter aquaticus* form acid from arabinose, xylose, glucose, fructose, galactose, mannose, melibiose, sucrose, mannitol, sorbitol, and inulin. Gelatin is not liquefied. Starch is not hydrolyzed. Additionally, some of the strains, including the type strain, have been shown to produce acid oxidatively from glycerol and ribose, to reduce nitrate to nitrite and ammonia, to curdle and peptonize litmus milk by rendering it alkaline, and to possess catalase, β-galactosidase, lipase, ornithine decarboxylase, oxidase, and urease. However, they have been shown not to hydrolyze agar, chitin, casein, cellulose, or esculin, nor to produce indole, acetyl methyl carbinol, or H_2S (Raj, 1970; Larkin et al., 1977).

Strains of *Ancylobacter aquaticus* may be grown in a defined medium[1] containing an ammonium salt as a sole nitrogen source; individual carbon sources may be tested in this medium as sole carbon sources for growth. Lactate and pyruvate are used by all strains of *A. aquaticus* under these conditions. In addition, the type strain and some others utilize acetate, citrate, formate, gluconate, malonate, oxaloacetate, and succinate as sole carbon sources (Raj, 1977). Some strains of *A. aquaticus* are able to degrade chlorinated compounds, such as 1,2-dichloroethane (DCE), 2-chloroethanol, chloroacetate, and 2-chloropropionate, and use them as sole carbon and energy sources (van den Wijngaard et al., 1992). All strains of *A. aquaticus* tested so far have been found to be facultative methylotrophs capable of utilizing C_1 compounds, such as methanol and formate (Van Ert and Staley, 1971; Namsaraev, 1973; Larkin et al., 1977). The one strain (Z-238) that has been analyzed for its enzyme content has been found to have ribulose bisphosphate carboxylase activity when grown on methanol (Loginova et al., 1978). Due to induced dehydrogenases, methanol is oxidized sequentially to formaldehyde, formate, and finally carbon. Carbon dioxide is assimilated by ribulose bisphosphate carboxylase and used in the Calvin cycle. Autotrophic growth of several strains has been achieved with hydrogen (Namsaraev and Nozhevnikova, 1978; Málek and Schlegel, 1981). A recent report indicates that some strains can grow as facultative chemolithoautotrophs using thiosulfate as an energy source (Stubner et al., 1998).

The pathways of glucose dissimilation have been determined by the use of position-radiolabeled glucose and gluconate (Kottel and Raj, 1973; Raj, 1977). In *Ancylobacter aquaticus* the Entner–Doudoroff pathway is the primary pathway and the pentose phosphate and Embden–Meyerhof–Parnas pathways are of lesser importance. In addition, a tricarboxylic acid cycle is present as a secondary pathway, as indicated by studies using specifically labeled acetate, glutamate, and pyruvate. The glyoxylic acid cycle does not appear to be operative in this species. Activities of key enzymes from each of these pathways have been demonstrated by assays of cell extracts (Kottel and Raj, 1973).

Strains that have been tested grow well on nitrogen-free media (Nikitin, 1971; Málek and Schlegel, 1981). Attempts to demonstrate nitrogenase activity by the acetylene reduction method or by $^{15}N_2$ incorporation, however, have been unsuccessful (Málek and Schlegel, 1981).

The type strain of *Ancylobacter aquaticus* is sensitive to the following antibiotics (concentrations, μg/disk): ampicillin, 10; cephalothin, 30; chlortetracycline, 30; demeclocycline, 30; dihydrostreptomycin, 10; doxycycline, 30; erythromycin, 15; kanamycin, 30; neomycin, 30; nalidixic acid, 30; nitrofurantoin, 300; novobiocin, 30; oxytetracycline, 30; streptomycin, 5; tetracycline, 5 (Raj, 1970, 1977; Larkin et al., 1977).

Ancylobacter is not known to be pathogenic to humans.

Ancylobacter aquaticus occurs in freshwater habitats, including ponds, creeks, and lakes (Van Ert and Staley, 1971; Konopka et al., 1976), and in rice paddies and soil environments (Stubner et al., 1998). A number of strains have also been isolated from pulp mill oxidation lagoons (Konopka et al., 1976; Fulthorpe et al., 1993; Fulthorpe and Allen, 1995).

Enrichment and Isolation Procedures

The original strain of *Ancylobacter aquaticus* was isolated on a medium consisting of agar (2%) and water (Ørskov, 1928). Gas-vacuolated strains can be isolated from enrichment cultures prepared with 100 ml of a freshwater source, such as creek water, added to a sterile aluminum foil-covered beaker containing 10 mg Bacto peptone (Difco). The enrichments are incubated at room temperature for 2 weeks, and dilutions are plated onto a hydrolysate medium[2] containing glucose (Van Ert and Staley 1971). These plates are incubated at 30°C for 1 week and examined for the development of chalky white colonies, which are indicative of gas vacuolate strains. Cells from such colonies should be observed by phase-contrast and electron microscopy to confirm that curved rods with refractile areas typical of gas vacuoles are in fact present.

Maintenance Procedures

Strains of *Ancylobacter aquaticus* are normally cultured on glucose–Casamino acids medium or TGEY medium.[3] After incubation at 20–30°C to allow abundant growth, the cultures may be maintained in a refrigerator (5°C) for at least 3 weeks. They may also be preserved indefinitely by lyophilization.

Differentiation of the genus *Ancylobacter* from other genera

Table BXII.α.166 provides the primary characteristics that can be used to differentiate this genus from morphologically similar, aerobic, nonmotile, nonphotosynthetic bacteria of the genera *Flectobacillus*, *Spirosoma*, and *Runella*. Two other genera of gas-vacuolated curved rods that may be confused with *Ancylobacter* are *"Brachyarcus"* and *Meniscus*. *"Brachyarcus"*, which has never been isolated, differs from *Ancylobacter* in having cells arranged in groups (coenobia) consisting of two, four, or more rings (Skuja, 1964). *Meniscus* is differentiated from *Ancylobacter* by be-

1. Defined medium has the following composition (per liter of distilled water): $(NH_4)_2SO4$, 0.25 g; glucose, 0.25 g (or molar equivalent of other carbon source); Na_2HPO_4, 0.071 g; modified Hutner's salt solution, 20 ml; and vitamin solution, 10 ml. The salt solution is as described by Van Ert and Staley (1971), except that the amount of sodium molybdate is 12.67 mg. The vitamin solution is as described by Staley (1968).

2. Glucose–Casamino acids medium (per liter of distilled water): glucose, 1.0 g; Bacto Casamino acids (Difco), 1.0 g; modified Hutner's salt solution (see defined medium), 20 ml; vitamin solution (see defined medium), 10 ml; agar, 15.0 g.

3. TGEY medium is Bacto tryptone glucose extract agar (Difco) supplemented with 0.1% yeast extract (Raj, 1970).

TABLE BXII.α.166. Differentiation of *Ancylobacter* from morphologically similar heterotrophic genera

Property	*Ancylobacter*	*Spirosoma*	*Flectobacillus*	*Runella*

Bacteroidetes		+	+	+

ing an aerotolerant anaerobe, rather than an aerobe, and by having a mol% G + C of 45 (Irgens, 1977). Furthermore, it is noteworthy that certain phototrophic bacteria, such as those of the purple nonsulfur genus *Rhodocyclus*, are morphological counterparts of *A. aquaticus*; however, *Rhodocyclus* species belong to a separate class of the *Proteobacteria*.

Taxonomic Comments

Significant changes have occurred in the taxonomy of the genus *Ancylobacter*. In the previous edition of *Bergey's Manual of Systematic Bacteriology*, the former genus name *Microcyclus*, which is on the Approved List of names, was still in use. Based on morphological features, *Ancylobacter* was placed in Section 3 of the *Manual*, entitled "Nonmotile (or Rarely Motile), Gram-Negative Curved Bacteria", along with, but not included in, a family of bacteria called the *Spirosomaceae* (Larkin and Borrall, 1978). Genera placed in the family *Spirosomaceae* were *Spirosoma*, *Runella*, and *Flectobacillus*. Subsequent phylogenetic analyses based on 16S rRNA sequences have shown that all genera of the *Spirosomaceae* are members of the *Flavobacterium–Cytophaga–Bacteroides* group, whereas *Ancylobacter* are members of the *Alphaproteobacteria* (Woese et al., 1990). The genus *Ancylobacter* forms part of the *Blastochloris viridis* subgroup of the *Alphaproteobacteria*, with *Starkeya novella* (formerly *Thiobacillus novellus*) as its closest relative (see Fig. BXII.α.197). Bacteria related to *Ancylobacter*, including members of the genera *Starkeya*, *Xanthobacter*, and *Blastochloris* (formerly *Rhodopseudo-*

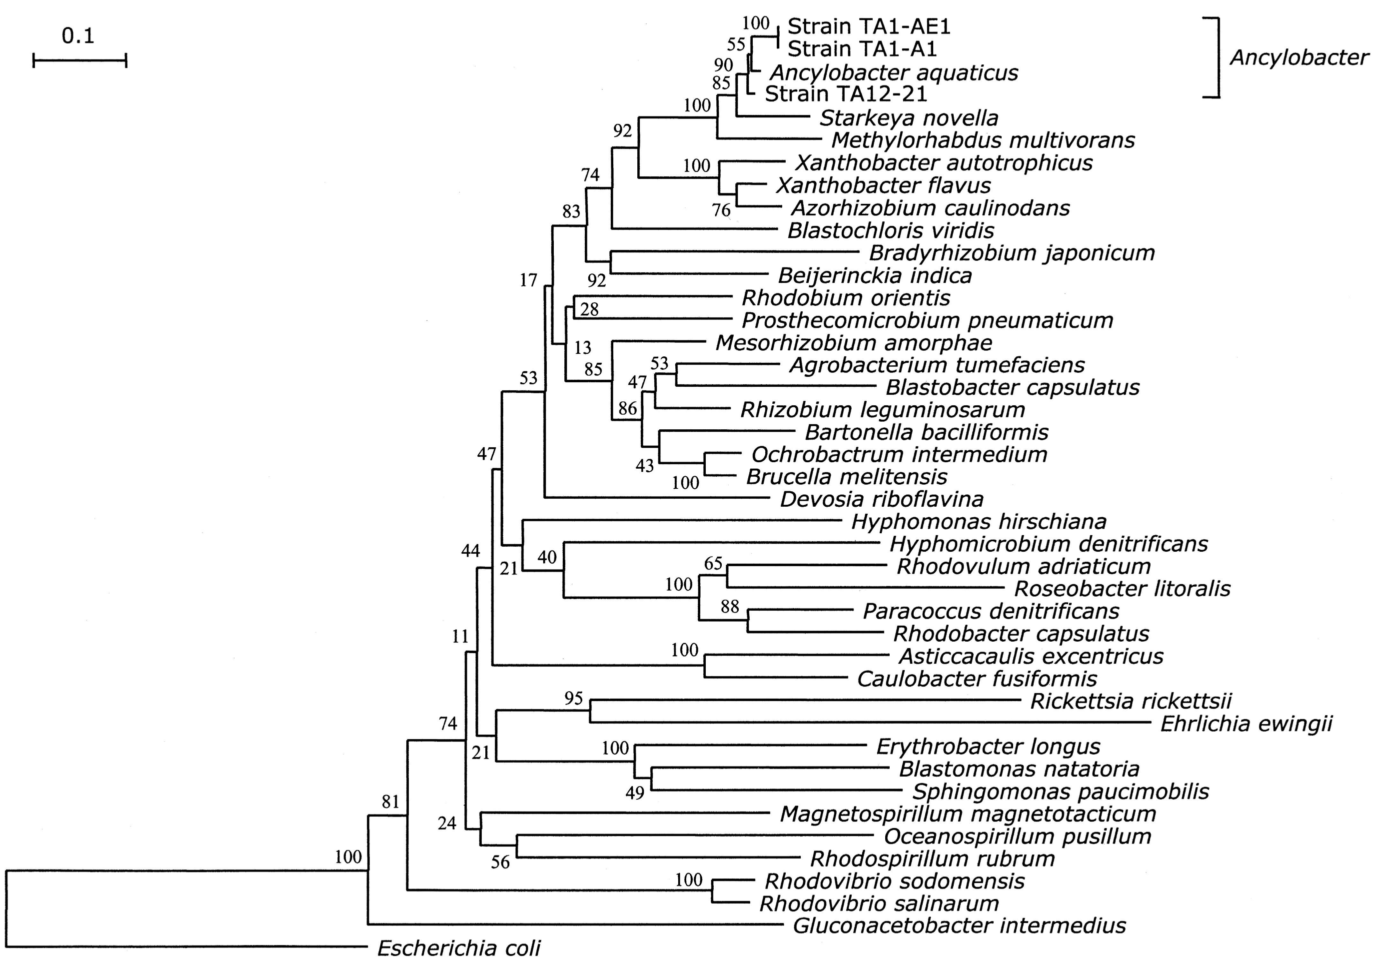

FIGURE BXII.α.197. Phylogenetic tree, based on 16S rRNA sequences, showing the position of *Ancylobacter* within the *Alphaproteobacteria*. Displayed in the tree are the type strain of *Ancylobacter aquaticus* and three additional strains, TA1-AE1, TA1-A1, and TA12-21, which were isolated from rice paddy soil. *Ancylobacter* forms part of the *Blastochloris viridis* subgroup of the *Alphaproteobacteria*, with the genera *Starkeya*, *Methylorhabdus*, and *Xanthobacter* as the closest relatives. The phylogenetic tree was constructed using Kimura distances, the neighbor-joining algorithm, and 100 bootstrap replicates within the program Treecon. The distance scale indicates 0.1 substitutions per site.

monas), are also physiologically similar to *Ancylobacter* in that they can grow autotrophically. In addition, *Xanthobacter* species and another close relative, *Methylorhabdus multivorans*, exhibit methylotrophy, another physiological feature shared with *Ancylobacter* strains.

DNA–DNA similarity studies of *A. aquaticus* strains B, H, M, M6, and W with the type strain show a much lower genetic relatedness (28–45%) than expected of strains of the same species, even though their mol% G + C values are very close (Konopka et al., 1976). These data indicate that the genus contains at least one other, as yet unnamed, species.

The finding that many strains of *Ancylobacter aquaticus* are facultative methylotrophs with a Calvin cycle and the report that several strains can grow as hydrogen autotrophs indicate these bacteria share some properties with methylotrophs and chemoautotrophic bacteria.

"Renobacter vacuolatum" Nikitin 1971, a new genus and species proposed for nonmotile, gas-vacuolated bacteria, is now regarded as a member of the genus *Ancylobacter* (Namsaraev, 1973; J. Larkin, personal communication).

The original strain described by Ørskov as the type strain of *A. aquaticus* has been lost (Ørskov, 1953). Subsequently, new strains have been isolated by Ørskov (1953), and Larkin and Borrall (1979) have proposed that one of these strains (ATCC 25396) be the neotype strain.

List of species of the genus Ancylobacter

1. **Ancylobacter aquaticus** (Ørskov 1928) Raj 1983, 297^{VP} (*Microcyclus aquaticus* Ørskov 1928, 128.)
   a.qua' ti.cus. L. adj. *aquaticus* living in water.

   The characteristics are as described for the genus. Occur in soil and freshwater.

   The mol% G + C of the DNA is: 66–69 (Bd).
   Type strain: Ørskov, ATCC 25396.
   GenBank accession number (16S rRNA): M62790.

Genus IV. **Angulomicrobium** *Vasilyeva, Lafitskaya and Namsaraev 1986, 354^{VP} (Effective publication: Vasilyeva, Lafitskaya and Namsaraev 1979, 1037)*

LEANA V. VASILYEVA

An' gu.lo.mi.cro' bi.um. M.L. fem. n. *angularis* angular; Gr. adj. *micros* small; Gr. masc. n. *bios* life; M.L.neut. n. *Angulomicrobium* angular microbe.

Unicellular bacterium, having polygonal cells with radial symmetry, ranging in dimensions from 1.1–1.5 µm. The shape of the cells is tetrahedral or mushroom-like. Flat, triangular bacteria are provisionally included within the genus.

Cells divide by budding. Buds are produced on the tetrahedron directly on the conical point of elongation of the mother cell, with a shot tube connecting two cells. **Gram negative. Nonmotile**. Cells lack prosthecae, lamellated membranous structures, and gas vacuoles.

Obligately aerobic, nonfermentative, **chemoorganotrophic**. A variety of organic acids, monosaccharides, and amino acids are utilized. Methanol and formate can serve as energy sources only in the presence of yeast extract. Methane and hydrogen are not utilized. **Catalase and oxidase positive**. Monotypic.

The mol% G + C of the DNA is: 64.3–68.

Type species: **Angulomicrobium tetraedrale** Vasilyeva, Lafitskaya and Namsaraev 1986, 354 (Effective publication: Vasilyeva, Lafitskaya and Namsaraev 1979, 1037.)

FURTHER DESCRIPTIVE INFORMATION

Budding bacteria that resemble a "mushroom" during some stages of the growth cycle have been isolated from aquatic environments (Whittenbury and Nicoll, 1971; Namsaraev and Zavarzin, 1972; Lafitskaya and Vasilyeva, 1976; Stanley et al., 1976). Slide cultures indicate that the bacteria reproduce by a budding process. Newly divided organisms are rounded on one side, while the area where cell separation occurs appears conical. This conical section elongates to form a tube, and at this stage, the cell outline resembles a mushroom. The growing tube then enlarges. Just before cell division, the mother and daughter cells are of equal size. The region between the mother and daughter cells constricts, and the two cells separate. Both mother and daughter cells synchronously produce lateral buds at the point of separation (see Fig. BXII.α.198).

The same cycle is observed for the flat, triangular bacteria. After separation, growth begins by elongation of the apex of the triangle at the point of division, and new buds are formed synchronously by the mother and daughter cells (Vasilyeva et al., 1979).

The cell wall structure is typical of Gram-negative bacteria, but the flat triangular form, in contrast to the form of the type strains, has no visible rigid layer in its cell wall. No membranous structures are observed, except for the small loops of membranes close to the cell wall (Fig. BXII.α.199).

All strains are capable of growth in the mineral medium with glucose or a variety of other carbohydrates as sole sources of energy and organic carbon. None of the strains grow anaerobically, with or without nitrate or sulfate. Sugars are used via the hexose–monophosphate and Entner–Doudoroff pathways.

Strain Z-2821 can grow with methanol or formate as a sole energy source, but in this case a limited amount of yeast extract should be added (Namsaraev and Zavarzin, 1974). Acetate enhances methylotrophic growth. Hydrolytic activity is absent (Lafitskaya and Vasilyeva, 1976).

DNA hybridization reassociation shows no relation of the mushroom-shaped bacteria to *Hyphomicrobium*, *Rhodopseudomonas*, *Ancalomicrobium*, or *Prosthecomicrobium* (Stanley et al., 1976).

The flat, triangular strain 1109 differs from the type strains and might be representative of another taxon. In particular, the shape of its flat cells suggests it may be closer to the prosthecobacteria *Stella* and *Labrys*. However, no further work has been done, and it is premature to establish a new species until additional isolates have been characterized.

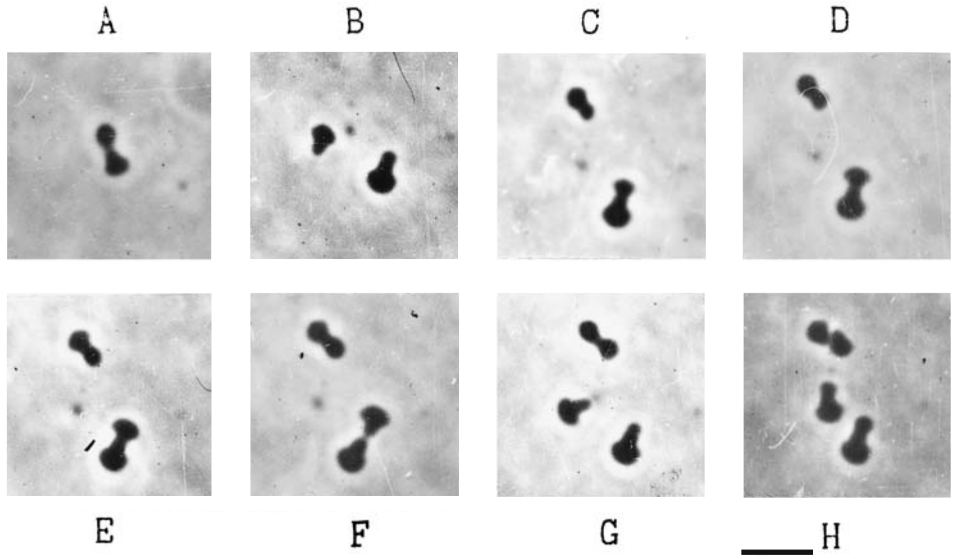

FIGURE BXII.α.198. *A. tetraedrale.* Sequential series of phase photomicrographs illustrating the growth cycle of the type strain. Time in hours: *A*, 0; *B*, 0.5; *C*, 1; *D*, 2; *E*, 2.5; *F*, 3.5; *G*, 4; and *H*, 4.5. Bar = 5 μm. (Reproduced with permission from L.V. Vasilyeva et al., Microbiologiya *48:* 1033–1039, 1979.)

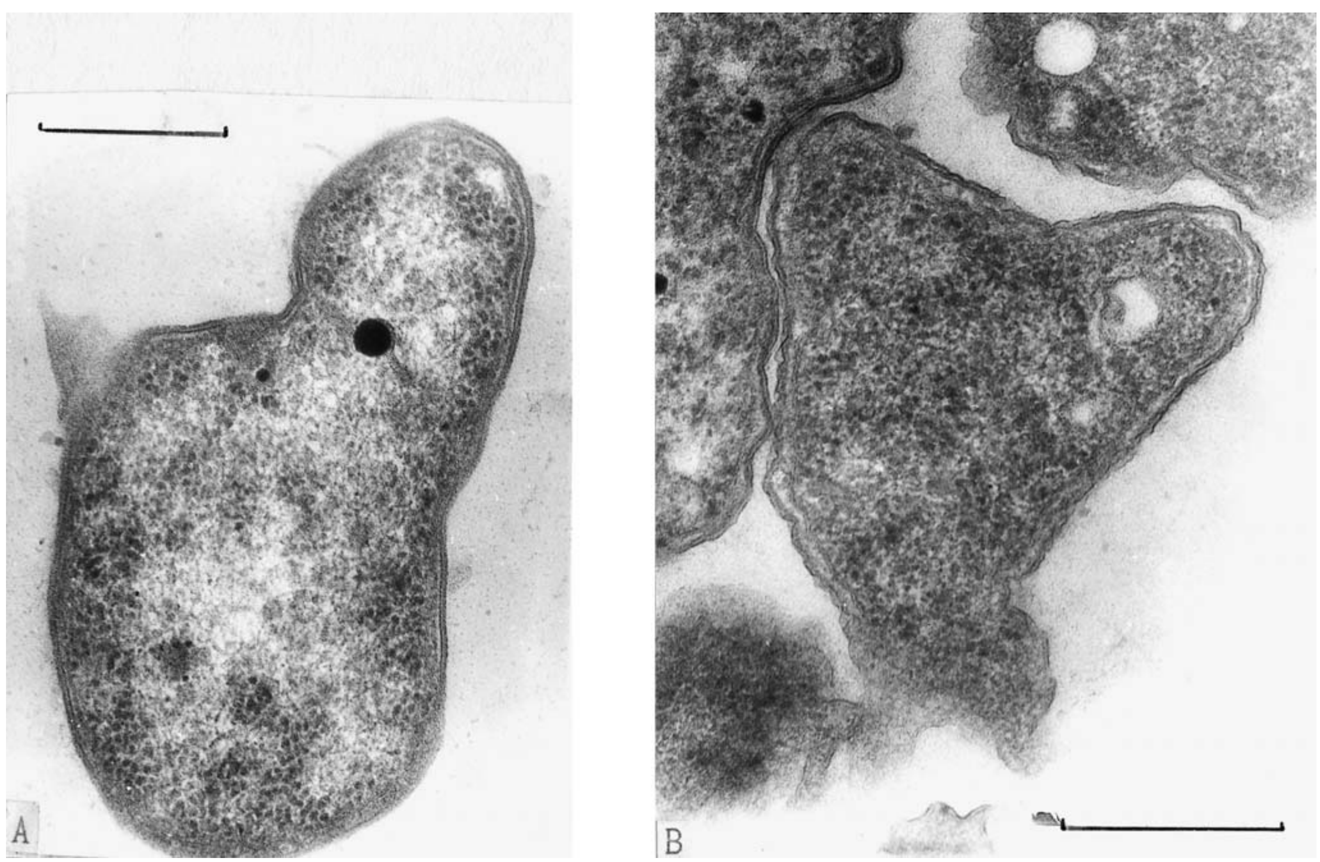

FIGURE BXII.α.199. Thin section of *Angulomicrobium*. *A*, type strain AUCM B-1335. Bar = 0.5 μm. *B*, flat triangular AUCM B-1336. Bar = 0.5 μm.

Enrichment and Isolation Procedures

No selective procedure for enrichment is known. Strains have been isolated as colonies on a mineral base medium supplemented by low concentrations of organic substances, e.g., glucose. Numerous colonies are examined in wet mounts by phase-contrast microscopy, and those containing cells with unusual morphology isolated. The type strain was isolated as a satellite in a methane-oxidizing community from a swamp (Namsaraev and Zavarzin, 1972). Another strain has been isolated from freshwater (Whittenbury and Nicoll, 1971). A pulp mill aeration lagoon has been found to contain up to 10^6 cells/ml (Stanley et

al., 1976). The flat triangle was isolated from a peat bog in the Moscow River valley (Lafitskaya and Vasilyeva, 1976).

Maintenance Procedures

Strains can be maintained on slants in the refrigerator for at least 6 months. Potato infusion agar and mineral base medium (e.g., MMB agar, see *Ancalomicrobium*), with glucose or other sugars, are favorable growth media. Lyophilization can be used for long term preservation.

Differentiation of the genus *Angulomicrobium* from other genera

Angulomicrobium is differentiated from other genera of budding bacteria by its characteristic morphology. It differs from *Labrys* by the absence of prosthecae, and it differs from *Nitrobacter* and similar budding bacteria by the absence of lamellated membranous structures. The flat, triangular strain 1109 might be compared with the flat, dividing bacteria with radial symmetry of the genus *Stella*.

Taxonomic Comments

Angulomicrobium represents a distinct morphological type in the oligocarbophilic "microflora of dispersal" (Zavarzin, 1970), or among the dissipotrophic microorganisms, as it is called now (Vasilyeva and Zavarzin, 1995). It utilizes either carbohydrates in low concentrations or methanol produced by incomplete oxidation of methane in methane-utilizing communities. Substrate utilization is similar for all strains, except the flat, triangular strain. It is not related to other genera of budding bacteria by DNA–DNA similarity studies. On the basis of DNA base composition (mol% G + C of the DNA = 68) the strains of *Angulomicrobium* cannot be closely related to other budding bacteria, such as *Gemmiger formicilis* (mol% G + C of the DNA = 59), *Nitrobacter* (mol% G + C of the DNA = 61–62), or *Hyphomicrobium* (mol% G + C of the DNA = 59–61); they are close to *Rhodopseudomonas palustris* (mol% G + C of the DNA = 65–66), but do not possess intracytoplasmic membranous structures (Stanley et al., 1976). DNA–DNA homology studies indicate a relatedness among all four strains of *Angulomicrobium* in the range of 40–85% (Stanley et al., 1976).

Sequencing 16S rRNA studies indicate that *Angulomicrobium tetraedrale* (strain WAL-4, Stanley et al., 1976) belongs to the *Alphaproteobacteria* and is most closely related to *Rhodopseudomonas acidophila* (now *Rhodoblastus acidophilus* and *R. palustris* (Vasilyeva, 1989).

List of species of the genus Angulomicrobium

1. **Angulomicrobium tetraedrale** Vasilyeva, Lafitskaya and Namsaraev 1986, 354[VP] (Effective publication: Vasilyeva, Lafitskaya and Namsaraev 1979, 1037.)
tet' ra.ed' ra.le. Gr. pref. *tetra-* four; Gr. n. *edra* seat, face; Gr. adj. *tetraedralis* tetrahedral.

Unicellular, budding bacterium. The cells have radial symmetry; cells of the type strain have a tetrahedral form, 1.1–1.5 μm (Fig. BXII.α.200); cells of other strains (1109) have a flat form, 0.95–1.2 μm (Fig. BXII.α.201). Single or in pairs. Gram negative. Nonmotile.

Multiplication is by budding from the top of the tetrahedron (Fig.BXII.α.198) or from the top of the triangle. Mother and daughter cells are similar in form and size. Ultrastructure typical of Gram-negative bacteria, with no complex membranous system (Fig. BXII.α.199).

Colonies are white, round, and mucous with a pearly shine.

Chemoorganotroph. Carbohydrates, amino acids, organic acids, and alcohols are utilized as sole sources of carbon and energy. All strains utilize arabinose, glucose, L-histidine, L-proline, acetate, and mannitol. Some strains utilize mannose, ribose, xylose, propionate, citrate, ethanol, methanol, and methylamine; no strains utilize lactose, raffinose, pectin, glycogen, gelatin, L-tryptophan, L-arginine, L-leucine, DL-methionine, or Tween-80.

Only the flat strain 1109 utilizes sucrose, cellobiose, and melibiose, but this strain does not utilize methanol, organic acids, or glycerol. Organic acids are not produced from carbohydrates.

Sugars are used via the hexose–monophosphate and Entner–Doudoroff pathways. Type strain has enzymes of the Embden–Meyerhof pathway (Lafitskaya and Vasilyeva, 1976).

Aerobic. Catalase and oxidase positive.

Organic growth factors are not required, but they stimulate growth. Strain 1109 requires yeast extract.

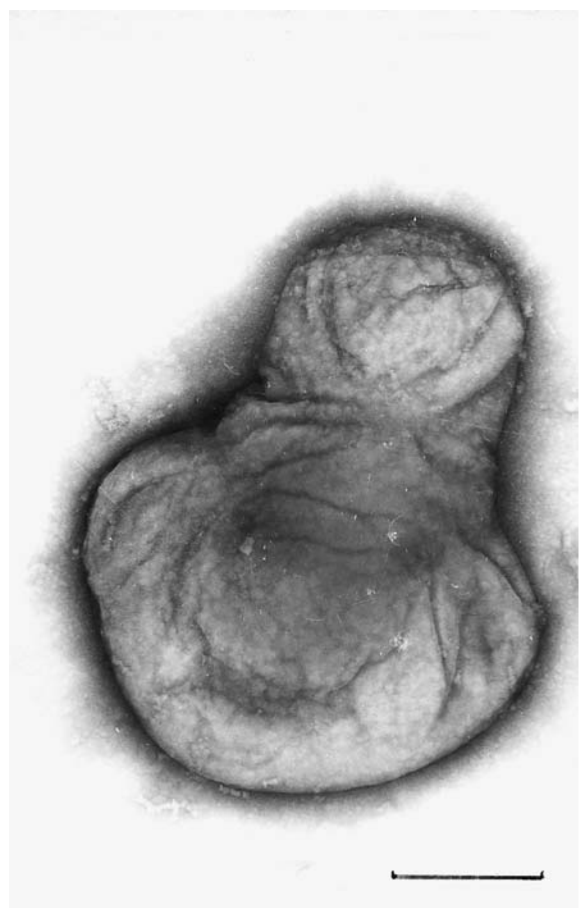

FIGURE BXII.α.200. Cell of type strain AUCM B-1335 with phosphotungstic acid. Bar = 0.5 μm. (Reproduced with permission from E.N. Michustin, Izvestiya Akademii Nauk S.S.S.R., Seriya Biologicheskaya *5:* 719–737, 1980.)

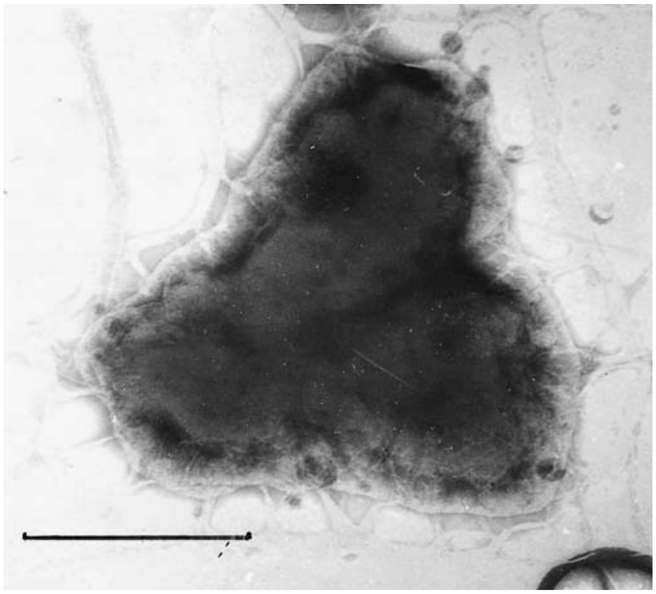

FIGURE BXII.α.201. Cell strain AUCM B-1336 with phosphotungstic acid. Bar = 0.5 μm. (Reproduced with permission from E.N. Michustin, Izvestiya Akademii Nauk S.S.S.R., Seriya Biologicheskaya *5:* 719–737, 1980.)

Temperature range: 15–35°C; optimal temperature: 28–30°C. Optimal pH for growth: near neutrality (6.8–7.0).

Sensitivity towards antibiotics (μg/ml) for type strain and 1109: penicillin G, 30 and 100, respectively; chloramphenicol, 100 and 0.5; erythromycin, 10 and 30; actinomycin D, 5.0 and 8.0; and polymyxin M, 50 and 10.

Habitat: type strain isolated from a swamp near Moscow. Other related strains isolated from a freshwater and pulp mill aeration lagoon.

The mol% G + C of the DNA is: 64.5 (T_m, type strain) (68.2 according to Stanley et al., 1976); 64.3 (strain 1109).

Type strain: Strain Z-2821, AUCM B-1335, DSM 5895.

GenBank accession number (16S rRNA): AS535708.

Genus V. **Aquabacter** *Irgens, Kersters, Segers, Gillis and Staley 1993, 864[VP] (Effective publication: Irgens, Kersters, Segers, Gillis and Staley 1991, 141)*

JAMES T. STALEY

Aq' ua.bac.ter. L. n. *aqua* water; Gr. neut. n. *bacter* masc. form of Gr. neut. n. *bacterion* a rod; N.L. masc. n. *Aquabacter* aquatic rod.

Rod-shaped cells, 0.5–1.0 × 1.5–3.0 μm. **Unicellular.** Encapsulated. **Motile by flagella, but only under certain conditions.** No resting stages known. **Gram negative.**

Aerobic. Chemoheterotrophic. Organic acids including some amino acids used aerobically as carbon source. Sugars not known to be used. Growth occurs on mineral medium with acetate, succinate, or pyruvate as sole carbon source and inorganic ammonium compounds as sole nitrogen source, along with B-vitamins. Oxidase and catalase positive. Type strain, which is gas vacuolate, was isolated from Spirit Lake, Washington following the eruption of Mt. St. Helens in 1980.

The mol% G + C of the DNA is: 67.

Type species: **Aquabacter spiritensis** Irgens, Kersters, Segers, Gillis and Staley 1993, 864 (Effective publication: Irgens, Kersters, Segers, Gillis and Staley 1991, 141.)

FURTHER DESCRIPTIVE INFORMATION

The 16S rDNA sequence has not yet been determined for the type species.

This monospecific genus belongs to the *Alphaproteobacteria* based on DNA–rRNA hybridization (Irgens et al., 1991). Within that group, it is most closely related to *Azorhizobium* and *Xanthobacter*, but it differs phenotypically and phylogenetically from these two genera (Table BXII.α.167).

Aquabacter spiritensis is not motile when grown in typical broth media. However, flagellation occurs when cells are grown on a semisolid medium as described by Lara and Konopka (1987).

Gas vacuoles are produced by the type strain when grown on typical broth or solid media.

The type strain uses a limited number of carbon sources. Some organic acids such as lactate, pyruvate, acetate, malate, succinate, propionate, and butyrate, as well as L-glutamate and L-alanine, are used as carbon sources in complex media. However, none of the sugars or alcohols that have been tested (D-glucose, D-fructose, DL-arabinose, rhamnose, sucrose, maltose, lactose, mannitol, sorbitol, glycerol, ethanol) are used as carbon sources for growth.

ENRICHMENT AND ISOLATION PROCEDURES

The sole strain of this genus was isolated from Spirit Lake, Washington, following the eruption of Mt. St. Helens volcano in 1980. A sample collected at 5.0 m depth in the lake on 10 April 1981, a little more than a year after the eruption, was diluted to 10^{-4} and plated out on dilute peptone agar containing (per liter): Bacto Peptone, 100 mg; Hutner's salts solution (see *Ancalomicrobium*, this volume), 20 ml; agar, 15 g. After prolonged incubation at room temperature, only one colony had the chalky white appearance typical of gas vacuolate bacteria.

MAINTENANCE PROCEDURES

The organism can be maintained by lyophilization.

DIFFERENTIATION OF THE GENUS *AQUABACTER* FROM OTHER GENERA

Table BXII.α.167 shows the differences between *Aquabacter*, *Xanthobacter*, and *Azorhizobium*. *Aquabacter spiritensis* does not use the typical carbon sources used by *Azorhizobium* and *Xanthobacter* spp. In addition, although all three genera resemble one another in morphology, the type strain and species of *Aquabacter* is gas vacuolate.

TABLE BXII.α.167. Differentiation of the genera *Aquabacter, Azorhizobium,* and *Xanthobacter*

Characteristics	*Aquabacter*	*Azorhizobium*	*Xanthobacter*
Motility	+[a]	+	D
Colony color	chalky white	cream	yellow
Gas vacuole formation	+[b]	−	−
Utilization of:			
Glucose	−	+	3/16[c]
DL-Proline	−	19/20[c]	3/16[c]
Methanol, ethanol	−	−	15/16[c]
Gluconate	−	+	12/16[c]
L-Lysine	−	+	−

[a]Motility is not ordinarily observed (see text).

[b]Only one strain has been described, and it is gas vacuolate.

[c]Fractions indicate the number of positive strains of the total number of strains tested.

List of species of the genus Aquabacter

1. **Aquabacter spiritensis** Irgens, Kersters, Segers, Gillis and Staley 1993, 864[VP] (Effective publication: Irgens, Kersters, Segers, Gillis and Staley 1991, 141.)
spi.ri.ten′sis. N.L. adj. *spiritensis* named after Spirit Lake, Washington, USA, from which the strain was isolated.

Gas vacuolate, nonflagellated rods. Typically nonmotile, however, flagella are produced under special conditions.

Obligately aerobic. Growth occurs at 25–37°C, but not at 20 or 40°C. Nitrate is reduced to nitrite. Nitrogen is not fixed. B-vitamins are required for growth on defined media. The following carbon sources are utilized: acetate, succinate, pyruvate, lactate, propionate, butyrate, L-glutamate, and L-alanine.

Colonies are circular, slightly convex in elevation, with an entire margin and smooth, glistening surface. Colonies may appear translucent or chalky white if cells are gas vacuolate. Growth on older slant cultures has a rubbery texture.

The type strain was isolated from Spirit Lake, WA USA.

The mol% G + C of the DNA is: 67 (T_m).

Type strain: SPL-1, ATCC 43981, DSM 9035, LMG 8611.

Genus VI. **Azorhizobium** *Dreyfus, Garcia and Gillis 1988, 89[VP]*

L. David Kuykendall

A.zo.rhi.zo′bi.um. Fr. n. *azote* nitrogen; M.L. neut. n. *Rhizobium* a bacterial generic name; M.L. neut. n. *Azorhizobium* a nitrogen (using) rhizobium.

Rods 0.5–0.6 × 1.5–2.5 µm. Motile by one polar or subpolar flagellum. **Nonsporeforming. Gram negative. Peritrichous flagella are formed on solid media, and a single lateral flagellum is formed in broth.** Growth temperature, 12–43°C. Broad optimum pH, 5.5–7.8. Colonies are circular and creamy. Urease negative. **Oxidase and catalase positive. Do not denitrify. Of sugars, only glucose is oxidized.** The organic acids lactic acid and succinic acid are preferred substrates for growth, both under and not under nitrogen-fixing conditions. Growth on malonate and DL-proline. Starch is not hydrolyzed. Nitrogen-fixing root- and stem-nodulating microsymbiont of *Sesbania rostrata.* Readily **fixes nitrogen *ex planta* under microaerobic conditions and with nicotinic acid provided**. Can grow on nitrogen-free medium, unlike all other legume microsymbionts, of the genera *Bradyrhizobium, Rhizobium,* and *Mesorhizobium,* which lie in distinct families.

The mol% G + C of the DNA is: 66–68.

Type species: **Azorhizobium caulinodans** Dreyfus, Garcia, and Gillis 1988, 89.

Further descriptive information

Nitrogen-fixing stem nodules are formed on *Sesbania rostrata* by *Azorhizobium caulinodans* ORS 571[T] (Fig. BXII.α.202). *Azorhizobium* Nod factors, responsible for the induction of nodule organogenesis, have been characterized by Mergaert et al., 1993. The nodulation genes, *nod,* have been studied by Goethals et al., (1989, 1990, 1992a, b), and by Geelen et al., (1993). A small rod-shaped cell of *Azorhizobium caulinodans* ORS 571[T] with a single lateral flagellum is depicted in Fig. BXII.α.203.

Enrichment and Isolation Procedures

Azorhizobia are readily isolated from stem nodules on *Sesbania rostrata,* using the same procedures described for the isolation of *Bradyrhizobium* from soybean.

Maintenance Procedures

Azorhizobium will grow on a chemically defined minimal medium without added nitrogen. LO medium was defined by Dreyfus et al., (1983). Storage recommendations are the same as given for *Rhizobium.*

Procedures for Testing Special Characters

For verification of *Sesbania* nodulation, plant seeds are both scarified and surface-sterilized by immersion in concentrated H_2SO_4 for 15–30 min, then washed several times with sterile water and germinated on semisolid agar. Seedlings are placed in 25 × 150-mm plugged culture tubes on agar slopes of Jensen seedling agar (Vincent, 1970).

Differentiation of the genus *Azorhizobium* from other genera

Growth on a nitrogen-free medium (Dreyfus et al., 1988) clearly distinguishes *Azorhizobium* from the other, not very closely related, legume-nodulating bacteria *Bradyrhizobium, Mesorhizobium,* and *Rhizobium. Azorhizobium* is distinguished from close relatives like *Xanthobacter, Aquabacter,* and other members of the *Hyphomicrobiaceae* by the inability of these species to form nitrogen-fixing nodules on *Sesbania.*

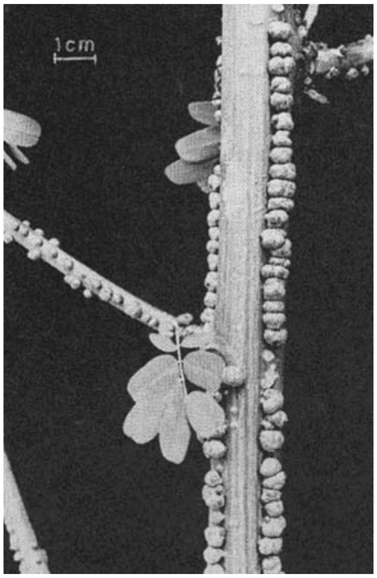

FIGURE BXII.α.202. Stem nodules formed by *Azorhizobium caulinodans* ORS 1^{T} on *Sesbania rostrata* (Reproduced with permission from B. Dreyfus et al., International Journal of Systematic Bacteriology *38:* 89–98, 1988, ©International Union of Microbiological Societies.)

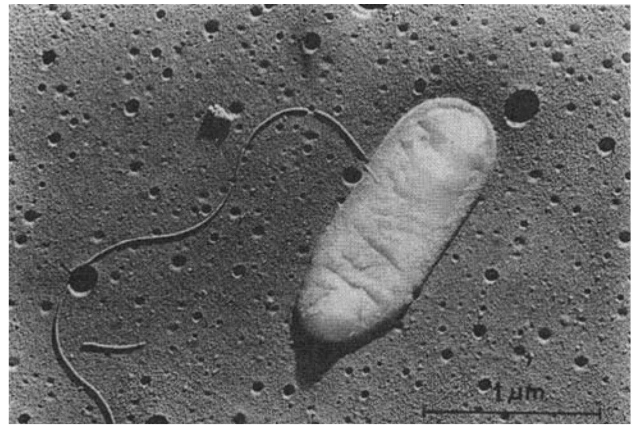

FIGURE BXII.α.203. A single lateral flagellum attached to a cell of *Azorhizobium caulinodans* ORS 1^{T}, as shown by negative staining and electron micrography of a diluted broth culture (Reproduced with permission from B. Dreyfus et al., International Journal of Systematic Bacteriology *38:* 89–98, 1988, ©International Union of Microbiological Societies.)

Taxonomic Comments

At the time of the first edition of *Bergey's Manual of Systematic Bacteriology*, the bacteria that form stem nodules on *Sesbania rostrata* had not yet been named, *Bradyrhizobium* was still within the family *Rhizobiaceae*, and the only three *Rhizobium* species were *R. leguminosarum*, *R. meliloti*, and *R. loti*. *R. loti* is now in the separate genus *Mesorhizobium*. Since the microsymbionts of *Sesbania rostrata* (Dreyfus et al., 1983) are distinctly different from *Bradyrhizobium* and *Rhizobium*, both genotypically and phenotypically, Dreyfus et al. (1988) placed them in a new genus. FAME and 16S rRNA analysis have been used to confirm the clear separation of *Azorhizobium* from both *Bradyrhizobium* and *Rhizobium* (So et al., 1994). Van Rossum et al. (1995) have also reconfirmed their distinct lineages. Because of their significant phylogenetic dissimilarity with the *Rhizobiaceae* and with the *Bradyrhizobiaceae*, it is appropriate that these organisms be in a distinct family, *Hyphomicrobiaceae*, based on 16S rRNA similarity.

Only one species of *Azorhizobium* is presently recognized. *Azorhizobium* has 98% 16S rDNA similarity with, and is thus very closely related to, *Xanthobacter* (Rainey and Wiegel, 1996) and these genera will probably be amalgamated, as might *Aquabacter*, since the latter shares approximately 97% 16S rDNA similarity with both *Azorhizobium* and *Xanthobacter*.

Acknowledgments

The author is indebted to Dr. B. Dreyfus for permission to reprint the photographs.

List of species of the genus Azorhizobium

1. **Azorhizobium caulinodans** Dreyfus, Garcia, and Gillis 1988, 89.

cau.li' no.dans. M.L. n. *caulis* stem; M.L. v. *nodare* to nodulate; M.L. part. adj. *caulinodans* stem-nodulating.

The characteristics are as described for the genus. Strains effectively nodulate the roots and stems of *Sesbania rostrata*. Grow with 8% potassium nitrate present. Possess arginine and lysine decarboxylase. Do not utilize D-mannitol. Grow on azelate, maleate, adipate, pimelate, suberate, gluconate, mucate, crotonate, nicotinate, 2-ketogluconate, propionate, butyrate, isobutyrate, valerate, isovalerate, caproate, laurate, 2-ketoglutarate, fumarate, glutarate, sebacate, DL-malate, citrate, pyruvate, aconitate, citraconitate, D-glucuronate, α-D-galacturonae, *m*-hydroxybenzoate, L-aspartate, quinate, L-α-alanine, L-lysine, L-asparagine, betaine, and sarcosine. Nicotinic acid must be supplied as a vitamin supplement for growth under nitrogen-limiting conditions.

The mol% G + C of the DNA is: 66–68 (T_m).

Type strain: ORS 571, LMG 6465.

GenBank accession number (16S rRNA): D13948, D11342, X67221, X94200.

Genus VII. **Blastochloris** *Hiraishi 1997, 218*^{VP}

Johannes F. Imhoff

Blas.to.chlo' ris. Gr. n. *blastos* bud shoot; Gr. adj. *chloros* green; M.L. fem. n. *Blastochloris* green bud shoot.

Cells are rod shaped to ovoid and motile by means of subpolar flagella. They exhibit polar growth, budding, and asymmetric cell division and form rosette-like cell aggregates. They are **Gram negative and belong to the *Alphaproteobacteria*.** Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. Photosynthetic pigments are **bacteriochlorophyll *b* and carotenoids**. **Straight-chain monounsaturated $C_{18:1}$ is the predominant component of cellular fatty acids. Ubiquinones and menaquinones are present,** and the lipopolysaccharides are characterized by a 2,3-diamino-2,3-deoxy-D-glucose (DAG)-containing, phosphate-free lipid A with amide-bound $C_{14:0\ 3OH}$.

Preferred growth mode is photoheterotrophically under anoxic conditions in the light. **Photoautotrophic growth may be**

possible under anoxic conditions with thiosulfate or sulfide as electron donor. **Chemotrophic growth is possible** under microoxic conditions in the dark. Growth factors may be required.

Mesophilic freshwater bacteria with a preference for neutral pH.

The mol% G + C of the DNA is: 66.3–71.4.

Type species: **Blastochloris viridis** (Drews and Giesbrecht 1966) Hiraishi 1997, 218 (*Rhodopseudomonas viridis* Drews and Giesbrecht 1966, 261.)

Further descriptive information

The cell morphology of the *Blastochloris* species is characterized by asymmetric growth and cell division. Most characteristic is the formation of prosthecae and rosette-like cell aggregates as in *Rhodopseudomonas* species.

Blastochloris sulfoviridis is unable to assimilate sulfate and depends on reduced sulfur compounds (Neutzling and Trüper, 1982), whereas *Blastochloris viridis* can grow with sulfate as the sole sulfur source and assimilates sulfate via the 3′-phosphoadenosine-5′-phosphosulfate pathway (Imhoff, 1982). Reduced sulfur compounds, sulfide, and thiosulfate are used as photosynthetic electron donors by *B. sulfoviridis*, but not *B. viridis*, and oxidized to sulfate (Keppen and Gorlenko, 1975). The lipid A structure of the lipopolysaccharide of *Blastochloris viridis* and *Blastochloris sulfoviridis* (Ahamed et al., 1982; Weckesser et al., 1995) contains the unusual 2,3-diamino-2,3-deoxy-D-glucose instead of glucosamine. This sugar has also been found in other species of the *Alphaproteobacteria* such as *Rhodopseudomonas palustris* and *Nitrobacter winogradskyi*, but not *Rhodomicrobium vannielii* and *Rhodoblastus acidophilus* (Weckesser et al., 1995).

Enrichment and Isolation Procedures

Standard procedures for the isolation of purple nonsulfur bacteria (PNSB) can be applied. A mineral salts medium, which is suitable for most PNSB, is also applicable for the cultivation of *Blastochloris* species (Imhoff, 1988; Imhoff and Trüper, 1992; see chapter Genus *Rhodospirillum* for this medium recipe). *B. viridis* and *B. sulfoviridis* can be selectively enriched with appropriate light filters, that allow only long wavelength radiation to penetrate, since both species, owing to their content of bacteriochlorophyll *b*, show absorption maxima above 1000 nm. The dependence on reduced sulfur compounds demands the addition of low concentrations of sulfide or cysteine into media for *B. sulfoviridis*.

Maintenance Procedures

Cultures of *Blastochloris* species can be preserved in liquid nitrogen or at −80°C in a mechanical freezer.

Differentiation of the genus *Blastochloris* from other genera

16S rDNA sequence analysis places the genus in the *Alphaproteobacteria*. *Rhodoplanes* species are the closest relatives among phototrophic bacteria. *Blastochloris* species may well be differentiated from other PNSB based on morphological and cultural characteristics. Their green to olive-green coloration, together with the characteristic long wavelength absorption maximum above 1000 nm, which is due to bacteriochlorophyll *b*, clearly separates *Blastochloris* species from other phototrophic *Alphaproteobacteria*. The rod-shaped cells, their asymmetric mode of growth and cell division, the formation of rosette-like aggregates, the lamellar structure of internal photosynthetic membranes lying parallel to and underlying the cytoplasmic membrane, as well as a number of chemotaxonomic characteristics and the sequences of 16S rDNA, differentiate *Blastochloris* species from other genera of the purple nonsulfur bacteria (see Tables 3 and 4 [pp. 125–127] as well as Fig. 2 [p. 128] of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria" in Volume 2, Part A).

Taxonomic Comments

Both species of this genus have been previously assigned to the genus *Rhodopseudomonas*, because of significant similarities in cell morphology and cell division to *Rhodopseudomonas palustris*. Significant differences in 16S rDNA sequences with respect to other PNSB have given reason to reconsider the taxonomic position of these bacteria and reevaluate phenotypic differences from the type species of *Rhodopseudomonas*, leading to their reassignment to the new genus *Blastochloris* as *Blastochloris viridis* and *Blastochloris sulfoviridis* (Kawasaki et al., 1993b; Hiraishi, 1997).

Differentiation of the species of the genus *Blastochloris*

Major differentiating properties between *Blastochloris* species and between *Blastochloris*, *Rhodomicrobium vannielii*, and *Rhodoplanes* species are shown in Tables BXII.α.168 and BXII.α.169.

List of species of the genus Blastochloris

1. **Blastochloris viridis** (Drews and Giesbrecht 1966) Hiraishi 1997, 218[VP] (*Rhodopseudomonas viridis* Drews and Giesbrecht 1966, 261.)

vi′ri.dis. L. adj. *viridis* green.

Cells are rod-shaped to ovoid, 0.6–0.9 × 1.2–2.0 μm. The mother cell produces a slender prostheca, 1.5–2.0 times the length of the original cell, at the pole opposite that bearing the flagella. The end of the prostheca swells, and the daughter cell grows, producing a dumbbell-shaped organism, just like *Rhodopseudomonas palustris* (see Fig. BXII.α.187 in the chapter describing the species *Rhodopseudomonas palustris*). Asymmetric division then takes place. In young cultures, swarmer cells motile by means of subpolar flagella are frequent. The formation of rosettes and clusters in which the individual cells are attached to each other at their flagellated poles are characteristic in older cultures. Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. The color of photosynthetic cultures is first yellowish green, then green to olive green. Aerobic cultures are colorless to light yellowish green. *In vivo* absorption spectra show characteristic maxima at 400, 420, 451, 483, 604, 835, and 1020 nm. Photosynthetic pigments are bacteriochlorophyll *b* (esterified with phytol), with 1,2-dihydroneurosporene and 1,2-dihydrolycopene as major carotenoids.

Cells grow photoheterotrophically under anoxic conditions with organic carbon sources. Photoautotrophic growth has not been demonstrated. Chemotrophic growth is possible under microoxic conditions in the dark. Carbon sources used are acetate, pyruvate, malate, and succinate. Poor growth occurs in the presence of ethanol, glutamate, peptone, glucose, and xylose. Longer chain fatty acids in-

hibit growth. Sulfide, thiosulfate, and hydrogen cannot be used as electron donors. Sulfate can be used as the sole sulfur source. Ammonia and dinitrogen are used as nitrogen sources; nitrate is not used. Most strains require biotin and *p*-aminobenzoate as growth factors; some strains require more growth factors and others none.

Mesophilic freshwater bacterium with optimal growth at 25–30°C and pH 6.5–7.0.

Ubiquinones and menaquinones with 9 isoprene (Q-9 and MK-9) units are present.

The mol% G + C of the DNA is: 66.3–71.4 (Bd).

Type strain: F, ATCC 19567, DSM 133.

GenBank accession number (16S rRNA): D25314.

2. **Blastochloris sulfoviridis** (Keppen and Gorlenko 1975) Hiraishi 1997, 218[VP] (*Rhodopseudomonas sulfoviridis* Keppen and Gorlenko 1975, 258.)

sul.fo.vi′ ri.dis. L. n. *sulfur* sulfur; L. adj. *viridis* green; M.L. adj. *sulfoviridis* green and with sulfur.

Cells are rod-shaped to ovoid and form sessile buds and rosettes. Swarmer cells are motile by means of subpolar flagella. If cells age, they become immotile and encapsulated by slime. Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. Color of cell suspensions is olive-green, sometimes with a brownish tinge. Photosynthetic pigments are bacteriochlorophyll *b* and carotenoids.

Growth is possible under anoxic conditions in the light or under microoxic conditions in the dark. Organic carbon sources, thiosulfate, and sulfide are used as photosynthetic electron donors. Sulfide and thiosulfate are oxidized to sulfate. Best growth occurs with glucose, fructose, maltose, sucrose, glycerol, propanol, fumarate, and malate as organic carbon sources. Cystine, cysteine, sulfide, and thiosulfate are used as sulfur sources, but sulfate is not used. Ammonia and casein hydrolysate are used as nitrogen sources, while arginine, glycine, alanine, asparagine, and urea inhibit growth. Yeast extract or biotin, pyridoxine, and *p*-aminobenzoate are required as growth factors.

Mesophilic freshwater bacterium with optimal growth at 28–30°C and pH 7.0.

The mol% G + C of the DNA is: 67.8–68.4 (chemical analysis).

Type strain: Pl, DSM 729.

GenBank accession number (16S rRNA): D86514.

Genus VIII. **Devosia** *Nakagawa, Sakane and Yokota 1996, 20[VP]*

YASUYOSHI NAKAGAWA, TAKESHI SAKANE AND AKIRA YOKOTA

De.vos'i.a. M.L. dim. ending *-ia* M.L. fem. n. *Devosia* honoring Paul De Vos, a Belgian microbiologist, for his contributions to the taxonomy of pseudomonads.

Rods, 0.4–0.8 × 2.0–8.0 μm. **Motile by means of several polar flagella.** Endospores are not formed. Gram negative. **Aerobic. Oxidase and catalase positive. The major respiratory quinone is ubiquinone-10. The major cellular hydroxy fatty acids are 3-hydroxytetracosenoic acid and 3-hydroxyhexacosenoic acid. 3-Hydroxy fatty acids that are shorter than 3-hydroxyoctadecanoic acid are absent.** Phylogenetically related to members of the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 61.4.

Type species: **Devosia riboflavina** Nakagawa, Sakane and Yokota 1996, 20.

FURTHER DESCRIPTIVE INFORMATION

The following description pertains to the type strain of the type species. Cells grow vigorously on nutrient agar at 30°C. The quinone type is ubiquinone-10 (Q-10), which suggests that the organism belongs to *Alphaproteobacteria*. 2-Hydroxy (2-OH) fatty acids are not detected by thin-layer chromatography analysis. The cells contain 3-hydroxytetracosenoic acid ($C_{24:1\ 3OH}$) and 3-hydroxyhexacosenoic acid ($C_{26:1\ 3OH}$) as the major 3-OH fatty acids, and 3-hydroxyoctadecanoic acid ($C_{18:0\ 3OH}$), 3-hydroxylcosanoic acid ($C_{20:0\ 3OH}$), 3-hydroxylcosenoic acid ($C_{20:1\ 3OH}$), 3-hydroxydocosanoic acid ($C_{22:0\ 3OH}$), and 3-hydroxydocosenoic acid ($C_{22:1\ 3OH}$) as minor components. The long-chain acids $C_{24:1\ 3OH}$, $C_{26:1\ 3OH}$, and $C_{22:1\ 3OH}$, as well as octadecanoic acid ($C_{18:0}$), octadecenoic acid ($C_{18:1}$), and hexadecanoic acid ($C_{16:0}$) as fatty acid components and glucose, galactose, mannose, and glucosamine as sugar components, exist in the lipopolysaccharides (LPS) purified from the cells by extraction with phenol–chloroform–petroleum ether. Thus, the long-chain 3-OH fatty acids are components of the LPS molecule, which is an important outer membrane component. No other bacteria that contain $C_{24:1\ 3OH}$ and $C_{26:1\ 3OH}$ as major components have been described.

ENRICHMENT AND ISOLATION PROCEDURES

Devosia riboflavina was originally isolated from riboflavin-rich soil (Foster, 1944). The procedures for this enrichment and isolation of the strain have also been described by Foster (1944). Soil is added to a solution of 0.1% riboflavin with small amounts of K_2HPO_4 and $MgSO_4 \cdot 7H_2O$, then incubated at room temperature. After the riboflavin has disappeared, as indicated by the loss of the orange color, the culture is streaked onto solid medium that contains same components.

Maintenance Procedures

Cultures can be preserved by liquid drying (L-drying). For L-drying, cells grown on nutrient agar for 48 h at 30°C are suspended in the protective medium SM1 (Sakane et al., 1996), which contains 30 g of sodium L(+)-glutamate monohydrate, 15 g of ribitol, 5 g of L-cysteine hydrochloride monohydrate in 1 liter of 0.1 M potassium phosphate buffer (pH 7.0), and dispensed in ampules. The suspension is then vacuum-dried from the liquid state without freezing and stored at 4°C. The results of an accelerated storage test suggest that cells should survive more than 20 years (Sakane and Kuroshima, 1997). Cultures may be also preserved by freezing at −80°C or −196°C. For freezing, cells are suspended in nutrient broth (Difco) containing 10% glycerol or 7% DMSO as a cryoprotective agent.

Differentiation of the genus *Devosia* from other genera

Table BXII.α.170 lists properties that are useful for distinguishing the genus *Devosia*. The genus *Devosia* can be differentiated from morphologically similar genera belonging to the *Alphaproteobacteria* by certain phenotypic and chemotaxonomic characteristics and 16S rRNA sequence signatures (Table BXII.α.171). The absence of 3-OH fatty acids that are shorter than $C_{18:0\ 3OH}$ and the presence of $C_{24:1\ 3OH}$ and $C_{26:1\ 3OH}$ as the major 3-OH fatty acids in the cells are the key differential characteristics.

Taxonomic Comments

Phylogenetic analysis derived from 16S rRNA sequences shows that the genus *Devosia* occupies a distinct position in the *Alphaproteobacteria* (Fig. BXII.α.204). The phylogenetic independence

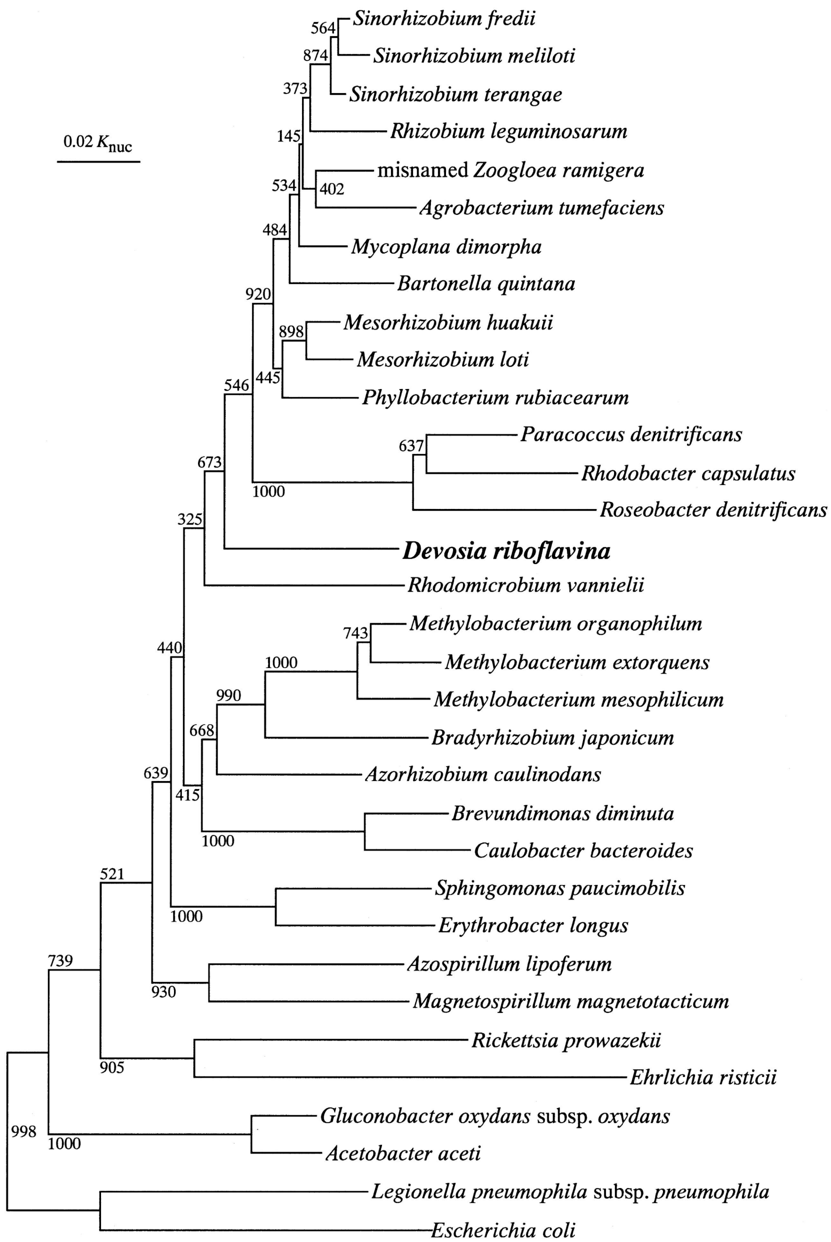

FIGURE BXII.α.204. Phylogenetic tree derived from 16S rRNA sequences of the *Alphaproteobacteria*. Clustal W ver. 1.7 (Thompson et al., 1994) was used to generate K_{nuc} values (Kimura, 1980) and to reconstruct a phylogenetic tree by the neighbor-joining method (Saitou and Nei, 1987). Scale bar = K_{nuc} values. The lengths of the vertical lines are not significant. The numbers of the branches refer to the confidence limits estimated by bootstrap analysis (Felsenstein, 1985) with 1000 replicates. The total number of nucleotides compared with 1143 after elimination of the positions at which secondary structures varied in the strains (Nakagawa et al., 1996) and all sites which were not determined in any sequences. *Escherichia coli* and *Legionella pneumophila* subsp. *pneumophila* were used as the outgroup. The accession numbers for nucleotide sequences are as follows: *Acetobacter aceti*, X74066; *Agrobacterium tumefaciens*, M11223; *Azorhizobium caulinodans*, D11342; *Azospirillum lipoferum*, M59601; *Bartonella quintana*, M11927; *Bradyrhizobium japonicum*, D11345; *Brevundimonas diminuta*, M59064; *Caulobacter bacteroides* (This species has recently been transferred to the genus *Brevundimonas* as *B. bacteroides*)., M83796; *Devosia riboflavina*, D49423; *Ehrlichia risticii*, M21290; *Erythrobacter longus*, M96744; *Escherichia coli*, J01695; *Gluconobacter oxydans* subsp. *oxydans*, X73820; *Legionella pneumophila* subsp. *pneumophila*, M59157; *Magnetospirillum magnetotacticum*, M58171; *Mesorhizobium huakuii*, D13431; *Mesorhizobium loti*, D14514; *Methylobacterium extorquens*, D32224; *Methylobacterium mesophilicum*, D32225; *Methylobacterium organophilum*, D32226; *Mycoplana dimorpha*, D12786; *Paracoccus denitrificans*, X69159; *Phyllobacterium rubiacearum*, D12790; *Rickettsia prowazekii*, M21789; *Rhizobium leguminosarum*, D12782; *Rhodobacter capsulatus*, D16428; *Rhodomicrobium vannielii*, M34127; *Roseobacter denitrificans*, M59063; *Sinorhizobium fredii*, D14516; *Sinorhizobium meliloti*, D01265; *Sinorhizobium terangae*, X68387; *Sphingomonas paucimobilis*, D16144; misnamed *Zoogloea ramigera*, X74915.

of the genus *Devosia* is also reflected by the 16S rRNA signature sequences (see above).

16S rRNA cataloging (Woese et al., 1984a) and DNA–rRNA hybridization (De Vos and De Ley, 1983; De Vos et al., 1985a, 1989) have revealed that members of the genus *Pseudomonas* belong to the *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria*. The level of heterogeneity in the genus *Pseudomonas* has been reduced by transferring various pseudomonads belonging to Palleroni's rRNA groups (Palleroni, 1984)—other than group I—to other existing new genera (Tamaoka et al., 1987; Willems et al., 1989, 1990; Yabuuchi et al., 1990a, 1992; Segers et al., 1994).

The organism presently named *Devosia riboflavina* is one of the misnamed pseudomonads. It was originally named *"Pseudomonas riboflavina"* Foster 1944, 30 and described as a soil bacterium that oxidized riboflavin to lumichrome. In the eighth edition of the *Determinative Manual*, *"P. riboflavina"* was treated as a *species incertae sedis* because it is not motile, even though the original description indicated that it was motile (Doudoroff and Palleroni, 1974). DNA–rRNA hybridization studies (De Vos et al., 1989; Segers et al., 1994) have shown that *"P. riboflavina"* belongs to rRNA superfamily IV (*Alphaproteobacteria*), but its precise position in the *Alphaproteobacteria* remained unknown until its 16S rRNA sequence was determined. The results of a phylogenetic analysis based on 16S rRNA sequence data (Nakagawa et al., 1996) have placed *"P. riboflavina"* IFO 13584^T in an independent position in the *Alphaproteobacteria*. The similarity rank analysis included in the Ribosomal Database Project (Maidak et al., 1997) suggests that the phylogenetic neighbors of the genus *Devosia* are members of the *Rhizobiaceae*, with which it exhibits 16S rRNA similarity values ranging from 91.9 to 93.6%.

Unfortunately, only one strain of the single species is available. Other strains belonging to the genus should be isolated and investigated in the future.

List of species of the genus Devosia

1. **Devosia riboflavina** Nakagawa, Sakane and Yokota 1996, 20[VP]

ri.bo.fla'vi.na. M.L. fem. adj. *riboflavina* referring to the ability of the organism to oxidize riboflavin.

The characteristics are as described for the genus and listed in Tables BXII.α.170, BXII.α.171, and BXII.α.172. In addition, colonies are circular with entire or slightly undulate margins and cream colored. Urease positive. Organic nitrogenous substances, such as amino acids, are required for growth. Glycine, urea, and ammonium chloride cannot be substituted for organic material as nitrogen sources in media containing riboflavin as the sole energy source. Acid is produced from D-arabinose. Neither acid nor gas are produced from D-galactose, D-glucose, inositol, lactose, D-fructose, maltose, mannitol, sucrose, D-xylose, and ethanol. Esculin is hydrolyzed. Gelatin and starch are not hydrolyzed. Nitrate is slightly reduced to nitrite. Indole is not produced. Vigorous growth occurs on nutrient agar at 28°C. As determined by API 20NE tests, the following substrates are assimilated by the type strain: D-arabinose, glucose, maltose, D-mannitol, D-mannose, and *N*-acetyl-D-glucosamine. The following substrates are not assimilated by the type strain, as determined by API 20NE tests: adipic acid, *n*-capric acid, DL-malic acid, phenyl acetate, potassium gluconate, and sodium citrate. β-Galactosidase and β-glucosidase activities are present in the type strain, as determined by API 20NE tests. Arginine dihydrolase activity is not present in the type strain, as determined by API 20NE tests.

The mol% G + C of the DNA is: 61.4 (HPLC).

Type strain: 4R3337, ATCC 9526, DSM 7230, IFO 13584.

GenBank accession number (16S rRNA): D49423.

Genus IX. **Dichotomicrobium** *Hirsch and Hoffman 1989b, 495^{VP} (Effective publication: Hirsch and Hoffman 1989a, 300)*

PETER HIRSCH

Di.cho' to.mi.cro.bi.um. Gr. adj. *dichotomus* divided, forked; Gr. adj. *micrus* small; Gr. n. *bius* life; M.L. neut. n. *Dichotomicrobium* a forked microbe.

Tetrahedral to spherical cells, 0.8–1.8 × 0.8–2.0 μm, with up to four prosthecae (hyphae) of 0.2–0.3 μm width and varying length. Cells and hyphae may be covered with short, rigid, bent pili. **Hyphae and mother cells may branch (fork) dichotomously.** Multiplication by terminal bud formation on hyphae or by intercalary budding. Propagation cells initially spherical or pear-shaped, later tetrahedral and never motile. Gram negative, do not form spores. **Poly-β-hydroxybutyrate (PHBA) granules may be produced, even within the hyphae.** Aerobic, moderately thermophilic and halophilic, require yeast extract for growth. Carbon sources are acetate, malate, succinate, and 2-oxoglutarate. Utilize organic nitrogen sources, such as amino acids or yeast extract; ammonium, nitrite, nitrate, molecular nitrogen, and urea do not serve as nitrogen sources. **Oxidase, catalase, and peroxidase positive.** Do not grow anaerobically. Occur in saline ponds and lakes with temperatures above 20°C.

The mol% G + C of the DNA is: 62–64.

Type species: **Dichotomicrobium thermohalophilum** Hirsch and Hoffmann 1989b, 495 (Effective publication: Hirsch and Hoffmann 1989a, 300.)

FURTHER DESCRIPTIVE INFORMATION

Some information on *Dichotomicrobium* isolates was initially published with the strain designation "genus D" (Gebers et al., 1985; Kölbel-Boelke et al., 1985; Roggentin and Hirsch, 1989; Sittig and Hirsch, 1992) or as *"Dichotomicrobium"* sp. (Stackebrandt et al., 1988a). All of these studies were concerned with at least isolate IFAM 954^T, the type strain for *D. thermohalophilum.*

A phylogenetic survey of budding and prosthecate bacteria by 16S rRNA cataloguing (Fig. BXII.α.205) has shown that *Dichotomicrobium* strain IFAM 954^T belongs to the *Alphaproteobacteria*, close to *Hyphomicrobium*, *Filomicrobium*, and *Pedomicrobium* species (Stackebrandt et al., 1988a).

The general morphology and life cycle of 13 strains that have been investigated is very similar (Hirsch and Hoffmann, 1989a). Mature cells are tetrahedral, triangular, or even cubical, they may be dichotomously branched. Up to four prosthecae (hyphae) grow out from the corners (Fig. BXII.α.206). The average cell size is 0.9 × 1.1 μm, with a rather constant hyphal diameter of 0.25 μm. The hyphae may branch; nearly spherical buds are produced from the hyphal tips, and only from one at a time. The buds are separated by a cross wall upon maturation and can be released, but motility of these daughter cells has never been observed. Rarely, intercalary buds are produced by a local enlargement of a hyphal portion. Sometimes, terminal buds remain attached to the hyphae and begin to grow new hyphae with a terminal bud, thus resulting in the formation of a cell chain or even a network of cells after hyphal branching. The hyphal length is dependent on nutrient concentrations: lack of nutrients (especially yeast extract) results in longer and lesser-branched hyphae. In some strains, hyphae are covered with short, rigid, but bent pili to give the appearance of a fur (Fig. BXII.α.207).

The fine structure resembles that of other typical Gram-negative bacteria. Internal membranes are absent, except for an occasional mesosome. DNA nucleoids are found in sections of mother cells and mature buds, but cannot be demonstrated in sections of hyphae. Mother cells and often hyphae store PHBA, and most cells contain polyphosphate granules. Hyphal cross sections reveal an exceptionally dense and structured periplasm. Colonies of *Dichotomicrobium* strains grow slowly; they are rather flat, reddish brown, and have fuzzy edges. Growth in liquid media is pinkish orange; the pigment has been identified as canthaxanthin, a carotenoid (A. Pudleiner, personal communication).

All *Dichotomicrobium* isolates tested by Hirsch and Hoffmann (1989a) require yeast extract for growth, the optimal concentration for five strains ranges from 0.25 to 5.0 g/l. Two of these five strains require Vitamin Solution No. 6 (Van Ert and Staley, 1971). Mass cultures of *Dichotomicrobium* IFAM 954^T have been grown at 43°C with aeration; the yield after 10 d amounted to 7 g dry weight per 7.5 liters. Most strains show growth in media with a 0.2–5.5 fold concentration of artificial seawater (ASW; Lyman and Fleming, 1940), which corresponds to a total salinity of 8–222‰. The optimum ranges from 2.0 to 3.5 × ASW (salinity of 80–142‰). The temperature optimum of nine strains ranges from 37 to 50°C.

Several organic acids are utilized for growth in the presence of 0.025% (w/v) yeast extract; malate is especially favorable, but succinate, 2-oxoglutarate, and acetate also support good growth. Utilization of amino acids, sugars, and sugar alcohols varies with different strains (Table BXII.α.173). Inorganic nitrogen sources do not serve for growth, but yeast extract and some amino acids can be utilized. None of the strains grow with peptone as a nitrogen source. Enzymatic activities are limited. Neither acid nor gas is produced from 0.1% glucose or fructose. Gelatin, starch, casein, and DNA are not hydrolyzed, nitrate is not reduced, and NH_3, H_2S, indole, acetoin, and extracellular phosphatase are not formed. All strains are methyl-red negative, Fe(II) and Mn(II) are not oxidized. The strains are oxidase, catalase, and peroxidase positive.

Chemotaxonomic characteristics of *Dichotomicrobium* strains have been studied by Sittig and Hirsch (1992). Of nine isolates, strains IFAM 951, 954^T, 956, 958, 1185, and 1186 came from the Solar Lake (Sinai) and strains IFAM 1422, 1423, and 1424 from a pond in Brazil. All these isolates have ubiquinone Q-10 and the following phospholipids: phosphatidylglycerol, phosphatidylcholine, bisphosphatidylglycerol, and phosphatidyldimethylethanolamine. The three strains from Brazil also contain phosphatidylethanolamine. The fatty acid distribution is also typical (and alike) for the Solar Lake strains, but differs in the Brazilian isolates (Tables BXII.α.174 and BXII.α.175). The fatty acids $C_{20:1\ 3OH}$, $C_{22:0}$, and $C_{22:1\ \omega7}$ are especially characteristic of the genus *Dichotomicrobium.* A relatively high percentage of $C_{19:0\ \omega7c}$ has been found in strains IFAM 954^T and 1423 (35.2% and 13.5%, respectively); this fatty acid has also been found in other budding, hyphal bacteria, namely *Filomicrobium fusiforme* and *Pedomicrobium* sp. E 1129.

The DNA base compositions of strains IFAM 954^T, 958, and 1185 have been determined to range from 62.7 to 63.6 mol% G + C (T_m; Gebers et al., 1985). The intrageneric heterogeneity (nucleotide distribution) of three *Dichotomicrobium* strains and

Hirsch, Distribution and pure culture studies of morphologically distinct Solar Lake microorganisms. *In* Nissenbaum (Editor), Hypersaline Brine and Evaporitic Environments, ©Elsevier Science B.V, pp 41–60.)

differences among these and closely related genera (*Pedomicrobium*, "genus T") have also been studied by plotting DNA base compositions against the widths of the melting transitions. The three *Dichotomicrobium* strains share a high level of similarity with respect to their DNA properties. The genome size of *Dichotomicrobium* strain IFAM 954^T has been determined by DNA renaturation kinetics and found to be 1.73 × 10^9 bp. When plotted against the mol% G + C ratio, strain 954^T was found to be widely separated from *Hyphomonas*, *Hyphomicrobium*, and *Filomicrobium* species (Kölbel-Boelke et al., 1985).

Antibiotic sensitivity of *Dichotomicrobium* for four antibiotics has been tested by Hirsch and Hoffmann (1989a), with liquid cultures containing 1–100 μg antibiotic per ml. Significant inhibition occurs with 1–10 μg/ml penicillin G or streptomycin sulfate or with 10–100 μg/ml ampicillin or cephalothin.

Bacteria with a *Dichotomicrobium*-like morphology have so far been isolated only from the hypersaline Solar Lake (Sinai) and the Lagoa Vermelha pond in Brazil, which have salinities ranging from 68.7 to 183.3‰ (Table BXII.α.176) and temperatures of 30°C and higher. However, Güde et al., (1985) have observed similar bacterial morphotypes in Lake Constance between 10 and 150 m depth and at a temperature of only 4.5°C. Unfortunately, all attempts to cultivate these forms have failed.

Conditions for Solar Lake dichotomicrobia during sampling time varied considerably within the profile: from 43°C and 144.4‰ salinity near the aerobic surface, through 53°C and 156‰ at 2.5 m depth, to the anaerobic sediment (rich in sulfide) with 42°C and 183.3‰ salinity (Hirsch, 1980; Table BXII.α.176). The Solar Lake dichotomicrobia are evidently well adapted to tolerate this range of conditions.

[a]Data from Sittig and Hirsch (1992).

Three strains have been isolated from enrichments kept under N_2/CO_2 (95:5), but when tested, these isolates could not grow anaerobically. Since viable dichotomicrobia have been obtained from the anaerobic enrichments and from the anaerobic sediment, a lack of oxygen must be tolerated by these bacteria at least for some time. Survival and limited growth in the anaerobic enrichments could have been made possible by the presence of oxygen-producing cyanobacteria and dim light.

Enrichment and Isolation Procedures

Two methods have successfully yielded *Dichotomicrobium* cultures. (1) Clean, sterile glass slides are exposed to the Solar Lake for

TABLE BXII.α.176. Origin and enrichment conditions of 13 strains of *Dichotomicrobium* sp.[a]

[b]nd, not determined.

8–10 d to allow dichotomicrobia to attach. The slides are then transferred to a sample of Solar Lake water. In the laboratory, samples and slides are incubated either directly or with the addition of 0.025% (w/v) of Bacto yeast extract (sterilized in the same water). Alternatively, Bacto peptone is added to other samples with exposed slides. The samples (enrichments) are then incubated up to four weeks at 30–45°C (Hirsch, 1980; Hirsch and Hoffmann, 1989a). (2) The other successful procedure consists of directly streaking water samples containing dichotomicrobia onto agar plates with medium 398, of the following composition (g/l): Bacto yeast extract, 1; DL-malate, 1; Hutner's basal salts (Cohen-Bazire et al., 1957), 20 ml; 3× ASW, 980 ml; final pH 7.2. Some strains grow better on medium 399 with the same ingredients, but only 2.5× concentrated ASW and a final pH of 8.5. Identification and isolation of dichotomicrobia on the same media is facilitated by the reddish-brown color and fuzzy edges of the individual colonies.

Maintenance Procedures

Pure cultures can be stored in liquid medium at 20°C for at least one year, but storage at 4°C is much less effective. Lyophilization in growth medium (398, 399) (see Enrichment and Isolation Procedures above) is better than in skim milk. Slants kept at 20°C must be subcultured every 4–6 months, but liquid cultures survive better, as long as medium evaporation is controlled.

Procedures for Testing Special Characters

Mass cultures for the isolation of DNA contain (g/l): Bacto peptone, 1; Bacto yeast extract, 1; glucose, 1; vitamin solution no. 6, 10 ml; Hutner's basal salts, 20 ml; ASW (2.5–3×), 970 ml; final pH 7.5 (Gebers et al., 1985). Cells are harvested at 16,000× g for 20 min, washed twice with 0.85% (w/v) NaCl, and the pellet stored at −20°C for further use.

Lysis of dichotomicrobia is achieved by suspending 1 g (wet weight) of cells in 20 ml of 1 M NaCl/0.1 M EDTA containing 1 g proteinase K and 1% (w/v) *N*-acetyl-*N,N,N*-trimethylammonium bromide (E. Merck), as well as 50 g of glass beads (Gebers et al., 1985). This mixture is treated for 5 sec in the cell homogenizer, followed by the addition of 1 volume chloroform–isoamyl alcohol and shaking at 100 rpm for 15 min. The resulting emulsion is centrifuged at 1350× g for 20 min; the upper aqueous phase is then removed and mixed with 1 volume double distilled water. Then, 0.6 volume of isopropanol is added, drop by drop, while the solution is stirred with a glass rod. Centrifugation at 1350× g for 10 min yields a nucleic acid pellet, which can be further purified as described by Marmur (1961).

Differentiation of the genus *Dichotomicrobium* from other genera

Differentiation of the genus *Dichotomicrobium* from other hyphal and budding bacteria is shown on Table BXII.α.177.

Taxonomic Comments

Ten *Dichotomicrobium* strains came from the Solar Lake, with IFAM 954[T] as a representative isolate. Three other strains from the shallower Lagoa Vermelha (Brazil) are physiologically slightly different; a representative strain is IFAM 1423. These isolates have lower salinity and temperature optima (Table BXII.α.176), and they have different percentages of non-hydroxy (Table BXII.α.174) and hydroxy fatty acids (Table BXII.α.175). Additionally, the average cell size of these Brazilian strains was lower. For these reasons, only the ten nearly identical strains IFAM 951–1186 are described as *D. thermohalophilum* (Hirsch and Hoffmann, 1989a) and the Lagoa Vermelha isolates have been recommended for further studies as possibly different species.

Acknowledgments

Skillful technical assistance rendered by B. Hoffmann and M. Beese is gratefully acknowledged. A. Höhn (Geesthacht) provided the Lagoa Vermelha water samples and physical data on the habitat. H. Güde (Langenargen) and M. Simon (Konstanz) contributed information on *Dichotomicrobium*-like morphotypes in Lake Constance. The Solar Lake studies were initiated by the late Prof. M. Shilo (Jerusalem) and supported by the Deutsche Forschungsgemeinschaft.

List of species of the genus Dichotomicrobium

1. **Dichotomicrobium thermohalophilum** Hirsch and Hoffmann 1989b, 495[VP] (Effective publication: Hirsch and Hoffmann 1989a, 300.)
ther.mo.ha.lo′ phi.lum. Gr. adj. *thermus* hot; Gr. n. *halus* salt; Gr. adj. *philus* loving; M.L. neut. adj. *thermohalophilum* heat and salt loving.

Morphological description is the same as for the genus. Temperature optimum for growth 44–50°C, temperature minimum 20–30°C, temperature maximum 61–65°C. Temperature survival range 13–65°C. Optimal pH 8.0–8.5, pH range for growth 5.8–9.5. Optimal salinity for growth 80–142‰ ASW, minimal salinity 8 to >40‰, maximal salinity 182 to >222‰. Optimal concentration of yeast extract 0.25–5.0 g/l (w/v). Other physiological and biochemical characteristics as for the genus. Habitat: hypersaline, meromictic, and heliothermal Solar Lake (Sinai), throughout the whole profile (0–4.5 m).

The mol% G + C of the DNA is: 62–64 (T_m).

Type strain: IFAM 954, ATCC 49408, DSM 5002.

Additional Remarks: Reference strains include IFAM 951, 952 (DSM 5001), 953, 955, 956, 957, 958, 1185, and 1186 (DSM 5006).

Genus X. **Filomicrobium** *Schlesner 1988, 220[VP] (Effective publication: Schlesner 1987, 65)*

Heinz Schlesner

Fi.lo.mi.cro′ bi.um. L. masc. n. *filum* thread; Gr. adj. *micros* small; Gr. n. *bios* life; M.L. neut. n. *Filomicrobium* threadlike microbe.

Fusiform cells, 0.5–0.7 × 1.5–4.0 μm, with two or three polar prosthecae, which are about 0.2 μm in diameter and have a length of up to 40 μm or more. Buds are formed at the tips of the prosthecae (Fig. BXII.α.208). **Nonmotile. Gram negative. Aerobic and chemoorganotrophic.** Utilize some organic acids. **C_1-compounds are not used as carbon sources.** The ubiquinone system is a **Q-9** system. Hydroxy fatty acids are of the **3-OH** type.

The mol% G + C of the DNA is: 62.

Type species: **Filomicrobium fusiforme** Schlesner 1988, 220 (Effective publication: Schlesner 1987, 65.)

Further descriptive information

Growth on solid media is poor. After 3 weeks of incubation at 25°C, microcolonies with diameters of about 0.1 mm can be ob-

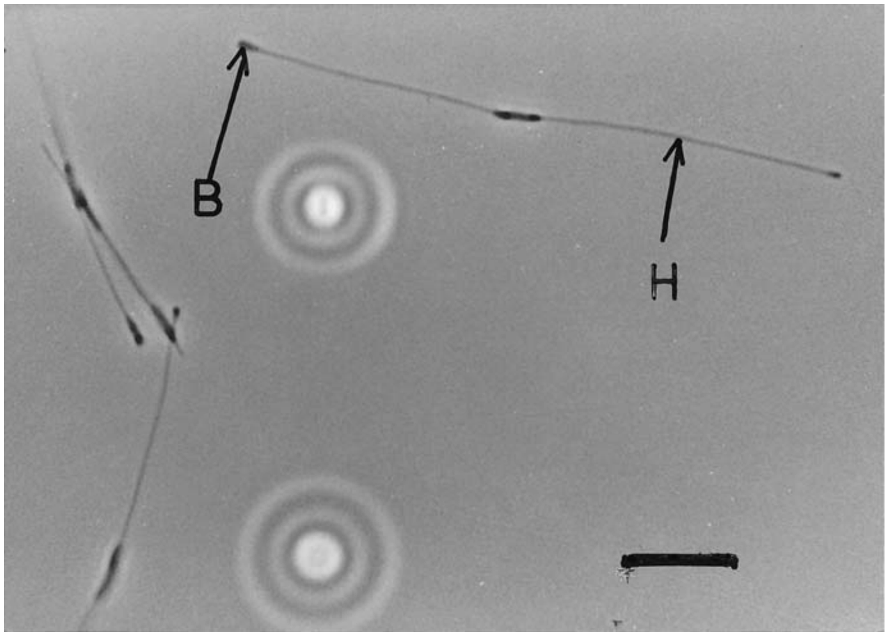

FIGURE BXII.α.208. *Filomicrobium fusiforme* IFAM 1315[T]. Cells with polarly inserted hyphae (*H*) at the tips of which buds (*B*) are being formed. Bar = 10 μm.

served. They are light red and have a rough surface. The red pigment is composed of canthaxanthin and echinone and can be extracted with ethanol and methanol but not with chloroform or petroleum ether. The genome size is 2.03×10^9 Da (Kölbel-Boelke et al., 1985).

Analysis of the 16S rDNA indicates that the genus *Filomicrobium* is a member of the *Alphaproteobacteria* and is related to two clusters of species of the genus *Hyphomicrobium* (Rainey et al., 1998).

Enrichment and Isolation Procedures

The type strain was isolated from a sample taken from the Kiel Bight (part of the Baltic Sea, Germany) at a depth of 2 m. For enrichment, the sample was incubated at 20–23°C in daylight for 12 months and then streaked on agar plates of medium 17 (M17): sodium acetate, 1.0 g; KNO_3, 1.0 g; Hunter's basal salts (Cohen-Bazire et al., 1957), 20 ml; vitamin solution (Staley, 1968), 10 ml; artificial sea water (Lyman and Fleming, 1940), 500 ml; distilled water to 1000 ml (Schlesner, 1987).

Maintenance Procedures

Storage on solid media is not recommended. The cells are easily revived from lyophilized cultures.

Procedures for Testing Special Characters

Cells of *Filomicrobium* are easily recognized by microscopy.

Differentiation of the genus *Filomicrobium* from other genera

Table BXII.α.55 in the entry describing the genus *Hirschia* lists the major features that differentiate *Filomicrobium* from other genera of budding, prosthecate bacteria.

Further Reading

Schlesner, H. 1987. *Filomicrobium fusiforme* gen. nov., sp. nov., a slender budding, hyphal bacterium from brackish water. Syst. Appl. Microbiol. *10*: 63–67.

List of species of the genus Filomicrobium

1. **Filomicrobium fusiforme** Schlesner 1988, 220[VP] (Effective publication: Schlesner 1987, 65.)
fu.si.for′ me. L. n. *fusus* spindle; L. n. *forma* shape, form; M.L. adj. *fusiformis* spindle-shaped.

Poor growth on solid media. Microcolonies 0.1–0.2 mm in diameter, with a rough surface, occur after 3 weeks incubation at 25°C. Growth is optimal between 20°C and 28°C; maximum growth temperature is 33°C. Vitamin B_{12} is required. Require eighth to full strength seawater for growth; optimal growth is with half-concentrated seawater. Carbon sources utilized for growth are acetate, propionate, fumarate, malate, succinate, and glutamic acid. Glucose is not fermented; nitrate is not reduced. Alginate, cellulose, chitin, and starch are not hydrolyzed. Ammonia, formamide, nitrate, and urea can serve as nitrogen sources. See Table BXII.α.178 for additional characteristics. Red pigment in type strain. Habitat is brackish water.

The mol% G + C of the DNA is: 62 (T_m).

Type strain: SH 128, ATCC 35158, DSM 5304, IFAM 1315.

GenBank accession number (16S rRNA): Y14313.

Genus XI. **Gemmiger** *Gossling and Moore 1975, 206*[AL]

JENNIFER GOSSLING

Gem'mi.ger. L. n. *gemma* a bud; L. v. *gero* to bear; M.L. masc. n. *Gemmiger* bud bearer.

Ovoid to hourglass-shaped bacteria, 0.9–2.5 × 1.0 µm, that apparently divide at a constriction, giving the **appearance of budding**. Rapidly growing organisms may form chains. Gram variable to Gram negative. Do not form spores. **Nonmotile** and with no external structures.

Obligately **anaerobic chemoorganotrophs using carbohydrate** as the only or major energy source. Growth on glucose or other sugars produces **butyrate**, usually lactate and formate, and sometimes small amounts of other compounds. Catalase-negative.

The mol% G + C of the DNA is: 59.

Type species: **Gemmiger formicilis** Gossling and Moore 1975, 206.

Further descriptive information

The cells most commonly have a bowling-pin shape and are 0.9–2.5 μm long; the diameter of the larger end is 0.5–1.0 μm, that of the smaller end is 0.2–0.8 μm, and that of the constriction is 0.2–0.5 μm (Figs. BXII.α.209 and BXII.α.210). The constriction may not be resolved under the light microscope, and the organism is seen as a pair of cocci, usually with one smaller than the other, resembling a budding yeast. Where the constriction is relatively long, secondary constrictions may be seen by electron microscopy. The bacteria are often seen in pairs, especially in logarithmic phase cultures; the two bacteria are attached to each other by the smaller ends (Figs. BXII.α.210 and BXII.α.211). Long chains are also formed, including pairs with the smaller ends together. At low concentrations of penicillin, sufficient to inhibit division but not growth, long filaments are formed (Salanitro et al., 1976).

There is a multilayered cell wall (Fig. BXII.α.211) (Gossling and Moore, 1975; Salanitro et al., 1976). Intracellular granules of a glycogen-like substance may be found (Salanitro et al., 1976).

Colonies are 1–2 mm in diameter after 48 h of growth. They are usually circular, entire, smooth, and low convex. They may be clear, translucent or opaque cream or white, depending on the medium. Broth cultures may become turbid initially, but the growth usually settles to form a ropy sediment.

Strict anaerobes, they have been cultured by using the roll tube, glove box, and steel wool (Mitsuoka, 1980) techniques but cannot be cultured on agar medium that has been exposed to air and is incubated in a conventional anaerobic jar (Gossling and Moore, 1975; Croucher and Barnes, 1983). Carbon dioxide is normally added to the gas phase for incubation and appears necessary for good growth.

Carbohydrates or related compounds are required for growth. Most strains use glucose; fresh isolates—from humans—that do not use glucose will use maltose (Holdeman et al., 1976; Mitsuoka, 1980). For strains from chickens, NH_4^+ has been shown to be the preferred nitrogen source (Salanitro et al., 1976; Croucher and Barnes, 1983). Various unidentified factors present in ruminal, fecal, liver or yeast extracts are necessary for growth. Growth of strains from chickens is stimulated by thiamine, riboflavin, pantothenate, and straight chain volatile fatty acids (Salanitro et al., 1976). Growth of some strains from humans is stimulated by Tween 80 (0.01–0.10%), but this is inhibitory to other strains (Gossling and Moore, 1975; Salanitro et al., 1976).

Glucose is fermented with the production of butyrate and usually formate and lactate; other products may include acetate, pyruvate, succinate, and malonate. All strains use and ferment a range of the following substances: amygdalin, arabinose, arabinoxylan, cellobiose, dextrin, esculin, fructose, galactose, glucose, glycogen, inulin, lactose, maltose, mannose, melibiose, raffinose, salicin, starch, sucrose, trehalose, and xylose. Lactate and nitrogenous compounds are not fermented.

A chicken isolate that has been tested for antibiotic susceptibility in broth was resistant to tetracycline (10 μg/ml), doxycycline (10 μg/ml), vancomycin (2.5 μg/ml), erythromycin

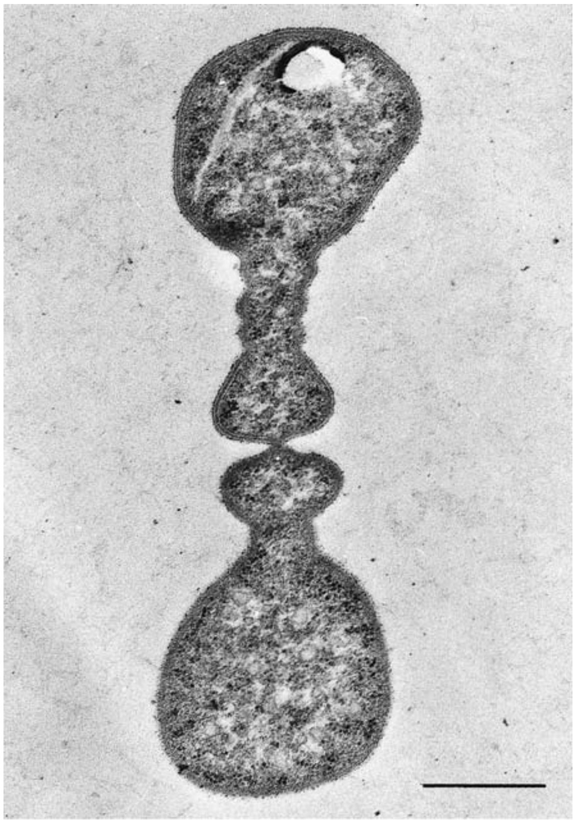

FIGURE BXII.α.211. *G. formicilis* strain L61. Transmission electron micrograph of a thin section. Bar = 0.5 μm. (Reproduced with permission from J. Gossling and W.E.C. Moore, International Journal of Systematic Bacteriology *25:* 202–207, 1975, ©International Union of Microbiological Societies.)

(5 μg/ml), kanamycin (100 μg/ml), neomycin (100 μg/ml), and nalidixic acid (100 μg/ml); it was inhibited by tetracycline (100 μg/ml), doxycycline (100 μg/ml), vancomycin (5 μg/ml), erythromycin (10 μg/ml), and clindamycin (1 μg/ml) (Croucher and Barnes, 1983).

Gemmiger isolates have been obtained from chickens and humans. In chickens up to 6 weeks of age, these bacteria live in the lumen of the large intestine and the ceca, forming a significant proportion—often >10%—of the flora (Salanitro et al., 1976; Croucher and Barnes, 1983). In adult humans they comprise about 2% of the fecal bacteria, giving counts of about 10^{10}/g dry wt (Moore and Holdeman, 1974; Gossling and Moore, 1975; Holdeman et al., 1976). They presumably live on residual carbohydrates that are not digested or absorbed in the small intestine.

Enrichment and Isolation Procedures

Via the roll tube technique, *Gemmiger* strains are isolated on media enriched with ruminal fluid, fecal extract, or liver extract and containing carbohydrates (glucose, maltose and/or cellobiose, soluble starch). No successful selection or enrichment techniques have been reported. Samples are diluted under strictly anaerobic conditions and streaked out on agar media for isolated colonies. After incubation for 3–7 days, large samples of colonies are picked for identification. *Gemmiger* can be distinguished microscopically by using phase contrast (Fig. BXII.α.209) or Gram stain (Mitsuoka, 1980).

Maintenance Procedures

Gemmiger strains are maintained by lyophilization, via methods suitable for strict anaerobes.

Differentiation of the genus *Gemmiger* from other genera

The key feature that distinguishes *Gemmiger* from aberrant minicell-producing bacilli, budding cocci, or streptococci is the appearance of two small forms between two large ones (Fig. BXII.α.209). Metabolically, *Gemmiger* can be distinguished from most other intestinal anaerobes by their requirement for carbohydrates together with the production of butyrate and no gas.

Taxonomic Comments

Gemmiger does not fit into any described higher taxon. Metabolically, these bacteria have been compared with other anaerobic intestinal bacilli, such as *Eubacterium* and the *Bacteroidaceae* (Moore and Holdeman, 1974; Salanitro et al., 1976), but *Gemmiger* has a higher mol% G + C of the DNA than do any of these. The mode of division may be similar to that of the facultative, prosthecate, freshwater bacterium *Ancalomicrobium* (Staley, 1968), but this bacterium has a higher mol% G + C of the DNA than does *Gemmiger*. Other bacteria that may have a similar mode of division are even more different metabolically (Whittenbury and Nicoll, 1971; Hirsch, 1974a).

Gemmiger have been grouped with the anaerobic cocci (Moore and Holdeman, 1974; Mitsuoka, 1980), but the formation of filaments in sublethal concentrations of penicillin (Salanitro et al., 1976) does not indicate a typical coccal morphology.

List of species of the genus Gemmiger

1. **Gemmiger formicilis** Gossling and Moore 1975, 206[AL]
for.mi' ci.lis. M.L. adj. *formicilis* pertaining to formic acid.

Strictly anaerobic, mesophilic bacteria conforming to the generic description. Require glucose, fructose, maltose, or other carbohydrate-like substances (see generic description) for growth. Produce butyrate and usually formate and lactate and no gas from glucose and other sugars. The predominant product varies with the strain and the sugar used. The terminal pH in weakly buffered media is 4.8–6.0. Erythritol, inositol, mannitol, melezitose, rhamnose, and ribose are not fermented. Indole, lecithinase, lipase, acetylmethylcarbinol, hydrogen sulfide, catalase, and urease are not produced. Nitrate is not reduced. Hippurate is not hydrolyzed. Casein and meat are not digested; there may be a weak action on gelatin (Gossling and Moore, 1975).

Study of chicken isolates indicates that most of them belong to one of two groups on the basis of fermentation products and the carbon sources used (Table BXII.α.179)

(Salanitro et al., 1976; Croucher and Barnes, 1983). Human isolates may be divided on the same characters, but the groups obtained do not correspond with the chicken groups.

All chicken isolates use raffinose and salicin; most human strains do not. However, the type strain is a human strain that uses salicin (Gossling and Moore, 1975).

It has been suggested that the human strains, which grow poorly in culture, do not use glucose on initial isolation, and do not produce formate, belong to a separate species (Holdeman et al., 1976); however, strains that normally produce formate may not do so when not growing well (Gossling and Moore, 1975).

The mol% G + C of the DNA is: 59 (T_m).

Type strain: ATCC 27749.

Genus XII. **Labrys** *Vasilyeva and Semenov 1985, 375*[VP] *(Effective publication: Vasilyeva and Semenov 1984, 92)*

Leana V. Vasilyeva

Lab'rys. Gr. n. *Labrys* double-headed ax, an organism resembling a Minoan ax, by the shape of the cell.

Unicellular flat bacterium; cells possess **triangular radial symmetry**. Dimensions are 1.1–1.3 × 1.3–1.5 μm. **Two to three tapering, short prosthecae** (<0.6 μm) protrude from two corners of the triangle; the third remains free and is associated with multiplication.

Cells divide by budding. Buds are produced directly from the mother cell at the tip of the triangle that lacks prosthecae. In this stage, the cell resembles a double-headed ax or labrys.

Gram negative, nonmotile, and do not possess fimbriae.

Obligately aerobic, nonfermentative, **chemoorganotrophic**. Utilize carbohydrates and some organic acids as sole carbon and energy sources. The type strain requires B vitamins for growth. Oxidase and catalase positive. Found in freshwater lakes.

The mol% G + C of the DNA is: 67.9.

Type species: **Labrys monachus** Vasilyeva and Semenov 1985, 375 (Effective publication: Vasilyeva and Semenov 1984, 92.)

Enrichment and Isolation Procedures

Strain was isolated from the silt samples from Lake Mustjarv (Estonia). The medium is horse manure extract, obtained by heating dry manure 1% (w/v) in distilled water. The sediment is left to settle, and a liquid medium is prepared from the supernatant; 2% agar is added for solidification and colony isolation. Incubation is at 28°C for 10–14 d.

Minute colonies are isolated and examined under a phase-contrast microscope for the presence of bacteria with unusual morphology. Repeated subculturing of individual colonies produces a pure culture.

Maintenance Procedures

Potato agar provides a favorable growth medium. Growth occurs on MMB agar (see *Ancalomicrobium*) with glucose, but only if supplemented by up to 0.25% yeast extract (Vasilyeva and Semenov, 1984). The type strain can be maintained on slants in the refrigerator for at least 3 months. Lyophilization can be used for long-term preservation.

Differentiation of the genus *Labrys* from other genera

Labrys combines morphological features typical of budding bacteria with prosthecae, such as *Prosthecomicrobium* and *Ancalomicrobium*, and of flat bacteria with radial symmetry, such as *Angulomicrobium* and *Stella* (Vasilyeva, 1980).

Physiological differences among these organisms are minimal.

Labrys, unlike *Angulomicrobium*, possesses prosthecae, which makes differentiation easy, in spite of the resemblance in cell shape and budding. Unlike *Ancalomicrobium*, *Labrys* has flat cells.

Taxonomic Comments

Labrys combines features of a number of genera, and inclusion of these organisms into other genera would necessarily change their descriptions. Only a single strain has so far been isolated. DNA–DNA hybridization studies have revealed no homology with *Stella* (Lysenko et al., 1984). Further work is needed to reveal a phylogenetic interrelation among budding prosthecobacteria.

List of species of the genus Labrys

1. **Labrys monachus** Vasilyeva and Semenov 1985, 375[VP] (Effective publication: Vasilyeva and Semenov 1984, 92.)
mon.ach'us. M.L., from ancient Gr. adj. *monachos* the only, unique, single.

The description is as for the genus.

Unicellular, flat, triangular, budding prosthecobacterium. Dimensions 1.1–1.5 μm. Prosthecae are short, <0.6 μm, tapering and protruding from two corners of triangle (Fig. BXII.α.212). Cells nonmotile. Gas vacuoles are not produced.

Gram negative. On the outer cell surface is an irregular, visible capsular microlayer (Fig. BXII.α.213). No laminated membranous structures in the cells.

Division is by budding on the corner that is free of prosthecae. The daughter cell separates when it approaches mother-cell size and shape (Fig. BXII.α.214).

Utilizes the following carbohydrates as sole sources of carbon and energy: D-erythrose, D-ribose, L-arabinose, D-xylose, D-lyxose, D-glucose, L-sorbose, L-rhamnose, D-fruc-

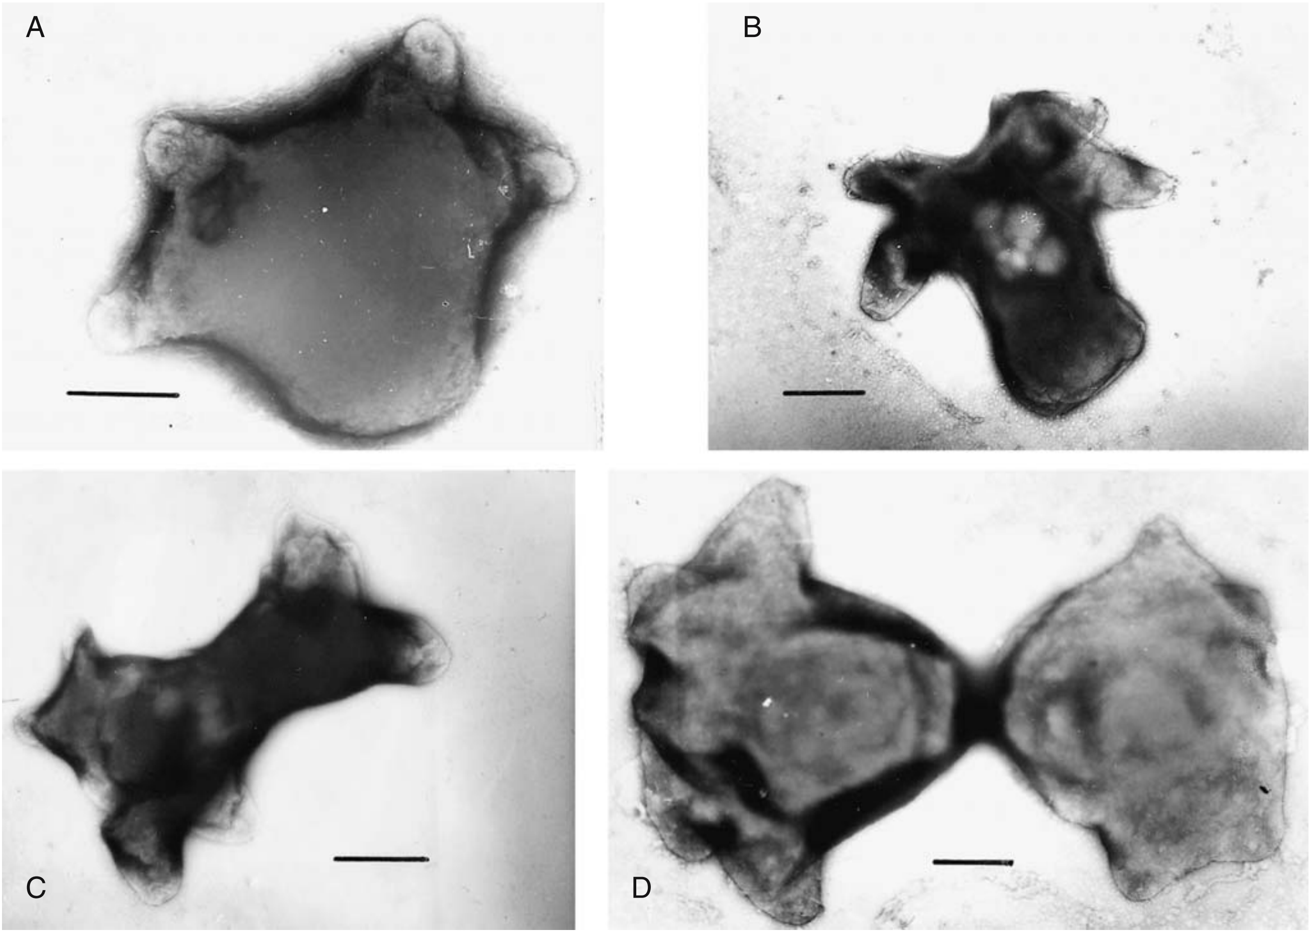

FIGURE BXII.α.212. *L. monachus. A–D*, electron microscopy showing cells in sequential stages of a multiplication. Note prosthecae protruding from two angles of the cell end, the "double ax" shape of the figure formed by the mother and daughter cells (*D*). Uranylacetate-negative stain. Bar = 0.5 μm.

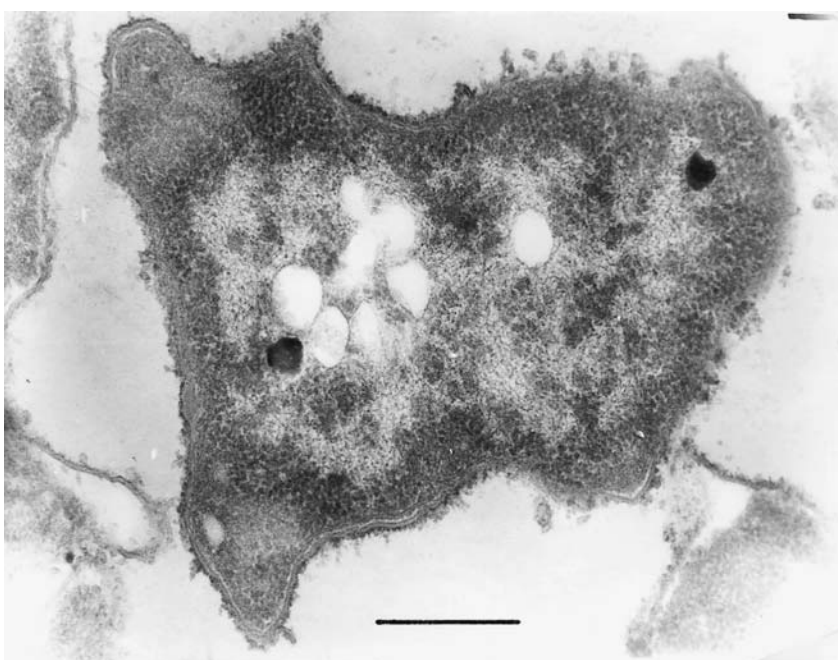

FIGURE BXII.α.213. *L. monachus.* Thin section. Note cytoplasm in prosthecae, granules of poly-β-hydroxybutyrate, and an external microcapsular layer on the outer side of the typical Gram-negative cell wall. Bar = 0.5 μm.

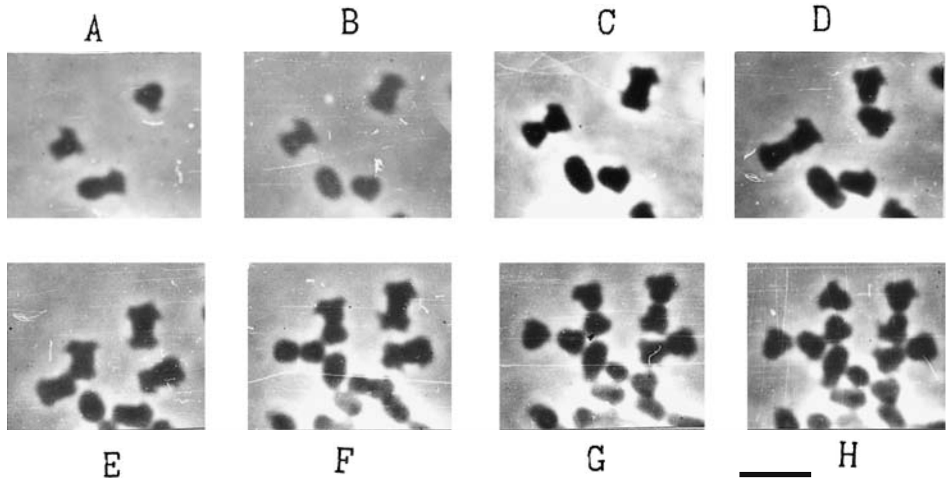

FIGURE BXII.α.214. *L. monachus*. Phase-contrast micrographs. Slide microculture. Hours: *A*, 0; *B*, 4; *C*, 7.5; *D*, 8.5; *E*, 11.5; *F*, 12.5; *G*, 13; and *H*, 15. Bar = 5.0 μm.

tose, D-talose, L-fucose, D-mannose, D-galactose, D-tagatose, trehalose, glycerol, mannitol, L-arabitol, adonitol, L-dulcitol, and D-sorbitol. Does not utilize D-lactose, D-cellobiose, D-melibiose, sucrose, D-raffinose, melezitose, starch, inulin, pectin, glycogen, dextrin, or inositol. The medium is acidified during growth on carbohydrates in all instances. Morphology is altered when luxurious growth occurs. Utilization of amino acids, organic acids, and alcohols is limited. Yeast extract above 0.25% inhibits growth; B vitamins are required for growth.

A considerable quantity of poly-β-hydroxybutyrate accumulates in cells immediately after inoculation on all utilized substrates.

Colonies circular, about 2 mm in diameter, colorless or gray, slightly convex, flat, opaque, glistening, smooth, and viscous.

Optimal temperature: 28°C; generation time: 8 h. Isolated from silt of Lake Mustjarv (Estonia).

The mol% G + C of the DNA is: 67.9 (T_m).

Type strain: 42, AUCM B-1479, ATCC 43932, DSM 5896.

Genus XIII. **Methylorhabdus** *Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1996a, 362^VP (Effective publication: Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1995, 97)*

Nina V. Doronina and Yuri A. Trotsenko

Me.thy.lo.rhab' dus. Fr. *méthyle* the methyl radical; G. n. *rhabdos* rod; M.L. masc. n. *Methylorhabdus* methyl rod.

Rods 0.4–0.6 × 1.2–2.5 μm. No endospores. Gram negative. Nonmotile. Multiplication is by fission, with constriction. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nitrate is reduced to nitrite. Nonpigmented. Growth occurs on nutrient agar and peptone–yeast extract–glucose (PYG) agar. Optimal temperature, 28–34°C; optimal pH, 6.8–7.4. Methyl red and Voges–Proskauer negative. Catalase and urease positive. Oxidase negative. Indole is formed from L-tryptophan in the mineral medium with methanol as a sole carbon and energy source and with KNO_3 as the sole nitrogen source. Ammonium ions inhibit deamination of the tryptophan. Chemoorganotrophic. **Facultatively methylotrophic;** assimilate C_1 compounds (dichloromethane, methanol, and methylamine) by the isocitrate lyase-negative variant of the serine pathway. The major ubiquinone is Q-10. The cellular fatty acid profile is characterized by the presence of *cis*-vaccenic, cyclopropane, and palmitic acids ($C_{18:1\ \omega7}$, $C_{19:0\ cyclo}$, and $C_{16:0}$, respectively). The dominant phospholipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylcholine, and cardiolipin. Belongs to the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 66.2 (T_m).

Type species: **Methylorhabdus multivorans** Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1996a, 36 (Effective publication: Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1995, 97.)

Further descriptive information

After division, cells remain connected by a constriction apparently formed by the outer membrane.

Facultative methylotroph. Dichloromethane-grown cells contain an inducible, glutathione-dependent dichloromethane dehalogenase, whereas methanol- or methylamine-grown cells possess the appropriate dehydrogenases. Formaldehyde is further oxidized to formate by glutathione-dependent formaldehyde dehydrogenase. The latter is oxidized to CO_2 by formate dehydrogenases. *Methylorhabdus multivorans* uses the isocitrate lyase-negative (icl^-) variant of the serine pathway and expresses hydroxypyruvate reductase, serine–glyoxylate aminotransferase, and malate lyase. Like other serine pathway methylobacteria, it has an NADP-dependent isocitrate dehydrogenase.

The primary assimilation of ammonia occurs by reductive amination of α-ketoglutarate.

Enrichment and Isolation Procedures

Methylorhabdus multivorans was isolated on dichloromethane agar from an enrichment culture that had been inoculated with a groundwater sample (Doronina et al., 1995).

Maintenance Procedures

The bacteria can be stored in liquid mineral medium with an appropriate C_1 substrate at 4°C for 1 month. For longer-term preservation, freeze-drying can be performed with a protectant (skim milk).

Differentiation of the genus *Methylorhabdus* from other genera

Methylorhabdus differs from some serine-pathway methylobacteria by its formation of constrictions as morphological features (Doronina et al., 1995). *Methylorhabdus multivorans* is distinguished from the genus *Methylobacterium* by its absence of pigmentation and by the presence of cyclopropane carboxylic acid in its cellular fatty acid composition. It is distinguished from nonpigmented members of the genus *Aminobacter* by its ability to use methanol, its expression of the isocitrate lyase-negative variant of the serine pathway, and the presence of amine dehydrogenase. It also differs from members of the genus *Hyphomicrobium* by its inability to form hyphae, the presence of the Q-10 quinone system, and the icl^- variant of the serine pathway, and its oxidation of methylamine by amine dehydrogenase. It differs from *Methylopila* by its oxidase-negative reaction and the presence of catalase. The major characteristics differentiating the genus *Methylorhabdus* from other related genera are summarized in Table BXII.α.180.

Taxonomic Comments

In the phylogenetic tree derived from 16S rDNA sequences, the genus *Methylorhabdus* forms a distinct branch within the *Alphaproteobacteria*. The highest degree of relationship is found with *Xanthobacter agilis* (92.6% similarity), *Thiobacillus novellus* (95.7% similarity), and *Ancylobacter aquaticus* (96.2% similarity).

There is less than 10% DNA–DNA similarity with members of *Methylopila*, *Methylobacterium*, *Aminobacter*, *Methylarcula*, and *Hyphomicrobium*.

List of species of the genus Methylorhabdus

1. **Methylorhabdus multivorans** Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1996a, 36^{VP} (Effective publication: Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1995, 97.)

mul.ti′vo.rans. L. adj. *multus* much; L. part. adj. *vorans* devouring, digesting; M.L. part. adj. *multivorans* digesting many compounds.

The characteristics are as described for the genus, with the following additional features. Fig. BXII.α.215 illustrates the morphological features. Colonies on peptone agar medium are white, round with uneven edges, of uniform mucous consistency, and 2–3 mm in diameter. Growth occurs at 10–45°C and at pH 6.0–8.0. No growth occurs in the presence of 3% NaCl. Starch and gelatin are hydrolyzed slowly. Acidification of the medium occurs with glucose, but no gas is formed. Utilizable carbon sources are dichloromethane, methanol, methylamine, L-arabinose, D-xylose, D-glucose, D-mannitol, inositol, glycerol, dulcitol, adonitol, ethanol, isopropanol, acetate, α-ketoglutarate, fumarate, pyruvate, succinate, oxaloacetate, *cis*-aconitate, propionate, L-glutamate, L-alanine, sarcosine, and *N,N*-dimethylglycine. Neither methane nor $H_2/O_2/CO_2$ supports growth. Methylamine is oxidized to formaldehyde by amine dehydrogenase. The type (and only) strain was isolated from groundwater in Switzerland.

The mol% G + C of the DNA is: 66.2 (T_m).

Type strain: DM13, ATCC 51890, VKM B-2030.

GenBank accession number (16S rRNA): AF004845.

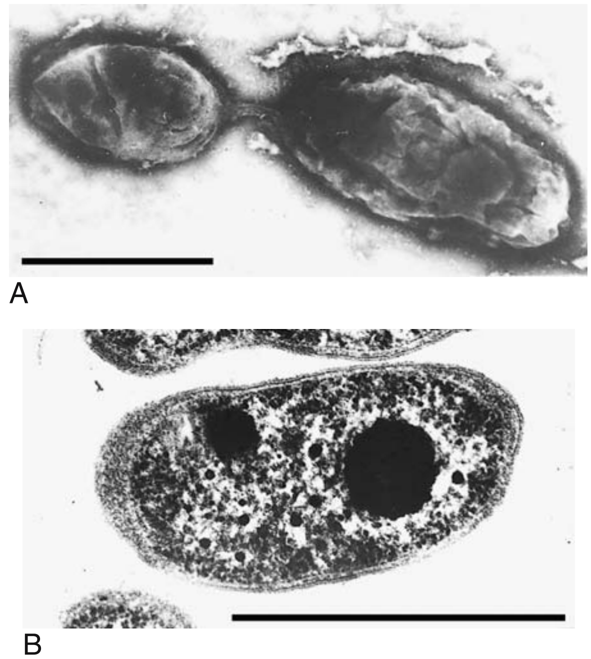

FIGURE BXII.α.215. *Methylorhabdus multivorans.* (*A*) Negatively stained cell. (*B*) Ultrathin section showing cell-wall structure and polyphosphate granules. Bars = 1 μm.

Genus XIV. **Pedomicrobium** *Aristovskaya 1961, 957^{AL} emend. Gebers and Beese 1988, 305*

PETER HIRSCH AND RAINER GEBERS

Pe.do.mi.cro′bi.um. Gr. n. *pedon* soil; Gr. adj. *micros* small; Gr. masc. n. *bios* life; M.L. neut. n. *Pedomicrobium* soil microbe.

Cells oval, spherical, or rod-shaped, 0.4–2.0 × 0.4–2.5 μm. **Up to 5 hyphae** (i.e., cellular outgrowths or prosthecae of constant diameter with reproductive function) are formed per cell body. Hyphae are 0.15–0.2 μm in diameter. **At least one hypha originates laterally**; others may appear at the cell poles. Multiplication is by **budding at the hyphal tips, with the long axis of the bud arranged perpendicular to the hyphal axis** (Figs. BXII.α.216 and BXII.α.217). Mature buds either separate from the hyphae as uniflagellated swarmers or remain attached. Extracellular polymers can be stained with ruthenium red and sometimes are visible in India ink mounts as thick capsules around mother cells. **Oxidized iron or manganese compounds are deposited on mother cells and later on hyphae**. Resting stages are not known. **Gram negative**, older cells variable. Swarmer cells are motile by a single subpolar or polar flagellum (Fig. BXII.α.218). Other stages of the cell cycle (Fig. BXII.α.219) are nonmotile. Colonies are yellowish or reddish brown to dark brown, due to accumulated iron or manganese oxides. Aerobic. Catalase positive (test is in absence of MnO_2 and at neutral pH). **Chemoorganotrophic**. Acetate is utilized as a carbon source; most strains also grow on caproate or pyruvate. Protein digests, such as yeast extract, peptone, Casamino acids, and soytone, serve as carbon and/or nitrogen sources. Organic nitrogen sources utilized by most strains are glutamate, aspartate, glycine, serine, threonine, and valine. Inorganic nitrogen compounds allow only poor growth of some isolates; nitrate is reduced by most strains. **Slow and poor growth occurs on agar media with 0.1–1% fulvic acid iron sesquioxide complexes as sole carbon and nitrogen sources.** Vitamin mixtures stimulate growth; lack of vitamins results in pleomorphic cells, which produce large granules of poly-β-hydroxybutyric acid. Growth is inhibited by polymyxin B and neomycin.

A partial oligonucleotide catalogue of the type species, *P. ferrugineum* (IFAM S-1290) has been published (Stackebrandt et al., 1988a).

The mol% G + C of the DNA is: 63–66.8.

Type species: **Pedomicrobium ferrugineum** Aristovskaya 1961, 957, emend. Gebers and Beese 1988, 308.

FURTHER DESCRIPTIVE INFORMATION

Phylogenetic treatment The phylogenetic position of *Pedomicrobium ferrugineum* IFAM S-1290^T and various other budding and prosthecate bacteria has been investigated by 16S rRNA cataloguing (Stackebrandt et al., 1988a), revealing an affiliation with *Alphaproteobacteria*. A coherent cluster has been found that em-

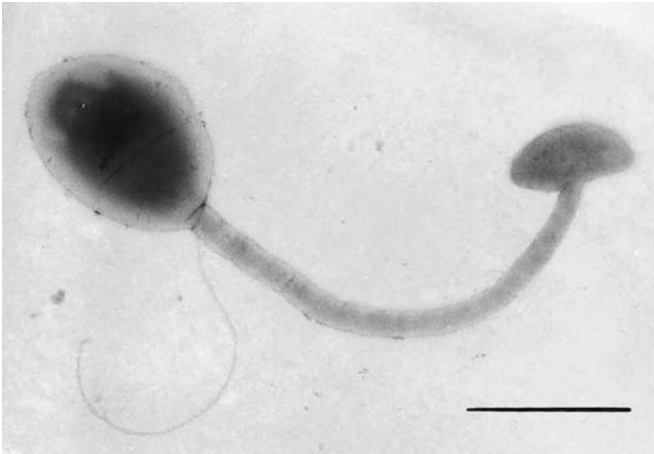

FIGURE BXII.α.216. *Pedomicrobium ferrugineum* IFAM S-1290^T. Transmission electron micrograph showing a mother cell with bud and flagellum. Note the orientation of the bud perpendicular to the hyphal tip. Uranylacetate negatively stained. Bar = 1 μm.

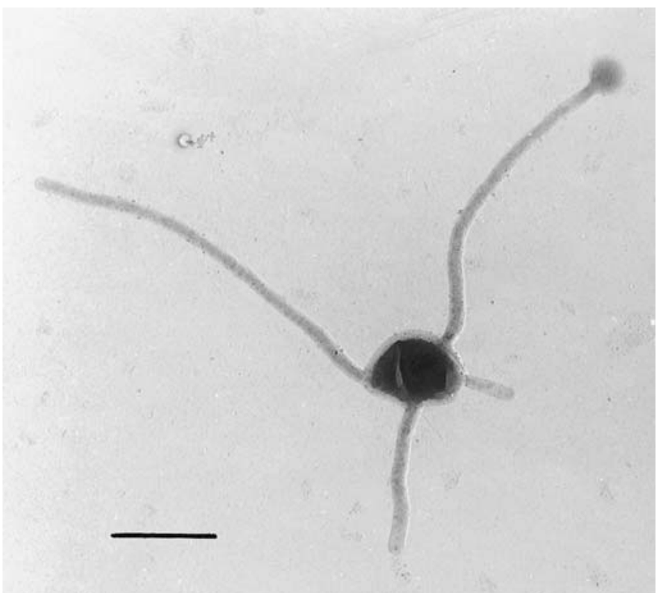

FIGURE BXII.α.217. *Pedomicrobium manganicum* IFAM E-1129^T. Electron micrograph of mother cell with hyphae and young bud. Platinum/carbon-shadowed. Bar = 1 μm.

braces strains of the genera *Hyphomicrobium*, *Filomicrobium*, *Pedomicrobium*, and *Dichotomicrobium*; *Pedomicrobium ferrugineum* and *Filomicrobium fusiforme* are more closely related to some *Hyphomicrobium* strains than they are to each other (Fig. BXII.α.205; see chapter on *Dichotomicrobium*). All of these bacteria share morphological features, such as the formation of prosthecae (hyphae) and reproduction by a budding process. However, the validity of *Pedomicrobium* and *Filomicrobium* as genera separate from *Hyphomicrobium* has been questioned based on morphological traits, which are considered less important for taxonomic separation (Stackebrandt et al., 1988a).

Roggentin and Hirsch (1989), have made an attempt to determine the relationships among 19 *Hyphomicrobium* strains by DNA–rRNA hybrid thermal stability. This study also included *Pedomicrobium ferrugineum* IFAM S-1290^T, *Hyphomonas* (three strains), *Rhodomicrobium* (one strain), and *Dichotomicrobium* (one strain). The dendrogram derived from average linkage clustering depicts the distant relationships of the *Pedomicrobium* and *Dichotomicrobium* strains to the hyphomicrobia (Fig. BXII.α.220).

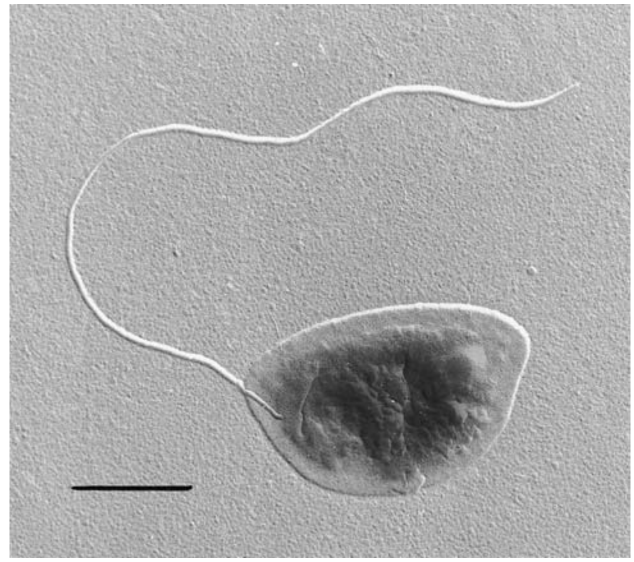

FIGURE BXII.α.218. *P. ferrugineum* IFAM S-1290^T. Electron micrograph showing swarmer cell with subpolar flagellum. Pt/C-shadowed. Bar = 0.5μm.

Cell morphology Cell shapes of some strains may vary; they can be rod- or spindle-shaped, tetrahedral, pear-, or bean-shaped. Hyphae vary in length according to cultural conditions; true branching occurs. Buds may arise in an intercalary fashion by localized hyphal swelling. Aristovskaya (1961) has occasionally observed direct budding and even cross division of single mother cells, but such observations have not been confirmed by other authors. Deposition of iron or manganese oxides has been observed among all strains studied so far (Aristovskaya, 1961; Khakmun, 1967; Gebers and Hirsch, 1978; Ghiorse and Hirsch, 1979). Many other bacteria with hyphae and buds may (depending on growth conditions) deposit iron or manganese oxides on their cell surfaces (Hirsch, 1968), but the perpendicular positioning of buds at the hyphal tips is a unique characteristic of pedomicrobia.

Chemotaxonomy The quinones, phospholipids, and fatty acids of ten *Pedomicrobium* strains have been studied (Sittig and Hirsch, 1992). All isolates have Q-10 as the respiratory quinone. The phospholipids present are phosphatidylglycerol, phosphatidylethanolamine, phosphatidylcholine, and bisphosphatidylglycerol. The fatty acid percentages are as follows: 8–22% normal, 64–89% unsaturated, 1–2% unsaturated/methylbranched, and 0–22% with a cyclopropane ring. Hydroxy fatty acids found in pedomicrobia were $C_{14:0\ 3OH}$ (82–84%), $C_{16:0\ 3OH}$ (5–8%), $C_{18:1\ 3OH}$ (4–5%), and $C_{18:0\ 3OH}$ (6–8%). A comparative study of pedomicrobia fatty acids (Eckhardt et al., 1979) indicates a strong influence of growth media and culture time on the percentage of octadecenoic acid.

The peptidoglycan of *P. ferrugineum* S-1290^T has been studied following alternating treatments with Pronase P and Na-dodecylsulfate solution with mercaptoethanol (Roggentin and Hirsch, 1982). It has been found to have so little D-alanine that only

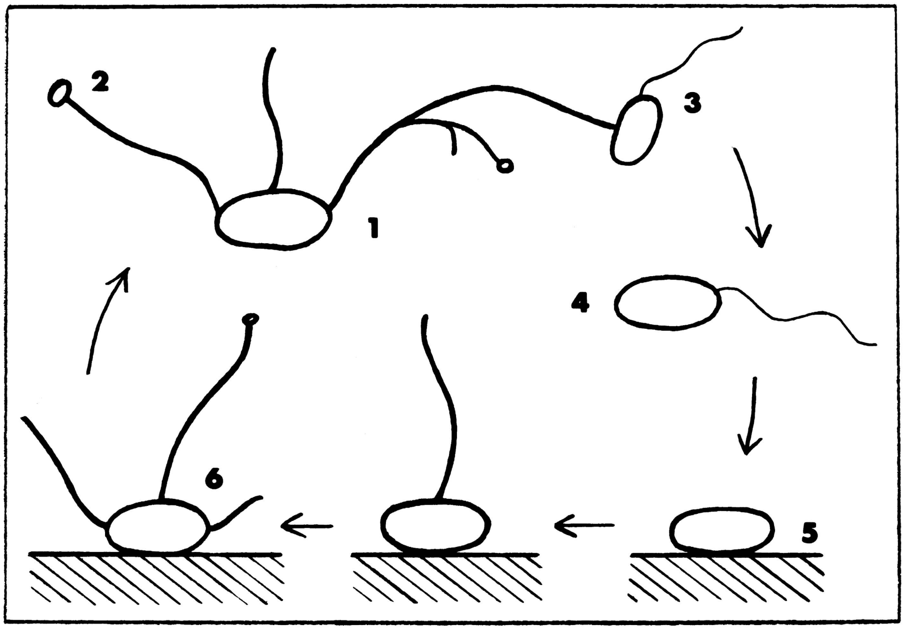

FIGURE BXII.α.219. Life cycle of *Pedomicrobium* species: *1*, mother cell with hyphae and buds; *2*, young bud; *3*, mature bud with flagellum; *4*, swarmer cell; *5*, young mother cell attached to solid surface; *6*, mature mother cell with hyphae and beginning bud formation.

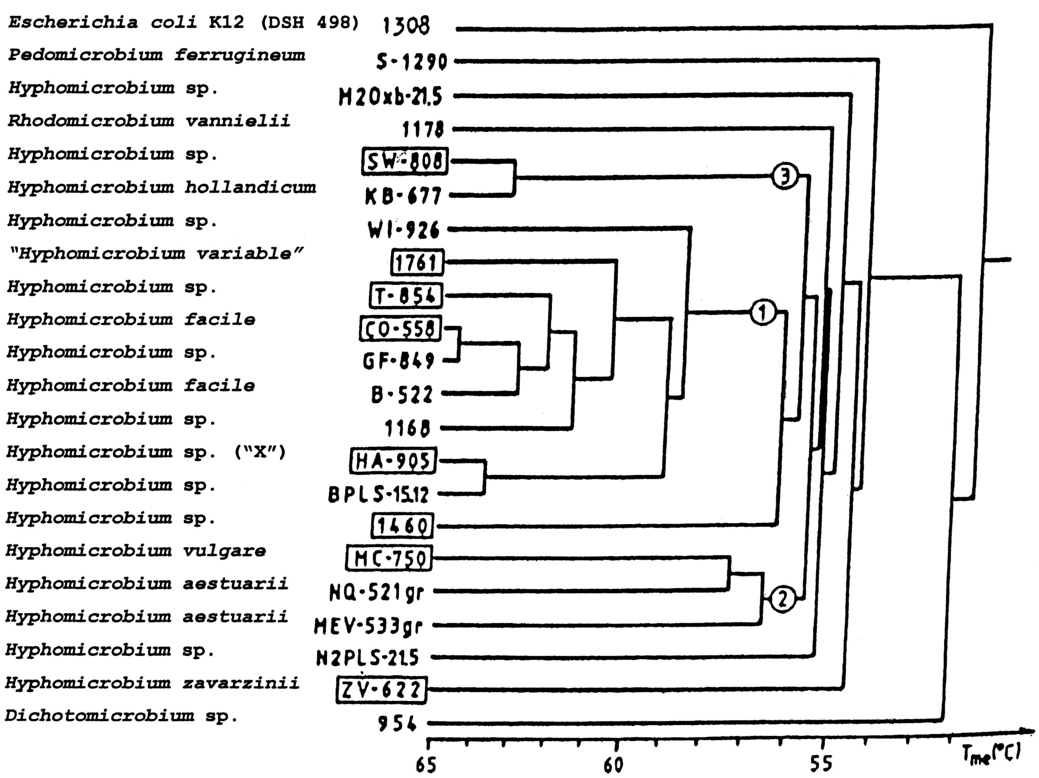

FIGURE BXII.α.220. Dendrogram derived from average linkage clustering showing relationships of *Pedomicrobium ferrugineum* IFAM S-1290^T, *Dichotomicrobium thermohalophilum* IFAM 954^T, *Rhodomicrobium vannielii* IFAM 1178^T (ATCC 17100^T), and various *Hyphomicrobium* strains. The data came from $T_{m(e)}$ values of DNA–rRNA duplexes. Strain numbers in boxes indicate strains that were used as ^{125}I labeled references (Roggentin and Hirsch 1989).

every eleventh side chain is cross-linked, a possible explanation as to why the cells can be pleomorphic on certain media.

DNA base compositions of pedomicrobia have been determined by Gebers et al. (1981a and 1985). They range from 64.8 to 65.7 mol% G + C (T_m) for *P. ferrugineum* isolates IFAM S-1290^T, P-1196, Q-1197, R-1198, and T-1130. *P. americanum* strains IFAM G-1381^T, BA-868, and BA-869 have 64.0, 64.7, and 64.4 mol% G + C, respectively (Gebers and Beese, 1988). For *P. manganicum* IFAM E-1129^T, the base ratio is 65.0 mol% G + C, and an unidentified strain (IFAM F-1225) has 64.9 mol% G + C. *Pedomicrobium australicum* strains IFAM ST-1306^T and WD-1255 have 65.0 and 62.8 mol% G + C, respectively.

Fine structure Electron microscopy of ultrathin sections of *Pedomicrobium* isolates IFAM Ba-868 and IFAM Ba-869 reveals a structured surface layer external to the outer membrane layer of the Gram-negative wall. This layer is composed of subunits with approximately 18.5 nm center-to-center spacing (Ghiorse and Hirsch, 1979). Additionally, an electron-dense polymer material is discovered on the mother cell surface of both strains, especially when ruthenium red is included in the fixative (Fig. BXII.α.221). The iron or manganese oxide deposits are present on or within this surface polymer layer. Up to three granules of poly-β-hydroxybutyric acid are stored per cell. Small, dense granules stainable with Loeffler methylene blue are suggestive of polyphosphate storage.

Cultural characteristics All pedomicrobia are aerobic to microaerophilic and grow in the range of 1–21% pO_2 (Gebers and Beese, 1988). On solid media, two types of colonies may develop. Type 1 colonies are round and convex and have even or radially frayed edges; sometimes they exhibit concentric rings. These colonies have a soft consistency. Type 2 colonies are round, flat and even; they may be crateriform (due to growth into the agar), and the edges are even or radially frayed. The cells in the center of these colonies are often lysed, giving colonies a granular appearance. Type 2 colonies have a cartilaginous consistency and may be removed from the agar intact. Upon spreading on solid media, both colony types give rise to type 1 and 2 colonies. Cultivation with frequent transfers to fresh medium favors large colonies over small ones.

Nutrition and growth conditions Generally, organic acids appear to be the most appropriate carbon sources for *Pedomicrobium* species. Alcohols and carbohydrates are utilized only in some cases (Tables BXII.α.181 and BXII.α.182). Several amino acids serve as nitrogen sources. All strains grow at 20–30°C and in the pH range of 7–9.

Genetics, molecular data Levels of genetic relatedness of nine *Pedomicrobium* isolates with the labeled type strain of *Hyphomicrobium vulgare* (IFAM MC-750^T) have been determined by DNA–DNA hybridization under optimal conditions; Table BXII.α.183 shows homologies of these strains with *H. vulgare* to be only 2–7% (Gebers et al., 1986). The *Pedomicrobium* hybridization data clearly indicate that the four type strains are distinct species.

Genome sizes have been determined for five *Pedomicrobium* strains by DNA renaturation kinetics. The M_r of these strains ranges from 2.81 to 3.0 × 10^9 Da (Kölbel-Boelke et al., 1985). Plotted against the G + C base ratios, pedomicrobia occupy an area quite distinct from those of other hyphal and budding gen-

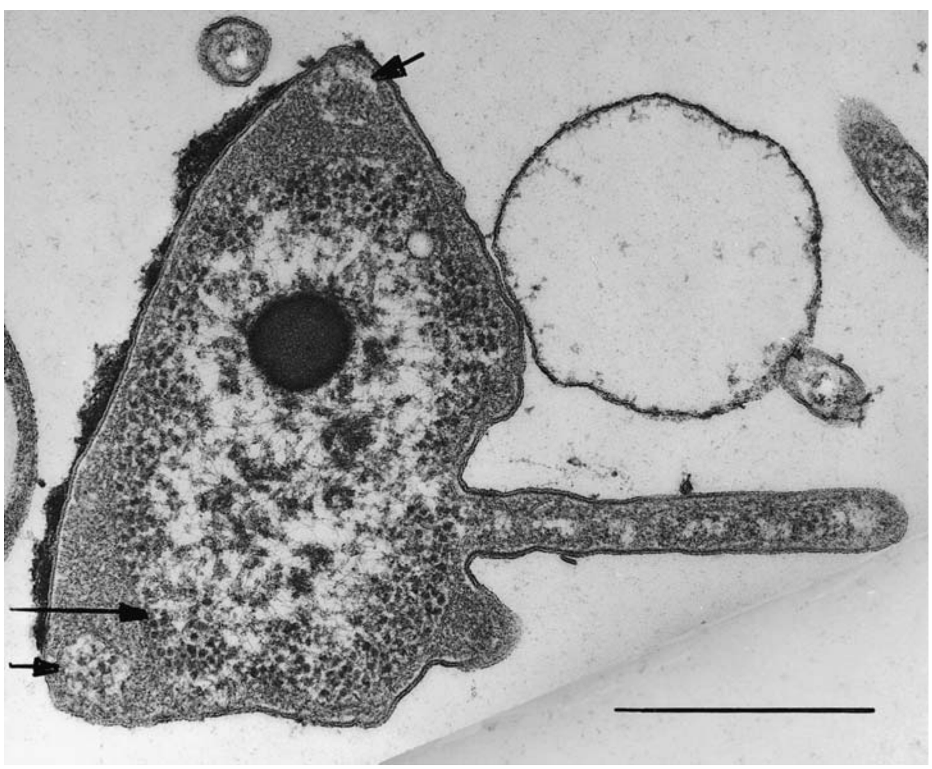

FIGURE BXII.α.221. Thin section of *Pedomicrobium australicum* IFAM ST-1306^T. Note intracytoplasmic membranes (*arrows*) and dense polyphosphate granule. Deposition of heavy metal oxides occurred primarily on polymer located on the cell surface opposite to the hyphal outgrowth. Bar = 0.5 μm (Reproduced with permission from R. Gebers and M. Beese, International Journal of Systematic Bacteriology, *38*: 305–315, 1988, ©International Union of Microbiological Societies.)

era, such as *Hyphomicrobium*, *Hyphomonas*, *Dichotomicrobium* ("genus D"), *Filomicrobium* ("genus F"), or "genus T".

Bacteriophages Samples from a freshwater lake (Fuhlensee, Kiel, Germany), inoculated with cultures of *Pedomicrobium americanum* IFAM G-1381[T] and shaken at 30°C, have resulted in the isolation of phage Pe-60 (C. Gliesche, personal communication). This DNA phage adsorbs to *Pedomicrobium* mother cells as well as to the hyphae (Figs. BXII.α.222 and BXII.α.223). The following IFAM pedomicrobia are lysed by phage Pe-60: G-1381[T], WD-1355, BA-868, BA-869, ST-1306[T], and S-1290[T]; however, two *Hyphomicrobium* isolates (B-522 and WI-926) are not susceptible (C. Gliesche, unpublished). Pe-60 has been partially characterized by Majewski (1986). It has a base composition of 57.2 mol% G + C, the molecular weight is 66.86 MDa, and it can be stored under chloroform or lyophilized. Phage Pe-60 belongs to the *Styloviridae*.

Antibiotic sensitivities The strains of *P. ferrugineum*, *P. americanum*, and *P. australicum* all show high sensitivity to eight antibiotics, but low inhibition by sulfanilamide (Table BXII.α.184). *P. manganicum* is not inhibited by most of these antibiotics (Gebers, 1981; Gebers and Beese, 1988).

Pathogenicity *Pedomicrobium ferrugineum* IFAM S-1290[T] and *P. manganicum* IFAM E-1129[T] are not pathogenic for mice or guinea pigs within 7 days after intraperitoneal or intravenous injection of up to 10^8 cells. They are not β-hemolytic and do not utilize mannitol, but all strains cause antibody formation, with agglutination dilution titers reaching 1:2 (Famureva et al., 1983).

Ecology *Pedomicrobium* species are widely distributed in podzolic and other soils, in freshwater lakes, ponds, and brooks, in iron springs, and in seawater; they are ubiquitous (Table BXII.α.185).

Enrichment and Isolation Procedures

Isolation of *P. ferrugineum* and *P. manganicum* from soil, especially from podzolic soil, can be achieved by Aristovskaya's procedure (Aristovskaya, 1961) as described by Gebers and Hirsch (1978, 1979). Podzolic soil samples are suspended by repeatedly shaking in 0.85% (w/v) saline solution and are streaked onto humic gel agar[1]. Since fulvic acids serve as sole carbon and nitrogen sources, this medium is rather selective, but allows only slow growth of *Pedomicrobium* species. After 3–12 weeks incubation at 20 or 30°C in the dark, *Pedomicrobium*-containing colonies of the agar plate "enrichment" may be recognized by their yellowish brown to dark brown color, due to accumulation of iron and/or manganese oxides. Identification of iron-depositing colonies by the Prussian blue reaction is difficult because humic gel usually contains Fe (III) and thus stains intensely. Screening for manganese-depositing colonies, however, is facilitated by flooding the enrichment plate with leuko-berbelin blue I or leuko-crystal violet. Since *Pedomicrobium*-containing colonies are strongly coherent, spreading onto agar plates is enhanced by sterile grinding of the inoculum in a drop of saline solution. Pedomicrobia obtained with this agar plate enrichment procedure grow, albeit slowly, on humic gel agar without any other additions.

For final purification streaks, humic gel agar is supplemented with a vitamin solution[2]. This is necessary because *Pedomicrobium*

1. Humic gel agar: Humic gel (fulvic acids complexed with metal sesquioxides) is prepared by hydrochloric acid extraction from (podzolic) humus soil (Ponomareva, 1964; Gebers and Hirsch, 1978). 5 g (wet weight) humic gel and 18 g agar (Difco) are suspended in 1000 ml of distilled water and autoclaved; the mixture is poured as thick layers into Petri plates; the final pH is 5–6.

2. Vitamin solution (Van Ert and Staley, 1971) consists of: 2 mg biotin, 2 mg folic acid, 5 mg thiamin·HCl, 5 mg calcium pantothenate, 0.1 mg cyanocobalamin, 5 mg riboflavin, 5 mg nicotinamide, 5 mg *p*-aminobenzoic acid, 10 mg pyridoxin·HCl, and 1000 ml distilled water.

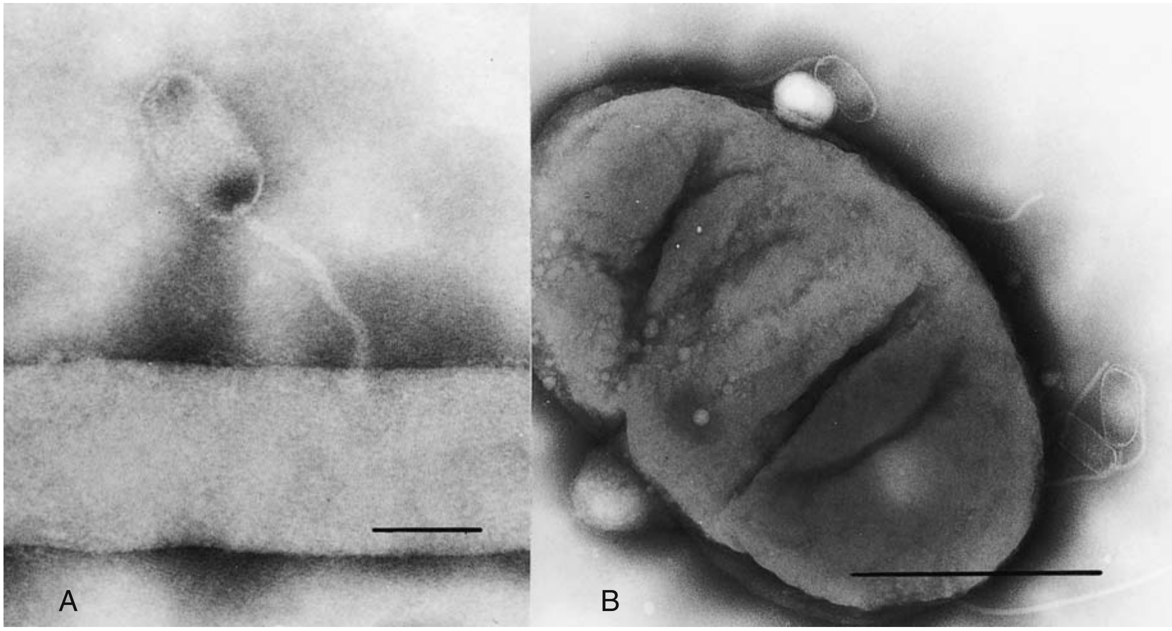

FIGURE BXII.α.222. Adsorption of phage Pe-60 of *Pedomicrobium americanum* IFAM G-1381^T to a hypha (*A*) or mother cell (*B*). Negatively stained with 1% uranylacetate. Bars = 0.1 μm (A) and 0.5 μm (B). (Courtesy of C. Gliesche and D.M. Majewski, unpublished.)

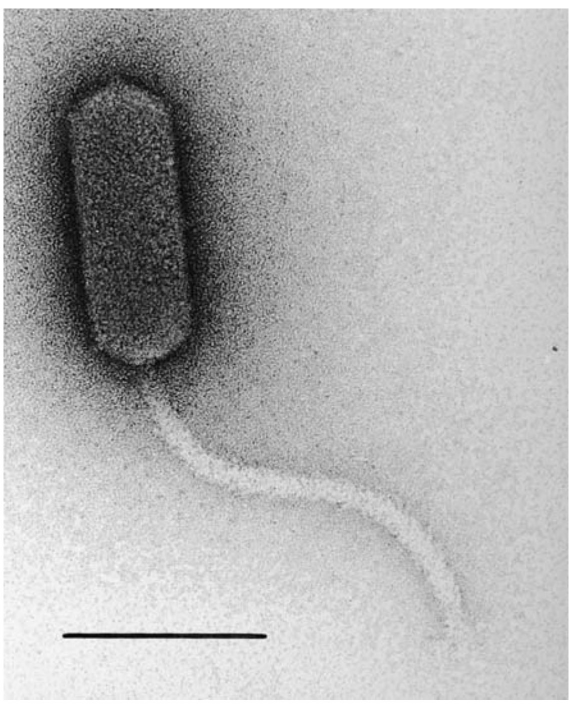

FIGURE BXII.α.223. Phage Pe-60 (*Styloviridae*) from *Pedomicrobium americanum* IFAM G-1381^T. Electron micrograph on carbon-coated mica negatively stained with 1% uranylacetate. Bar = 0.1 μm. (Courtesy of C. Gliesche and D.M. Majewski, unpublished.)

cells have an irregular, pleomorphic appearance when grown without vitamins. Pedomicrobia also grow at pH 7.0 in synthetic media, which contain (besides some nutrients) either 400 mg/50 ml iron powder, an iron paper clip (400 mg), or 630 mg FeS (Gebers and Hirsch, 1979). *Pedomicrobium* standard medium (PSM)[3] supplemented with 0.015% (w/v) Actidione (Roth, Germany) and 1.8% agar may serve as an alternative medium for enrichment and isolation of pedomicrobia. Actidione inhibits many fungi, but this medium also allows growth of contaminating bacteria; therefore, the selectivity for *Pedomicrobium* species is low.

Aquatic strains of *Pedomicrobium* spp. have been enriched by Staley et al. (1980) as follows: water samples are diluted in a series of test tubes with peptone medium DPM[4] up to the 10^{-9} dilution. Inoculated tubes are incubated at 20–30°C until surface pellicles develop in the highest dilution tubes. For isolation of pedomicrobia, the pellicles are streaked onto DPM solidified with 1.8% agar. A combination of growth on indicator medium PC and micromanipulation has enabled Sly and Arunpairojana (1987) to isolate manganese-oxidizing pedomicrobia from freshwater. The PC medium employed here contains (w/v): 0.005% Difco yeast extract, 0.002% $MnSO_4 \cdot 4H_2O$, 2% Bacto agar, and 50 μg/ml of Actidione (Upjohn, USA).

Maintenance Procedures

Pedomicrobium species grown on PSM agar slants survive for more than 2 years in tightly sealed screw-capped tubes at 20–30°C. For longer preservation, 1 part of an exponentially growing liquid

3. PSM consists of 10 mM sodium acetate, 0.5 g yeast extract (Difco), 1 ml "metals 44" (see below), 10 ml vitamin solution, and distilled water to 1000 ml. Adjust the pH to 9.0; final pH after autoclaving: 7.0. "Metals 44" (Cohen-Bazire et al., 1957) consists of: 125 mg EDTA, 547.5 mg $ZnSO_4 \cdot 7H_2O$, 250 mg $FeSO_4 \cdot 7H_2O$, 77 mg $MnSO_4 \cdot H_2O$, 19.6 mg $CuSO_4 \cdot 5H_2O$, 12.4 mg $Co(NO_3)_2 \cdot 6H_2O$, 8.85 mg $Na_2B_4O_4 \cdot 10H_2O$, and 50 ml distilled water. Adjust pH to 6.8.

4. DPM consists of 0.1 g peptone (Difco), 20 ml Hutner's modified salts solution (see below), 10 ml vitamin solution, and distilled water up to 1000 ml. Hutner's modified salts solution (Cohen-Bazire et al., 1957) contains (per liter, w/v): 10 g nitrilotriacetic acid, 29.7 g $MgSO_4 \cdot 7H_2O$, 3.3 g $CaCl_2 \cdot 2H_2O$, 12.7 mg $NaMoO_4 \cdot 2H_2O$, 99.0 mg $FeSO_4 \cdot H_2O$, and 50 ml "metals 44". Distilled water is added after pH adjustment. The nitrilotriacetic acid is first neutralized with potassium hydroxide. Then, the remaining ingredients are added before the pH is adjusted to 7.2 with KOH and H_2SO_4. Finally, distilled water is added to make 1 liter of solution.

culture is freeze-dried at −55°C; addition of milk can be omitted. Viability of these lyophils needs to be tested frequently, and counting of the percentage of survivors is necessary. Medium PSM, either autoclaved or sterile-filtered, is recommended for the revival of such lyophilized cultures and for subculturing. Freeze-dried cultures are stored at 4°C and should not be kept for more than 2–3 years. Storage in liquid nitrogen may be required.

Procedures for Testing Special Characters

Testing for iron and manganese oxide accumulation from fulvic acid sesquioxide complexes is impractical because these humic substances are available solely from podzolic soils, which occur only in certain regions on earth. Therefore, it is recommended that instead of fulvic acid complexes embedded in agar media, elemental iron, FeS, or $MnSO_4$, be employed. The specificity of the test is reduced, however, since autoxidation of elemental iron and pyrite occurs at physiological pH, and various bacteria are capable of accumulating the oxidized products. The presence of ferric iron is indicated by a blue color around cells or colonies when a solution of 2% $K_4[(Fe(CN)_6]$, acidified with HCl, is added (Prussian blue reaction). The presence of manganese (IV) is demonstrated by a blue color reaction with a 0.4% (w/v) solution of leuko-berbelin blue I (Krumbein and Altmann, 1973) or with Feigl's reagent (1% [w/v] benzidiniumhydrochloride in a 7% [v/v] acetic acid solution). In contrast to Feigl's reagent, leuko-berbelin blue I does not inhibit viability of the cells.

Methods used for cell wall disintegration, DNA extraction, and purification have been described by Gebers et al. (1985). Shearing of DNA and radioactive labeling have been described by Gebers et al. (1981b, 1986). DNA reassociation procedures, S1 nuclease treatment, and specific conditions for hybridization reactions are given by Gebers and Beese (1988).

Differentiation of the genus *Pedomicrobium* from other genera

Table BXII.α.186 provides primary characteristics that can be used to differentiate the genus *Pedomicrobium* from morphologically similar taxa. The most important property of pedomicrobia is the bud elongation perpendicular to the hyphal long axis; deposition of oxidized iron or manganese on the cell surface is not restricted to *Pedomicrobium* species, but either is often dependent on the production of polyanionic surface polymers (Ghiorse and Hirsch, 1978a).

Taxonomic Comments

Originally, five species of *Pedomicrobium* were described: *P. ferrugineum*, *P. manganicum* (Aristovskaya, 1961), *"P. podsolicum"* (Aristovskaya, 1963), *P. americanum*, and *P. australicum* (Gebers and Beese, 1988). None of several *Pedomicrobium*-like isolates known fit the description of *"P. podsolicum"*, and cultures of this species are not available. In addition, it is not mentioned in the Approved Lists of Bacterial Names.

Some manganese oxide-depositing bacteria discussed in the literature have been considered to be pedomicrobia, either because of their growth on organomineral complexes of fulvic acids and/or because of the presence of a large number of hyphae on the mother cells. Khakmun (1967) has observed such bacteria in soils of Sakhalin and named them *Pedomicrobium manganicum* biovar sachalinicum because of their more oval cell shape. Neither a pure culture nor a formal description of these is available. A micrograph published shows *Hyphomicrobium*-like, possibly budding bacteria, but lacks any indication of a perpendicular bud location on the hyphal tips. Epicellular iron-depositing aquatic bacteria studied by Hirsch (1968) or Hirsch and Rheinheimer (1968) were originally considered to represent pedomicrobia, but these bacteria also resemble hyphomicrobia and lack the perpendicular bud orientation on the hyphal tips. A bacterial isolate (strain T37) with manganese oxide deposition on the cell surface has been obtained from manganese oxide sludge on the inside of hydroelectric pipelines (Tyler and Marshall, 1967). This organism resembles hyphomicrobia morphologically, grows with methanol, and does not show the characteristic positioning of the buds. After subculturing, it eventually loses the ability to oxidize and deposit manganese, but instead oxidizes iron (Ghiorse and Hirsch, 1978b).

Real pedomicrobia have been observed by Kutuzova et al. (1972) after exposing slit peloscopes in ooze-containing vessels.

TABLE BXII.α.185. Differential characteristics of *Pedomicrobium* species[a]

[b]Data from Gebers and Beese (1988).

[c]Data from Gebers (1981).

[d]W.C. Ghiorse (personal communication).

One of her electron micrographs labeled "*Pedomicrobium*-type organism" (Fig.1e) shows a tetrahedral mother cell, but with a straight bud attachment to the hypha, somewhat similar to that of *Dichotomicrobium* spp. However, Fig. 2g in that reference shows a bacterium with the morphology of a *Pedomicrobium* sp.; pure cultures have not been isolated.

Recently, Sly et al. (1988) have isolated eight strains of manganese-oxidizing pedomicrobia from "dirty drinking water" and biofilm samplings of southeast Queensland, Australia. Pure cultures have been obtained by micromanipulation and inoculation of PC agar, which contains (w/v): 0.005% Difco yeast extract, 0.002% $MnSO_4 \cdot 4H_2O$, and 2% Bacto agar (Sly and Arunpairojana, 1987). To control fungal growth, 50 μg/ml of Actidione (Pfizer, USA) were added. The morphology of these new isolates is thought to correspond closely to that of the *P. manganicum* type strain (IFAM E-1129[T]), although cells and mature swarmer

cells of the new isolates are slightly smaller: 0.4–0.6 × 0.8–1.2 µm and 0.4 × 0.6 µm, respectively, as compared to IFAM E-1129[T], whose cells and swarmer cells are 0.4–0.9 × 0.4–1.5 µm and 0.9 × 1.5 µm, respectively. The buds develop at hyphal tips in a lateral (perpendicular) as well as a polar orientation; mother cells have no more than four hyphae. There are also some physiological differences from the type strain. The eight new isolates fail to grow with acetate or glutamate as the sole carbon source; Vitamin Solution no. 6 does not stimulate growth, and besides manganese they oxidize iron, albeit much less rapidly. Their DNA base ratio range is 65.6–66.6 mol% G + C.

Sly et al. (1988) considered these eight isolates to be new strains of *P. manganicum*, which may have appeared justifiable in view of the fact that this species was based on only one isolate and thus its variability was not yet known. The observation of lateral, as well as polar, positions of buds on hyphal tips raises questions about an important differentiating characteristic of the genus. This aspect needs further investigation.

The phylogenetic relationships of six *Pedomicrobium* strains and some other hyphal and budding *Alphaproteobacteria* have been recently investigated by 16S rRNA sequence analysis (Cox and Sly, 1997, Fig. 1). Unfortunately, *Pedomicrobium australicum* strains IFAM ST-1306[T] and IFAM WD-1355 could not be revived from lyophilized cultures (P. Hirsch, personal communication) and thus, DNA of these strains had to be extracted from the lyophils. The other pedomicrobia studied came as viable cultures from the Australian Culture Collection (ACM). The whole 16S rRNA genes were sequenced in both the forward and reverse directions and the sequences aligned manually with sequences of *Hyphomicrobium vulgare*, *Hyphomonas jannaschiana*, *Hirschia baltica*, *Rhodomicrobium vannielii*, *Escherichia coli*, *Neisseria gonorrhoeae*, *Desulfovibrio desulfuricans*, and *Campylobacter jejuni*. The pedomicrobia cluster coherently and separately from the other genera of budding *Alphaproteobacteria* and have sequence similarities of 96.2–99.9%. Within this cluster, *P. manganicum* IFAM E-1129[T] is the most distantly related strain to the other pedomicrobia. Strain

ACM 3067, one of the eight manganese-oxidizing isolates from "dirty drinking water" (Sly et al., 1988), is highly related to *P. americanum* IFAM G-1381^T, and the two *P. australicum* strains (IFAM ST-1306^T and IFAM WD-1355) are almost identical, with a sequence similarity of 99.9%. Also highly related, with sequence similarities greater than 99%, are *P. americanum*, the two *P. australicum* strains, and the isolate ACM 3067. Because of their data and some phenotypic differences, Cox and Sly (1997) have questioned the taxonomic validity of *Pedomicrobium australicum*, but suggested retaining *P. americanum*. Differences between these two species in the utilization of carbon sources (Table BXII.α.182) and temperature optima (Table BXII.α.185) may well be an expression of their variability, as similar differences also exist among the three isolates of *P. americanum*. However, since the low DNA–DNA similarity data (Table BXII.α.183) clearly indicate differences on the species level, more phenotypic information and further studies of viable cultures (as well as a neotype culture) of *P. australicum* are needed to solve this problem.

Acknowledgments

We gratefully acknowledge provision of *Pedomicrobium*-like strains by J.A. Babinchak, E. Dale, W.C. Ghiorse, and J.T. Staley. Skillful technical assistance was rendered by M. Beese, B. Hoffmann, J. Kock, K. Lutter-Mohr, and U. Wehmeyer. We are also grateful for help and discussions with T.V. Aristovskaya (St. Petersburg).

Differentiation of the species of the genus *Pedomicrobium*

The differential characteristics of the species of *Pedomicrobium* are listed in Table BXII.α.185. Other descriptive characteristics are summarized in Tables BXII.α.181, BXII.α.182, BXII.α.183, and BXII.α.184.

List of species of the genus Pedomicrobium

1. **Pedomicrobium ferrugineum** Aristovskaya 1961, 957^{AL} emend. Gebers and Beese 1988, 308.
fer.ru.gi' ne.um. M.L. neut. adj. *ferrugineum* of iron color.

Cells oval, spherical, rod-shaped, tetrahedral, or bean-shaped, 0.6–2.0 × 0.6-2.5 μm. Oxidized iron, but not manganese, is deposited on mother cells and occasionally later on hyphae. Swarmer cells with one polar or subpolar flagellum. Morphology of colonies as given for the genus. Further morphological and physiological characteristics are listed in Tables BXII.α.181, BXII.α.182, BXII.α.183, BXII.α.184, BXII.α.185, and BXII.α.186.

Heterotrophic, aerobic to microaerophilic. The temperature for optimal growth is 29–30°C, and the temperature range is 10–40°C. Optimal pH for growth: 9.0; the pH range is 3.5–10.0. Growth occurs in the presence of up to 0.1% (w/v) NaCl; no growth, but survival, has been observed in the presence of 1–5% NaCl. Higher concentrations of NaCl are bacteriocidal. Requires cyanocobalamine (1 μg/l) for growth.

Isolated from podzolic soils in northern Germany.

The mol% G + C of the DNA is: 64.5–66.8 (T_m, Bd).

Type strain: IFAM S-1290, ATCC 33119, DSM 1540.

GenBank accession number (16S rRNA): X97690.

Additional Remarks: Other strains include IFAM P-1196 (ATCC 33116), IFAM Q-1197 (ATCC 33117), IFAM R-1198 (ATCC 33118), and IFAM T-1130 (ATCC 33120).

2. **Pedomicrobium americanum** Gebers and Beese 1988, 310^{VP}
a.me.ri.ca' num. M.L. neut. adj. *americanum* obtained from America.

Cells oval, tetrahedral, short rods, bean-, or spindle-shaped, up to 1.3 × 1.8 μm (Fig. BXII.α.224). Mother cells with 1–3 hyphae originating laterally or polarly. Bud attachment perpendicular to the hyphal tip; intercalary budding occurs. Swarmer cells with one subpolar flagellum. Extracellular polyanionic polymer located primarily on cell surfaces opposite lateral hyphae, with incrustations of iron or manganese oxides (depending on growth conditions). Intracytoplasmic membranes have been observed.

The temperature optimum for growth is 32–38°C; the range is 15–41°C. The pH optimum for growth in HEPES-buffered media is 7.6–8.4. Growth on carbon sources varies with the strains; all isolates grow on acetate, but none utilizes caproate, D-lactate, D-glucose, D-ribose, methanol, or ethanol. Strain IFAM BA-869 also grows on citrate, formate, gluconate, glycerol, D,L-malate, propanol, and succinate. Good growth occurs with (w/v) 0.05% yeast extract or 0.025% yeast extract plus 0.025% peptone. Nitrate does not

FIGURE BXII.α.224. *Pedomicrobium americanum* IFAM G-1381^T, Pt/C-shadowed. Note orientation of buds. Bar = 2 μm. (Electron micrograph courtesy of H. Völker, Kiel.)

serve as a sole nitrogen source, but ammonia and several amino acids support growth (Table BXII.α.181). Cyanocobalamin (1 μg/l) is required for growth of the type strain, IFAM G-1381^T. Growth of strain IFAM BA-868 is stimulated by 0.1% NaCl. Catalase is produced, except by strain IFAM BA-869. Nitrate is reduced by all strains. The three isolates are inhibited by several antibiotics (Table BXII.α.184), but the type strain is resistant to sulfanilamide.

Habitat: bogwater and freshwater puddles in North America.

The mol% G + C of the DNA is: 64–65 (T_m).

Type strain: ACM 3090, ATCC 43612, IFAM G-1381.

GenBank accession number (16S rRNA): X97692.

Additional Remarks: Other strains include IFAM BA-868 (ATCC 43613) and IFAM BA-869 (ATCC 43615).

3. **Pedomicrobium australicum** Gebers and Beese 1988, 313^{VP}
au.stra' li.cum. M.L. neut. adj. *australicum* isolated from Australia.

Cells oval, tetrahedral, short rods, bean- or spindle-shaped, 1.2 × 1.8 μm with up to 3 hyphae originating laterally or polarly. Cells may produce up to 3 buds at the same time; intercalary budding has been observed. Motile swarmers have one subpolar flagellum. Extracellular polyanionic polymer is produced primarily on the cell surface opposite the lateral hypha (Fig. BXII.α.221). Iron oxides are deposited on the surface when cells are grown on fulvic acid iron sesquioxide complexes or in the presence of 5 mg/l of $FeSO_4 \cdot 7H_2O$. Deposition of manganese oxides occurs on PSM agar in the presence of 1.54 mg/l $MnSO_4 \cdot H_2O$. Ultrathin sections reveal intracytoplasmic membranes, which form compartments, possibly due to unfavorable growth conditions.

The temperature optimum for growth is 29–32°C; the range is 15–36°C. The optimal pH for growth in buffered media is 7.3–7.6. Utilization of carbon sources varies between the two strains (Table BXII.α.182): both grow with acetate, D,L-malate, lactose, and gluconate, but not with D-lactate, citrate, or D-ribose. Good growth occurs with (w/v) 0.05% yeast extract or with 0.025% yeast extract plus 0.025% peptone. Organic nitrogen sources include several amino acids (Table BXII.α.181); ammonia may serve as a nitrogen source, but nitrate does not. Strain WD-1355 is stimulated by cyanocobalamin (1 μg/l) and by the presence of 0.1% NaCl. Both strains are positive for catalase and for nitrate reduction. The strains are inhibited by a variety of antibiotics (Table BXII.α.184), but not by sulfanilamide.

DNA–DNA similarity studies (Table BXII.α.183) clearly demonstrate species identity between the two isolates.

Habitat: a freshwater reservoir in New South Wales, Australia.

The mol% G + C of the DNA is: 65 (ST-1306^T) and 63 (WD-1355) (T_m).

Type strain: ATCC 43611, IFAM ST-1306.

GenBank accession number (16S rRNA): X97693.

Additional Remarks: Other strains include IFAM WD-1355 (ATCC43614).

4. **Pedomicrobium manganicum** Aristovskaya 1961, 957^{AL} emend. Gebers 1981, 315.
man.ga' ni.cum. M.L. neut. adj. *manganicum* of manganese.

Cells primarily spherical, oval, or short rods, 0.4–0.9 × 0.4–1.5 μm, with 1–5 hyphae per cell. Colonial morphology as for the genus. Cells have polyanionic polymer and manganese oxide deposits, but only rarely deposits of iron oxide. Buds may be formed intercalary in hyphae. Intracytoplasmic membranes occur. Cells grow on acetate, caproate, formate, D-glucose, D-lactate, pyruvate, and D-ribose. Optimal growth temperature 30°C. Growth is stimulated by vitamin mixtures, but inhibited by gentamicin and bacitracin. Further physiological characteristics are listed in Tables BXII.α.181, BXII.α.182, BXII.α.183, BXII.α.184, BXII.α.185, and BXII.α.186.

Isolated from a quartzite rock pool in France.

The mol% G + C of the DNA is: 65 (T_m).

Type strain: ACM 3038, ATCC 33121, DSM 1545, IFAM E-1129.

GenBank accession number (16S rRNA): X97691.

Genus XV. **Prosthecomicrobium** *Staley 1968, 1940^{AL} emend. Staley 1984, 304*

CHERYL JENKINS , FRED A. RAINEY, NAOMI L. WARD AND JAMES T. STALEY

Pros.the' co.mi.cro.bi.um. Gr. fem. n. *prosthece* appendage; Gr. adj. *micros* small; Gr. masc. n. *bios* life; M.L. neut. n. *Prosthecomicrobium* appendage (-bearing) microbe.

Unicellular bacterium with coccobacillary to rod-shaped cells ranging in diameter from 0.8 to 1.2 μm and containing **numerous prosthecae** extending from all locations on the cell surface. Prosthecae, which may number from 10 to more than 30/cell, are typically short (i.e., <1.0 μm in length); some species, however, also produce longer prosthecae (>2.0 μm). **Cells divide by budding**. Buds are produced directly from the mother cell, never from tips of prosthecae. **Gram negative**. Motile and nonmotile species exist. Motile organisms produce single polar to subpolar flagella; one species forms gas vacuoles but not flagella. **Obligately aerobic, nonfermentative, heterotrophic**. A variety of sugars and organic acids are used as energy sources for growth. All strains tested require one or more B vitamins for growth. Oxidase and catalase positive. Found in soils and fresh and marine waters.

The mol% G + C of the DNA is: 64–70.

Type species: **Prosthecomicrobium pneumaticum** Staley 1968, 1940.

FURTHER DESCRIPTIVE INFORMATION

The genus *Prosthecomicrobium* comprises a diverse collection of multiply-appendaged prosthecate bacteria. All produce short prosthecae, i.e., prosthecae that are typically <1.0 μm in length. The shortest prosthecae appear as small bumps on the surface of the cell and cannot be readily discerned by light microscopic examination of cells. The "corn cob" organism (now named *"P. polyspheroidum"*) was so named because of the numerous short stubby prosthecae that are regularly arranged on the surface of the cell. Somewhat longer prosthecae are conical in shape and are typical for many species. These range in length from <0.25 to >1.0 μm, depending on the species and the growth medium

(longer prosthecae may be produced when phosphate is limiting growth). Even longer prosthecae are produced by some strains. For example, *P. pneumaticum* occasionally produces prosthecae >2.0 μm long. This, however, occurs rarely (Staley, 1968). Some strains of the marine species *P. litoralum* also produce longer appendages. One species, *P. hirschii*, produces both short appendaged as well as long-appendaged cells. The long-appendaged cells closely resemble those of *Ancalomicrobium adetum* and could be confused with them if morphology is used as the sole criterion for identification of organisms from natural samples.

Buds are produced as outgrowths at or near one pole of the cell (Vasilyeva, 1972a; Staley, 1984). These typically appear as a forked protuberance from the dividing pole. The bud enlarges and differentiates to produce a mirror image of the mother cell. As in *Ancalomicrobium*, buds appear to be synthesized *de novo* (Staley, 1973b; Staley et al., 1981).

Some species of *Prosthecomicrobium* produce flagella. Flagella are always single and may be found in a polar or subpolar position on the cell. One species, *P. pneumaticum*, does not produce flagella but produces gas vacuoles. Some species are nonmotile and do not produce flagella or gas vacuoles.

All species are obligately aerobic chemoorganotrophs that use a variety of sugars, organic acids, and sugar alcohols for growth. All species can grow on a simple, defined medium (Staley, 1981a). All species require one or more water-soluble vitamins for growth.

Prosthecomicrobium species are not known to be pathogenic to humans.

Prosthecomicrobium species are found in soils, freshwater habitats of all trophic states (Staley et al., 1980), as well as in the marine habitat (Bauld et al., 1983). They have been reported as important components of biofilms in sewage treatment processes and in pulp mill aeration lagoons (Stanley et al., 1979). Bacteria that resemble these forms have also been reported in the intestinal tracts of insects and other animals (Cruden and Markovetz, 1981); however, it is uncertain whether they have been concentrated from the foodstuff or are truly indigenous to this environment.

Enrichment and Isolation Procedures

The same procedures described for *Ancalomicrobium* isolation can be used for isolation of *Prosthecomicrobium*. The dilute peptone enrichment procedure has been used successfully for the isolation of most strains. Recognition of short-appendaged species in the enrichment culture is difficult because they are not as noticeable as the longer appendaged species. Nonetheless, even with the phase-contrast microscope, they can be detected because of their slightly irregular surface (Fig. BXII.α.225). However, it may be desirable to observe preparations from wet mounts with the transmission electron microscope to confirm their presence in the enrichments. When their numbers have reached significant proportions of the total numbers of bacteria (i.e., 5%), then attempts at isolation should be made. Dilute peptone agar plates should be streaked and incubated at room temperature for 2 weeks or more. Colonies are typically small. Wet mounts of each colony type should be prepared and examined by phase-contrast microscopy for identification. The morphology of the resulting pure culture should be confirmed by examination of whole cells with the transmission electron microscope. Additional information on isolation has been published elsewhere (Staley, 1981a).

Maintenance Procedures

Strains can be maintained on slants in the refrigerator for at least 1 month. MMB agar (Staley, 1981a) with glucose as a carbon source provides a favorable growth medium. Lyophilization can be used for long-term preservation.

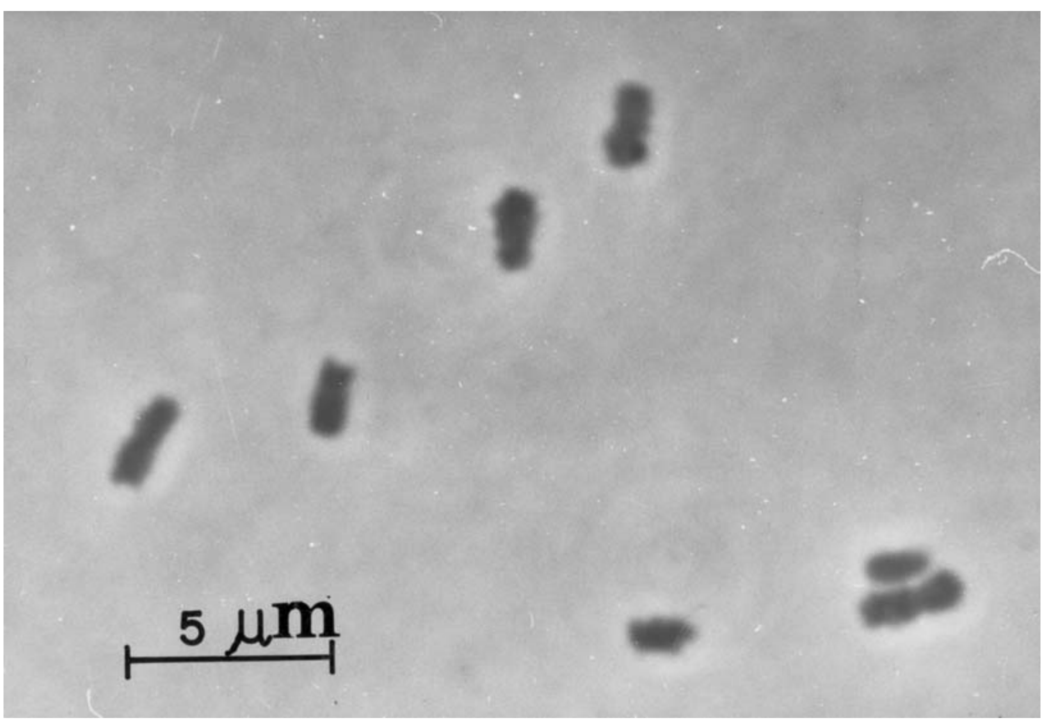

FIGURE BXII.α.225. Phase contrast photomicrograph of *P. enhydrum* showing several cells. Note the irregular surface of the cells due to the presence of numerous short prosthecae.

Differentiation of the genus *Prosthecomicrobium* from other genera

Only two genera pose major problems for differentiation. These are the genera *Ancalomicrobium* and *Verrucomicrobium*. Differentiation from the former genus is discussed in detail in the section on *Ancalomicrobium*. Morphologically, *Ancalomicrobium* can be distinguished from *Prosthecomicrobium* because of its conical cells and lack of short-appendaged cells. Furthermore, *Ancalomicrobium* is a genus of facultative anaerobes that ferments selected sugars. Thus, the Hugh–Leifson test can be used to distinguish between these two groups (cf. Table BXII.α.165 in *Ancalomicrobium*). The major phenotypic feature differentiating cells of the genus *Verrucomicrobium* from those of *Prosthecomicrobium* is the presence of fimbriae, which extend from the tips of the prosthecae. These are absent in cells of the genus *Prosthecomicrobium*.

Taxonomic Comments

Morphologically, *Prosthecomicrobium* comprises a diverse collection of bacteria. There are differences in appendage length, motility, gas vacuole formation, habitat, and carbon source utilization among the species so far described.

The mol% G + C of the DNA within the genus ranges from 64 to 70 (Staley and Mandel, 1973). Results of DNA–DNA hybridization studies (Moore and Staley, 1976) suggest that additional species exist that have not yet been fully described. Several unnamed strains have been deposited in the ATCC (ATCC 27825, 27826, and 27833). *Ancalomicrobium adetum* shows only low levels of homology with *Prosthecomicrobium* species that have been tested.

Phylogenetic analysis of the 16S ribosomal RNA gene sequences of *P. pneumaticum*, *P. enhydrum*, and several uncharacterized *Prosthecomicrobium*-like strains demonstrates that these organisms belong to the *Alphaproteobacteria*. Morphologically similar organisms of the genus *Ancalomicrobium* also belong to the *Alphaproteobacteria* but form a separate and distinct genus based on 16S rRNA analyses. These findings are consistent with earlier 16S rRNA cataloging studies on these genera (Schlesner et al., 1989). Members of the genus *Verrucomicrobium* are not phylogenetically affiliated with *Prosthecomicrobium* strains, despite being morphologically similar, and fall within a separate bacterial division.

Analyses of the 16S rRNA genes of *Prosthecomicrobium* strains also demonstrate that the genus *Prosthecomicrobium* is polyphyletic (Fig. BXII.α.226). Of the strains that have been sequenced, only strain P4.10, an isolate from a pulp mill oxidation lagoon, clusters with the type species, *P. pneumaticum*. Four additional strains, including *P. enhydrum*, cluster with *Devosia riboflavina* (formerly *"Pseudomonas riboflavina"*), a non-prosthecate organism. One additional strain SCH71 does not cluster with either of these groups. Thus, the taxonomy of members of the genus *Prosthecomicrobium* should be reexamined.

16S rRNA sequencing of the remaining characterized species *P. litoralum* and *P. hirschii* has not yet been completed and is required to assess the extent of diversity within the *Prosthecomicrobium* genus. Such studies would also help to clarify the taxonomic relationships of the strains *"P. polyspheroidum"*, *"P. consociatum"*, *"P. mishustinii"*, which are at present only unofficially named (Vasilyeva and Lafitskaya, 1976; Vasilyeva et al., 1991).

Reclassification of *P. enhydrum* and related strains is also required as they do not cluster with the type species of *Prosthecomicrobium*, *P. pneumaticum*. These strains should therefore be reassigned to a different genus.

Differentiation of the species of the genus *Prosthecomicrobium*

The characteristics differentiating among the species of the genus *Prosthecomicrobium* are listed in Table BXII.α.187.

List of species of the genus Prosthecomicrobium

1. **Prosthecomicrobium pneumaticum** Staley 1968, 1940[AL]
pneu.ma' ti.cum. N.L. adj. *pneumaticum* inflated, containing gas vacuoles.

Most prosthecae are short (i.e., <1.0 µm in length); however, long prosthecae are occasionally produced (Fig. BXII.α.227). Gas vacuoles are formed by the type strain. Flagella are not produced. Ammonium, but not nitrate, can be used as a sole nitrogen source for growth. A variety of sugars, both hexoses and pentoses, monosaccharides and disaccharides, can be used as carbon sources for growth (Table BXII.α.187). Sugar alcohols and methyl sugars fucose and rhamnose can also be used. Biotin, thiamine, and vitamin B_{12} are required for growth. The temperature range for the type strain is 9–42°C. Optimal pH: 6.0–6.5, although good growth also occurs at pH 7.0. Colonies are translucent to opaque white (the chalky white color is due to the formation of gas vacuoles). Colony size is quite variable.

The mol% G + C of the DNA is: 69–70 (Bd).

Type strain: ATCC 23633, VKM B-1389.

2. **Prosthecomicrobium enhydrum** Staley 1968, 1940[AL]
en.hy' drum. N.L. adj. *enhydrum* living in water, aquatic.

Prosthecae are always short, i.e., <0.5 µm, giving the cell an irregular surface when observed by phase-contrast microscopy (Fig. BXII.α.225). Cells are motile by a polar to subpolar flagellum (Fig. BXII.α.228). Gas vacuoles are not produced. Ammonium but not nitrate can be used as a sole source of nitrogen in media containing an appropriate carbon source and vitamins. Pentoses and hexoses are commonly used by the type strain. Some disaccharides and organic acids are also used as carbon sources (Table BXII.α.187). Thiamine is required for growth. The temperature range for growth of the type strain is 9–37°C. The pH optimum for growth is 7.0. Colonies may be white (type strain) or pigmented yellow or red.

The mol% G + C of the DNA is: 65.8 (Bd).

Type strain: ATCC 23634, VKM B-1376.

3. **Prosthecomicrobium hirschii** Staley 1984, 304[VP]
hirsch' i.i. N.L. gen. *hirschii* of Hirsch; named in honor of P. Hirsch, an authority on budding bacteria.

Prosthecae may be short (i.e.,< 1.0 µm in length) or long (>2.0 µm in length), depending on the cell. Both short- and long-appendaged cells occur simultaneously in culture (Fig. BXII.α.229). Cells may be motile by single polar or subpolar flagella. Gas vacuoles are not formed. Sugars and organic acids are commonly used as carbon sources. Long chain organic acids such as valerate and caproate are used. Methanol and ethanol can also be used as

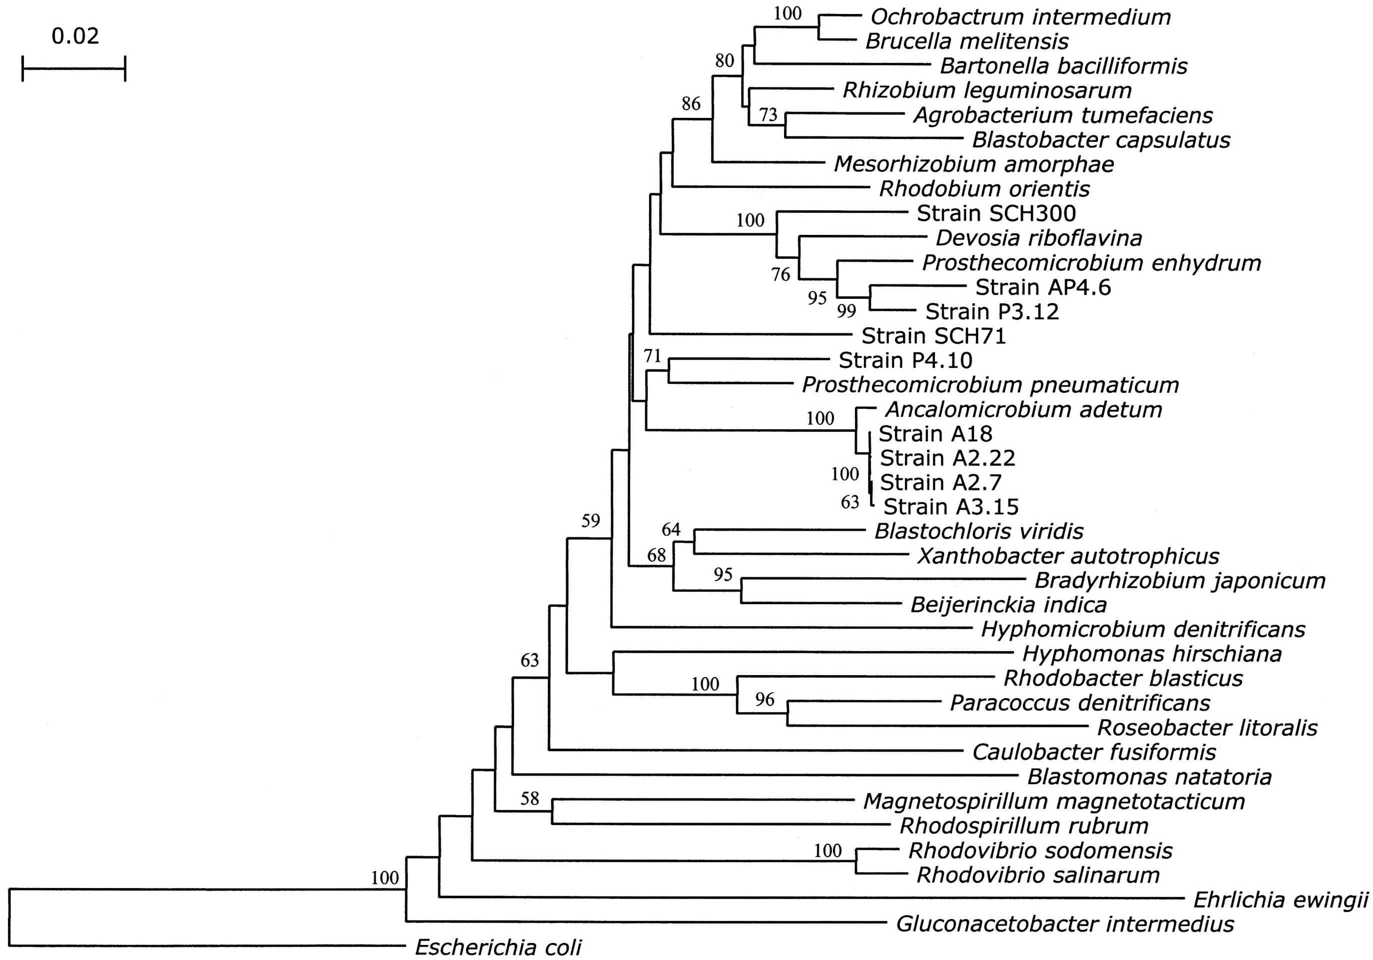

FIGURE BXII.α.226. Phylogenetic tree of 16S rRNA sequences showing the positions of various *Prosthecomicrobium* strains within the *Alphaproteobacteria.* The genus is polyphyletic, with the type strain *P. pneumaticum* and the pulp mill aeration lagoon isolate P4.10 forming one clade, while *P. enhydrum* and the *Prosthecomicrobium*-like strains AP4.6, P3.12, and SCH300 form a separate clade that includes the nonprosthecate organism *Devosia riboflavina.* Strain SCH71, which is also *Prosthecomicrobium*-like in morphology, forms a third group with no clear phylogenetic affiliation. The tree was constructed using Kimura-2-parameter distances and the neighbor joining algorithm with 100 bootstrap replications within the program TreeCon. Bootstrap values above 50% are shown. Bar indicates 0.02 substitutions per site.

[a]Symbols: +, 90% or more strains are positive; −, 90% or more strains are negative; nd, not determined; ±, indefinite.

[b]Strains of both species rarely produce long appendages.

[c]These are formed rarely.

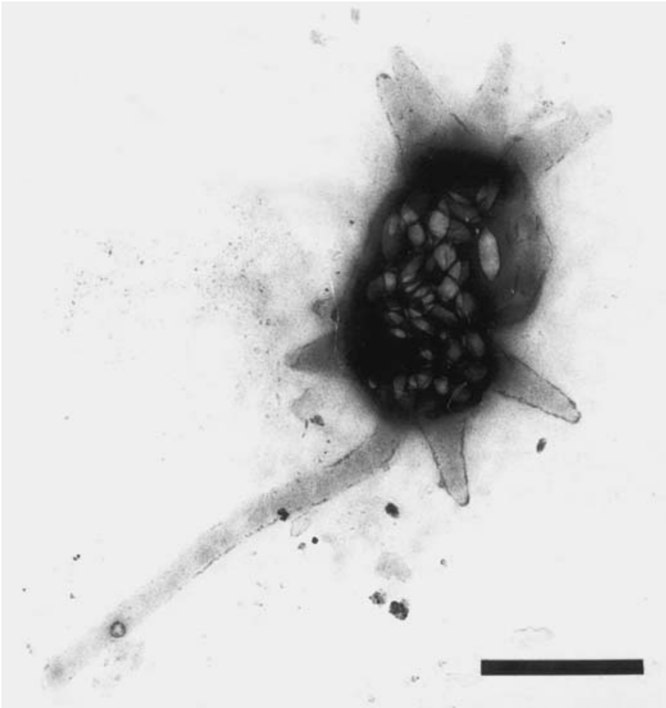

FIGURE BXII.α.227. *P. pneumaticum* as observed by electron microscopy. Note the gas vesicles within the cell and the single long prostheca. Bar = 1.0 μm.

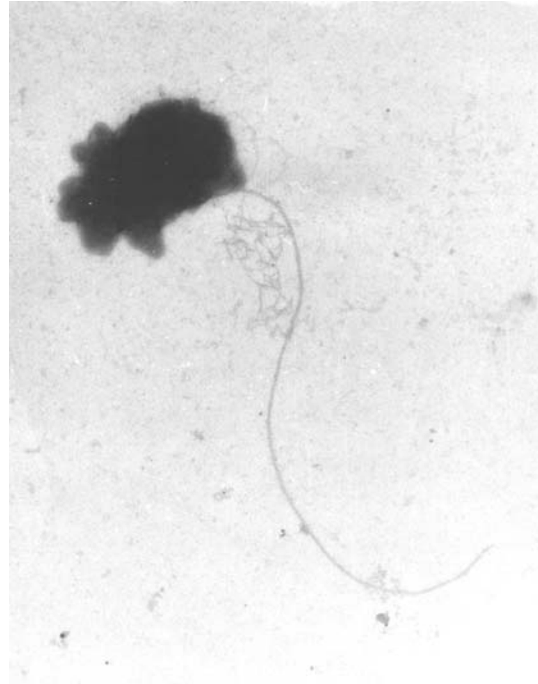

FIGURE BXII.α.228. Electron micrograph of *P. enhydrum*. Note the subpolar location of the single flagellum.

carbon sources. Biotin, nicotinic acid, pantothenate, and thiamine are required for growth. Colonies are circular in form and umbonate in elevation. They have an entire margin and are pink in color.

The mol% G + C of the DNA is: 67.9–69.9 (Bd).

Type strain: ATCC 27832.

4. **Prosthecomicrobium litoralum** Bauld, Bigford and Staley 1983, 613[VP]

li.to.ra′ lum. L. adj. *litoralis* of the seashore.

Prosthecae are mostly short (i.e., <0.5 μm in length), although occasionally long prosthecae are formed. Nonmotile. Neither flagella nor gas vacuoles are produced. Ammonium can be used as a sole source of nitrogen. A variety of pentoses and hexoses can be used for growth as well as some sugar alcohols and organic acids (Table BXII.α.187). Agar digestion occurs on prolonged incubation. Sodium ions are required for growth. The minimum salinity at which growth occurs is 5‰ the optimum, 25‰ (Table BXII.α.187). These bacteria are psychrotrophic. Their minimum temperature for growth is 1–5°C, depending on the strain, and their optimum is between 27° and 34°C. Colonies are white and raised initially and, after prolonged incubation, become cream-colored and umbonate. Agar digestion is noticeable around colonies on plates incubated at least 30 days at room temperature.

The mol% G + C of the DNA is: 66–67 (Bd).

Type strain: 524-16, ATCC 35022.

5. **"Prosthecomicrobium polyspheroidum"** (Nikitin and Vasilyeva 1968) Vasilyeva and Lafitskaya 1976, 768 (**"Agrobacterium polyspheroidum"** Nikitin and Vasilyeva 1968, 444.)

po.ly.spher.oi′ dum. N.L. adj. *polyspheroidum* many spheroids, i.e., having numerous bumps.

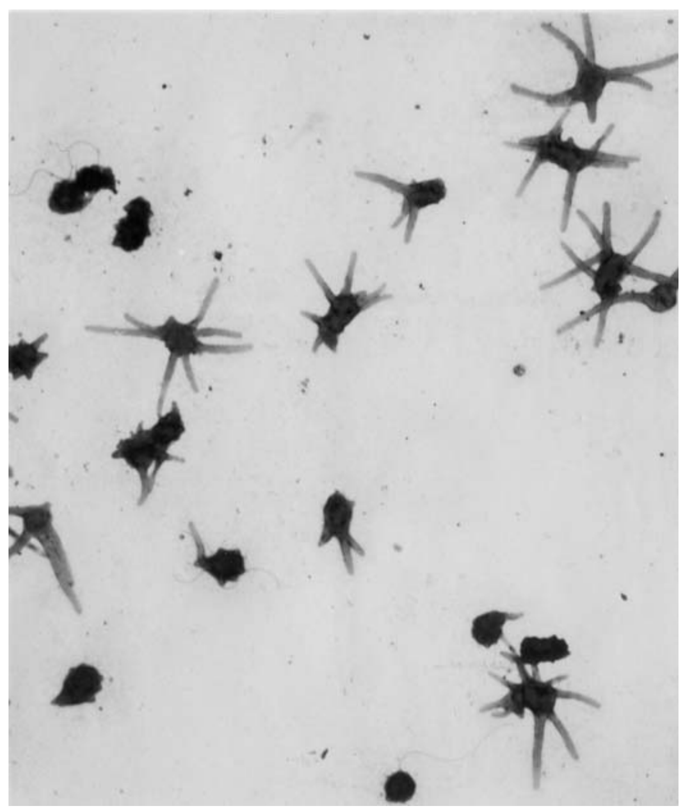

FIGURE BXII.α.229. Electron micrograph of *P. hirschii* showing short-appendaged cells, long-appendaged cells, and flagella.

Cells have many (up to 230/cell) short prosthecae (i.e., <0.1 μm in length). They are distributed in slightly spiral rows along the length of the rod-shaped cells, giving the appearance of a corn cob (Fig. BXII.α.230). Cells, which measure about 0.5 μm in diameter and up to 5.1 μm in length, are motile by a polar flagellum. Lateral buds may be formed under some conditions of growth. Prosthecae may not be evident in cultures containing more than 0.1% organic nutrients. Monosaccharides and disaccharides are metabolized by pentose phosphate and the Entner–Doudoroff pathway, with the formation of alcohols, organic acids, and aromatics (cf. Lafitskaya et al., 1976). Thiamine and riboflavin are required for growth. Nitrate reduced to nitrite. Voges–Proskauer and methyl red tests are negative. Colonies are punctiform after 2–3 days of growth and attain a diameter of about 1 mm after 10 days. They are raised with entire margins, opaque, cream colored, and slimy. Optimal temperature: 28–30°C; optimal pH: 6.5–7.1.

The mol% G + C of the DNA is: 64 to 67 (Bd).

Deposited strain: AUCM B-1313.

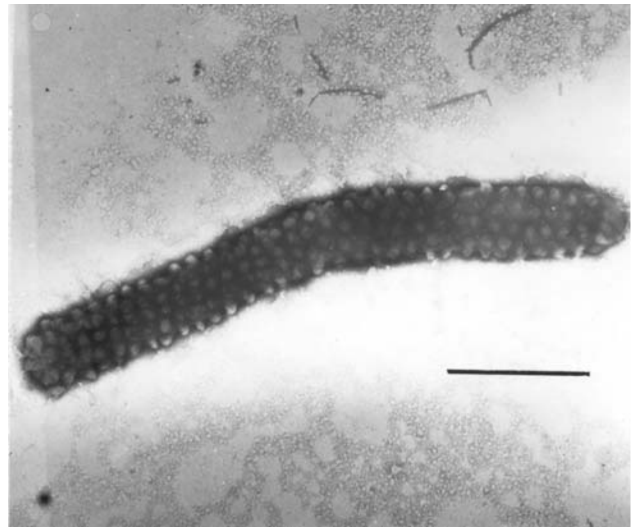

FIGURE BXII.α.230. Electron micrograph of *"P. polyspheroidum"*. Note the arrangement of the numerous short prosthecae in rows. Bar = 2.0 μm. (Photograph courtesy of L.V. Vasilyeva.)

Genus XVI. **Rhodomicrobium** *Duchow and Douglas 1949, 415^AL emend. Imhoff, Trüper and Pfennig 1984, 341*

Johannes F. Imhoff

Rho.do.mi.cro'bi.um. Gr. n. *rhodon* the rose; Gr. adj. *micros* small; Gr. n. *bios* life; M.L. neut. n. *Rhodomicroibum* red microbe.

Ovoid to elongate-ovoid bacteria showing polar growth and performing a characteristic vegetative growth cycle. This cycle includes the formation of peritrichously flagellated swarmer cells and nonmotile "mother cells", which form prosthecae from one to several times the length of the mother cell. Daughter cells originate as spherical buds at the end of the prosthecae and may undergo differentiation in various ways. **Gram negative, belonging to the *Alphaproteobacteria*. Internal photosynthetic membranes are of the lamellar type. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series.** The **predominant cellular fatty acid is $C_{18:1}$**, which comprises more than 80% of the membrane-bound fatty acids. **Ubiquinone and rhodoquinone with 10 isoprene units** are present, and the lipopolysaccharides are characterized by a glucosamine-containing, phosphate-free lipid A with amide-bound $C_{16:0\ 3OH}$.

Cells grow preferably photoheterotrophically under anoxic conditions in the light. Photoautotrophic growth may be possible with hydrogen and sulfide as electron sources. Various **organic substrates, molecular hydrogen, ferrous iron, and sulfide at low concentrations may be used as photosynthetic electron donors**. Cells are also **able to grow under microoxic to oxic conditions in the dark**.

Mesophilic freshwater bacteria with a preference for acidic pH, between 5.2 and 6.5.

The mol% G + C of the DNA is: 61.8–63.8.

Type species: **Rhodomicrobium vannielii** Duchow and Douglas 1949, 415.

Further descriptive information

Rhodomicrobium vannielii is the sole species of this genus. Its morphology and growth cycle resemble those of the nonphototrophic *Hyphomicrobium* species (Hirsch, 1974a). The characteristic growth cycle has been the object of intensive studies (Whittenbury and Dow, 1977) and is outlined in the species description. *Rhodomicrobium vannielii* grows best under anoxic conditions in the light with a number of carbon sources at low light intensities and acidic pH (5.5–6.5). Dinitrogen and ammonia are the best nitrogen sources. Ammonia is assimilated via glutamine synthetase/glutamate synthase (NADH-dependent); low activities of a glutamate dehydrogenase (NADPH-dependent) are also present (Brown and Herbert, 1977). Sulfate can be used as the sole sulfur source and is assimilated via adenosine-5′-phosphosulfate (Imhoff, 1982). Sulfide is tolerated at 2–3 mM and oxidized exclusively to tetrathionate in sulfide-limited chemostat culture. In batch culture, sulfide may react with the tetrathionate formed, and under these conditions, thiosulfate and elemental sulfur are the major end products (Hansen, 1974).

Particular similarities have been found in the amino acid sequences of the "small type" cytochromes c_2 of *Rhodomicrobium vannielii*, *Blastochloris viridis*, and *Rhodoblastus acidophilus* (Ambler et al., 1979). As in a few other purple nonsulfur bacteria (*Rhodopila globiformis*, *Rubrivivax gelatinosus*, and *Rhodocyclus tenuis*), a high potential iron–sulfur protein (HiPIP) is present (T.E. Meyer, personal communication). High proportions of unusual aminolipids have been found in *Rhodomicrobium vannielii* (Park and

Berger, 1967; Imhoff et al., 1982). The fatty acid composition is characterized by an extremely high proportion of $C_{18:1}$, comprising more than 85% of the membrane-bound fatty acids, as in *Hyphomicrobium* species, *Pedomicrobium* species, *"Nitrobacter agilis"*, and *Nitrobacter winogradskyi* (Auran and Schmidt, 1972; Eckhardt et al., 1979). Ubiquinone and rhodoquinone with 10 isoprene units are present (Hiraishi and Hoshino, 1984). As is the case with *Rhodoblastus acidophilus*, but not with most of the phototrophic *Alphaproteobacteria*, the lipid A of *R. vannielii* contains glucosamine (not 2,3-diamino-2,3-dideoxyglucose) as the sole amino sugar and amide-bound $C_{16:0\ 3OH}$ (Weckesser et al., 1995).

A new isolate, which has been tentatively identified as *R. vannielii* and grown in the light with ferrous iron as the sole energy source, has been found to use ferrous iron as a photosynthetic electron donor, as has the type strain (Widdel et al., 1993; Heising and Schink, 1998). It has been noted that growth is not supported over prolonged time periods when ferrous iron is the exclusive electron source, and that acetate and succinate stimulate growth with ferrous iron (Heising and Schink, 1998). Ferric iron is not reduced in the dark, and manganese salts are neither oxidized nor reduced.

Enrichment and Isolation Procedures

Rhodomicrobium is commonly found in mud and water of ponds and lakes, as well as in wastewater. About 50% of enrichment cultures with freshwater sediments prove to contain *Rhodomicrobium* species (Whittenbury and Dow, 1977). *Rhodomicrobium* has also been isolated from brackish-water and seawater habitats (Hirsch and Rheinheimer, 1968).

Enrichment, isolation, and growth occur under conditions suitable for most of the other species of the purple nonsulfur bacteria (see chapter Genus *Rhodospirillum*) with organic acids or other organic substrates as carbon and electron sources (Imhoff, 1988; Imhoff and Trüper, 1992). For selective enrichments, a succinate–mineral medium with an initial pH of 5.2–5.5 should be used, and growth factors should be omitted (Pfennig, 1969a).

Maintenance Procedures

Cultures of *Rhodomicrobium vannielii* are well preserved in liquid nitrogen, by lyophilization, or at −80°C in a mechanical freezer. Late-exponential-phase cell suspensions should be mixed with glycerol or DMSO to yield the final cryoprotectant concentrations of 10% and 5%, respectively, kept at 0°C for 15 min, and then frozen immediately.

Differentiation of the genus *Rhodomicrobium* from other genera

The lamellar structure of the internal photosynthetic membranes, the polar growth mode, and the budding type of multiplication are similar to those of other budding purple nonsulfur bacteria. Prostheca formation and the characteristic growth cycle are the most obvious distinguishing properties. In addition, according to rRNA–DNA hybridization studies, *Rhodomicrobium* is clearly distinguished from other purple nonsulfur bacteria (Gillis et al., 1982).

Among the closest phylogenetic relatives of *Rhodomicrobium*, based on 16S rDNA sequence analysis, are *Hyphomicrobium vulgare*, *Blastochloris viridis*, and *Rhodopseudomonas palustris* (Kawasaki et al., 1993b). Other outstanding characteristics are the compositions of lipid A, polar lipids, and fatty acids. Major differentiating properties between *Rhodomicrobium* and other phototrophic *Alphaproteobacteria* are shown in Tables BXII.α.168 and BXII.α.169 of the chapter on the genus *Blastochloris* as well as in Tables 3 (pp. 125–126) and 4 (p.127) in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. The phylogenetic relationships of these bacteria, based on 16S rDNA sequences, are shown in Fig. 2 (p. 128) of that chapter.

List of species of the genus Rhodomicrobium

1. **Rhodomicrobium vannielii** Duchow and Douglas 1949, 415^{AL}

van.niel′i.i. M.L. gen. n. *vannielii* of van Niel; named for C.B. van Niel, an American microbiologist.

Mature cells are ovoid to lemon-shaped, 1.0–1.2 × 2.0–2.8 μm, and multiply by polar growth and budding (Fig. BXII.α.231). Cells perform a characteristic vegetative growth cycle; the motile, peritrichously flagellated swarmer cells, which lose their flagella later in the growth cycle, form prosthecae of about 0.3 μm in diameter, and a daughter cell arises as a spherical bud at the end of each prostheca. This daughter cell may separate from the prostheca and start a new cycle as a swarmer cell. After the swarmer cell is released, the pole of the prostheca is free for the formation of another bud. Alternatively, the daughter cell may remain attached to the prostheca and form another prostheca at the opposite pole. Branching of prosthecae may occur by lateral outgrowth of new prosthecae from the primary prostheca, upon which the first daughter cell formed. A branched prostheca can be formed only on the most recently synthesized prostheca, and plug formation occurs in the prostheca of each daughter cell before that prostheca branches to form the next daughter cell. Only one daughter cell is formed at a time. Because cells tend to remain attached to the prosthecae, aggregates containing large numbers of cells are usually formed. In addition, smaller cells, called exospores, may eventually be produced. These polyhedral cells are 1.0–1.5 μm in diameter. One to four such cells are formed sequentially as buds at a common branching point at the end of a prostheca (Fig. BXII.α.231). The exospores are more resistant to dryness and heat than are normal vegetative cells.

Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. No lamellae are present in the prosthecae. The color of cell suspensions is from salmon pink to deep orange-brown to red. Absorption spectra of living cells have maxima at 378, 461, 488–490, 522–525, 800–807, and 869–872 nm. Aerobically grown cells are colorless to pale orange-brown. Photosynthetic pigments are bacteriochlorophyll *a* (esteri-

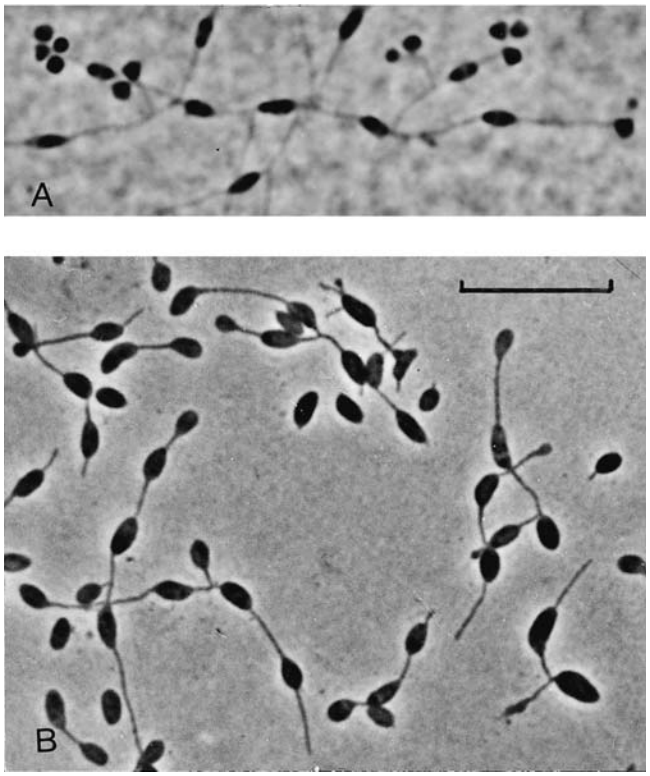

FIGURE BXII.α.231. *Rhodomicrobium vannielii* strain DSM 163. *A*, polyhedral exospores as buds at the ends of short filaments with common branching points. *B*, cells with filaments and buds of various sizes. Phase-contrast micrographs. Bar = 10 μm. (Courtesy of N. Pfennig.)

fied with phytol) and carotenoids of the spirilloxanthin series, with rhodopin as the major component and with small amounts of beta-carotene.

Cells grow preferably photoheterotrophically under anoxic conditions in the light, but photoautotrophic growth and chemotrophic growth under microoxic to oxic conditions is possible. Substrates used are acetate, propionate, butyrate, valerate, caproate, caprylate, ethanol, propanol, butanol, lactate, pyruvate, malate, fumarate, succinate, and malonate. Some strains also use methanol, formate, oxalacetate, OH-butyrate, and glycerol. Not used are citrate, tartrate, fructose, glucose, mannose, mannitol, sorbitol, glycolate, oxalate, pelargonate, benzoate, aspartate, arginine, and glutamate. Addition of HCO_3^- is essential only when CO_2 cannot be generated from the organic carbon source.

Molecular hydrogen and sulfide may serve as electron donors for photoautotrophic growth. The latter is oxidized to tetrathionate in sulfide-limited continuous culture, but thiosulfate and elemental sulfur are formed as major oxidation products in batch culture. In addition, ferrous iron is oxidized in the light, but may not support growth over prolonged times if supplied as the exclusive electron donor. Growth with ferrous iron is stimulated by acetate and succinate. Ammonia and dinitrogen, as well as Casamino acids and yeast extract, are used as nitrogen sources. Some strains grow poorly with nitrate and urea. Sulfate can serve as the sole sulfur source. No organic growth factors are required.

Mesophilic freshwater bacteria with a preference for slightly acidic pH showing optimal growth at 30°C and pH 6.0 (pH range: 5.2–7.5).

The mol% G + C of the DNA is: 61.8–63.8 (Bd).

Type strain: ATCC 17100, DSM 162.

Genus XVII. **Rhodoplanes** *Hiraishi and Ueda 1994b, 671*[VP]

Akira Hiraishi and Johannes F. Imhoff

Rho.do.pla'nes. Gr. n. *rhodon* rose; Gr. n. *planos* a wanderer; M.L. masc. n. *Rhodoplanes* a red wanderer.

Cells are rod-shaped, motile by means of polar, subpolar, or lateral flagella, and **multiply by budding and asymmetric cell division**. They are **Gram-negative and belong to the *Alphaproteobacteria*. Internal photosynthetic membranes are present as lamellar stacks** parallel to the cytoplasmic membrane (Fig. BXII.α.232). **Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. Straight-chain, monounsaturated $C_{18:1}$ is the predominant component of the cellular fatty acids and $C_{16:0}$ is a second major component. Ubiquinones and rhodoquinones with 10 isoprene units (Q-10 and RQ-10) are present.**

Growth is preferably photoheterotrophic under anoxic conditions in the light, with simple organic substrates as carbon and electron sources. Photoautotrophic growth with sulfide as the electron donor does not occur. **Chemotrophic growth is possible under oxic conditions in the dark** at full atmospheric oxygen tension and by denitrification under anoxic conditions in the presence of nitrate. Growth factors may be required.

Mesophilic freshwater bacteria with preference for neutral pH. Some representatives may be thermotolerant.

Habitats: freshwater and wastewater environments.

The mol% G + C of the DNA is: 66.8–69.7.

Type species: **Rhodoplanes roseus** (Janssen and Harfoot 1991) Hiraishi and Ueda 1994b, 671 (*Rhodopseudomonas rosea* Janssen and Harfoot 1991, 27.)

Further descriptive information

Based on the 16S rDNA sequence information, *Rhodoplanes* species belong to the *Alphaproteobacteria* (Hiraishi and Ueda, 1994b). The nearest phylogenetic neighbors are *Blastochloris* species, which show approximately 94% identity of 16S rDNA sequences to those of *Rhodoplanes* species.

Although all *Rhodoplanes* species reproduce by budding and asymmetric cell division, the mode of budding differs somewhat with the species (Fig. BXII.α.233). *Rhodoplanes roseus* exhibits a sessile budding mode without formation of prosthecae, like *Rhodobium marinum* and *Rhodobacter blasticus. Rhodoplanes elegans*, however, does form prosthecae and rosette-like cell aggregates similar to those of *Blastochloris* species and *Rhodopseudomonas palustris.*

Cells of *Rhodoplanes* species are motile in young cultures, but motile cells become extremely rare at the late-exponential phase of growth. Electron microscopy of negatively stained cells shows that cells with single polar or subpolar flagella are dominant (Fig. BXII.α.234). In addition, cells having two lateral or subpolar

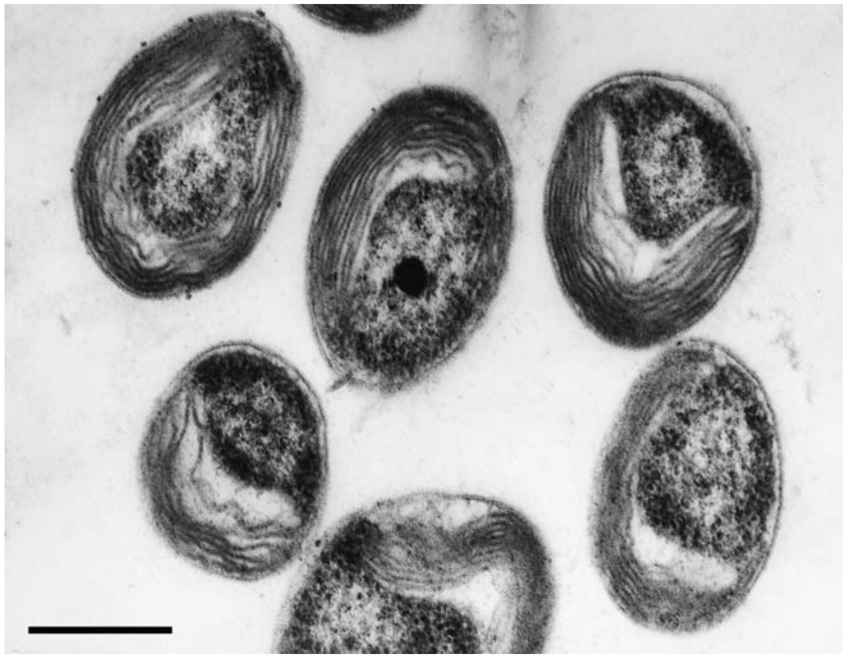

FIGURE BXII.α.232. Thin-section electron micrograph showing the internal photosynthetic membrane system of *Rhodoplanes roseus* DSM 5909. The lamellar type of photosynthetic membranes are observed. Bar = 0.5 μm.

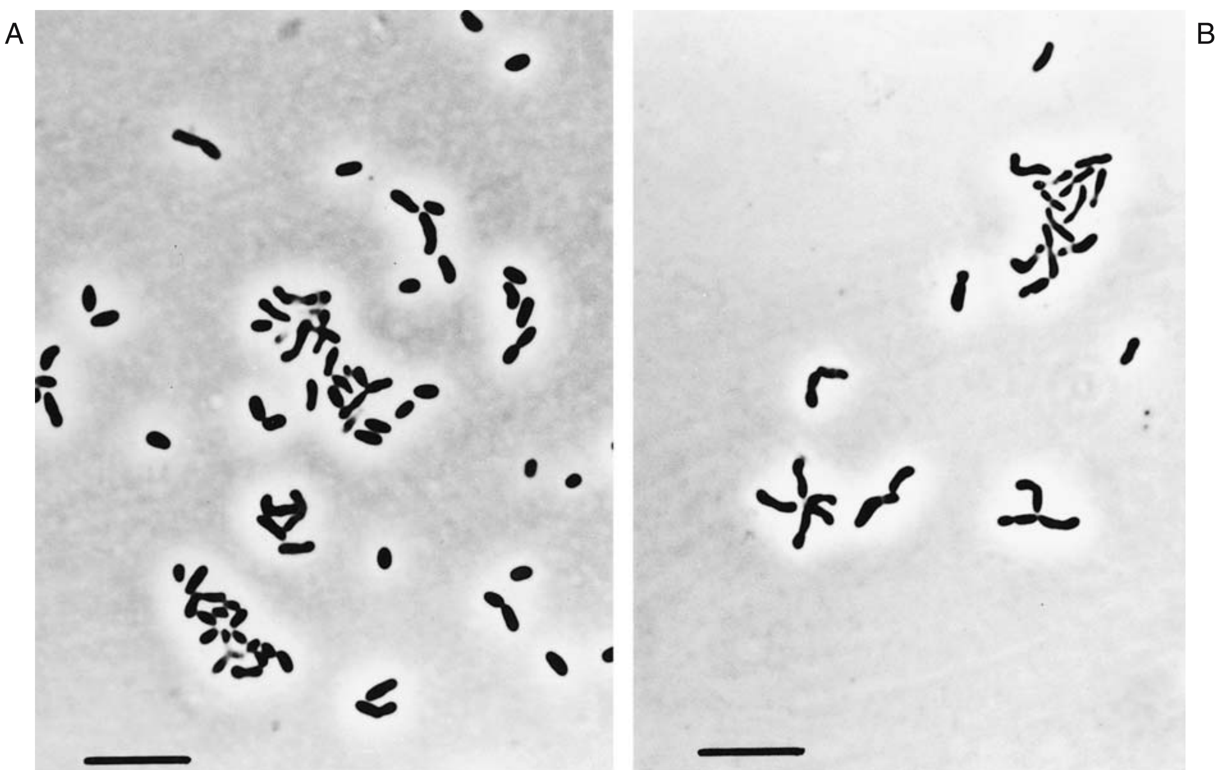

FIGURE BXII.α.233. Phase-contrast photomicrographs showing cell morphology of *Rhodoplanes*. *A*, *Rhodoplanes roseus* DSM 5909; *B*, *Rhodoplanes elegans* AS130. Bars = 8 μm.

flagella are frequently observed in *R. elegans* (Fig. BXII.α.235). Randomly distributed flagella are rarely found.

Photoheterotrophy, with simple organic compounds as electron donors and carbon sources, is the preferred mode of growth. Pyruvate is the best substrate. Other simple organic acids, including acetate, lactate, and intermediates of the tricarboxylic acid cycle serve as good carbon sources. However, no growth occurs on sugars or sugar alcohols. While other species of pho-

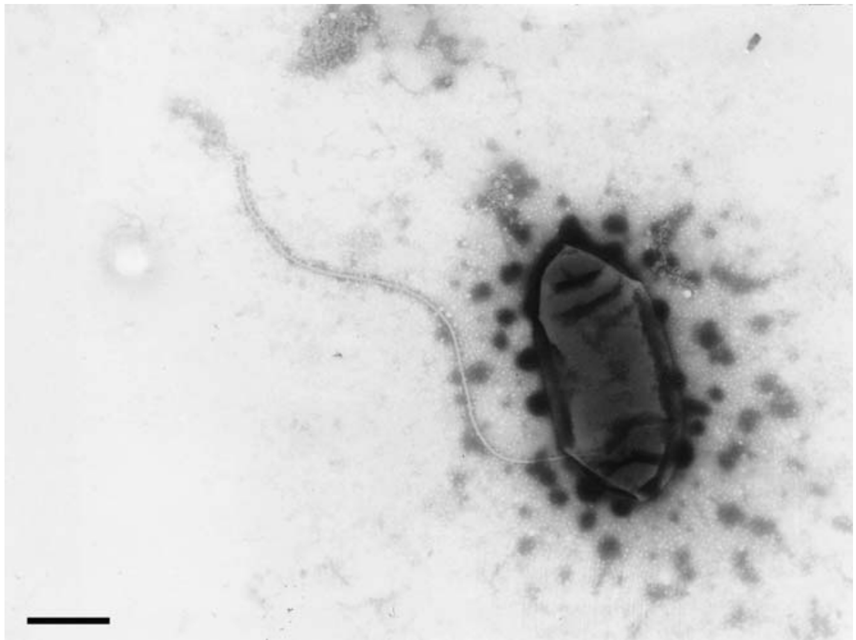

FIGURE BXII.α.234. Electron micrograph of a negatively stained cell of *Rhodoplanes roseus* DSM 5909 having a polar flagellum. Bar = 1 μm.

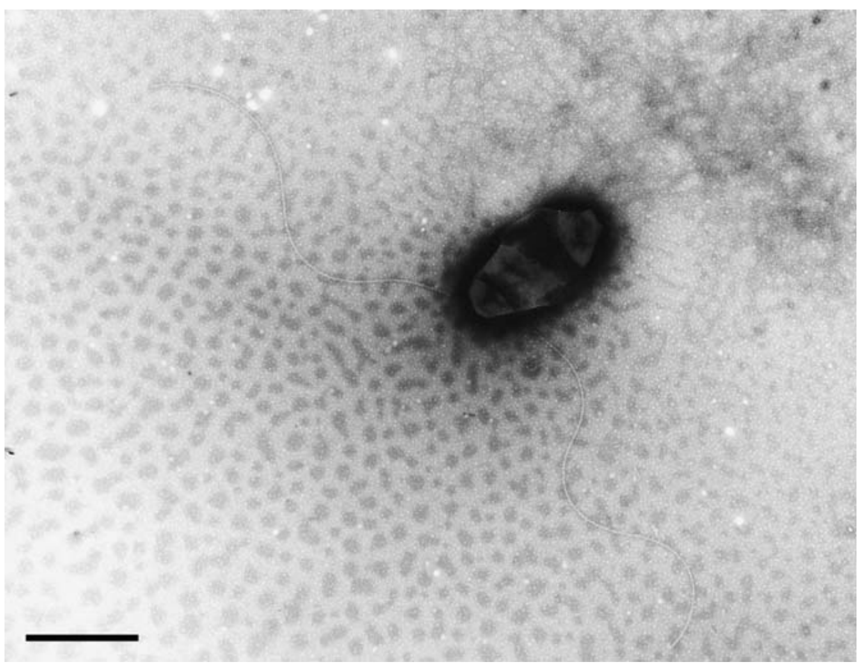

FIGURE BXII.α.235. Electron micrograph of a negatively stained cell of *Rhodoplanes elegans* AS130 having two subpolar flagella. Bar = 1 μm.

totrophic purple nonsulfur bacteria utilize straight-chain, saturated fatty acids as carbon sources, those acids ($>C_5$) have inhibitory effects on growth of *Rhodoplanes* (Janssen and Harfoot, 1987; 1991; Hiraishi and Ueda, 1994b).

Denitrification is a characteristic property of *Rhodoplanes* species. Growth under denitrifying conditions is very slow (doubling time >20 h) and is accompanied by little production of nitrogen gas. The growth yield under denitrifying conditions is 10–50% of the yield under the optimal phototrophic growth conditions. Activities of denitrifying enzymes in *Rhodoplanes elegans* are much lower than those of other denitrifying phototrophic bacteria, such as *Rhodobacter sphaeroides* IL106 and *Rhodobacter azotoformans* (Hiraishi et al., 1995a).

The capacity for nitrogen fixation has not yet been studied intensively. However, this ability appears to be absent, as suggested by the observation that nitrogenase-dependent H_2 gas production does not occur in an ammonium-deficient medium (Hiraishi and Ueda, 1994b). Hydrolytic activities against starch,

gelatin, casein, and Tween 80 are absent. In *R. elegans*, cardiolipin, phosphatidylglycerol, phosphatidylethanolamine, and phosphatidylcholine are present as the major phospholipids (A. Hiraishi, unpublished data). In all species, straight-chain, monounsaturated $C_{18:1}$ is the predominant component of cellular fatty acids, constituting 60–70% of the total content. Considerable amounts of $C_{16:0}$ (10–20%) are also present.

Since only a few strains of *Rhodoplanes* have hitherto been isolated and studied, their natural habitats and ecological significance are not yet fully understood. The type strain of *R. roseus* was isolated after enrichment in a Winogradsky column packed with mud from a duck pond in New Zealand (Janssen and Harfoot, 1991), whereas strains of *R. elegans* have been isolated from activated sludge (Hiraishi and Ueda, 1994b). As suggested by their sources and physiological characteristics, the natural habitats of *Rhodoplanes* species are freshwater environments highly polluted with organic matter, although sulfide-rich water bodies may not provide favorable conditions for their growth. Strains of *Rhodoplanes*, as well as those of *Rhodopseudomonas palustris*, *Rhodobacter blasticus*, and *Rhodobacter sphaeroides*, are frequently detected on agar plates inoculated with relatively high dilutions (10^{-5} to 10^{-6}) of activated sludge samples (A. Hiraishi, unpublished data). This suggests that *Rhodoplanes* may play an active role in the purification process of polluted water.

Phylogenetic and chemotaxonomic analyses of phototrophic purple nonsulfur bacteria that have been isolated recently from hot springs of New Zealand and are able to grow at elevated temperatures up to 46°C (P. Charlton, personal communication) have demonstrated that they belong to the genus *Rhodoplanes*.

Enrichment and Isolation Procedures

Rhodoplanes species can be cultivated in a chemically defined medium containing simple organic compounds, such as carbon sources and yeast extract, as growth factor supplements, as is commonly employed for other members of the phototrophic purple nonsulfur bacteria (Imhoff, 1988; Imhoff and Trüper, 1992). A suitable medium for growth of *Rhodoplanes* consists of (per liter of distilled water): $(NH_4)_2SO_4$, 1 g; KH_2PO_4, 1 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; $CaCl_2 \cdot 2H_2O$, 0.05 g; trace element solution SL12 (Pfennig and Trüper, 1992), 1 ml; yeast extract (Difco Laboratories), 1 g; 20 mM pyruvate (final concentration; filter-sterilized; pH 6.8).

Alternatively, a mineral medium supplemented with 0.2% tartrate and 0.1% succinate as carbon sources and niacin, thiamine, and *p*-aminobenzoic acid as growth factors is most effective for the enrichment of *Rhodoplanes*. The bacteria are enriched by anaerobic incubation in screw-capped test tubes filled with the medium under incandescent illumination. Direct plating or membrane-filter plating techniques using anaerobic jars can also be used for isolation of *Rhodoplanes* species.

Maintenance Procedures

Cultures are well preserved in liquid nitrogen, by lyophilization, or at −80°C in a mechanical freezer.

Differentiation of the genus *Rhodoplanes* from other genera

The genus *Rhodoplanes* is phenotypically similar to other genera of the budding phototrophic bacteria, especially the genus *Rhodopseudomonas*, but is separated from the latter genus by its phylogenetic position and outstanding physiological and chemotaxonomic characteristics. Characteristic features of the genus *Rhodoplanes* are denitrification, inability to grow on sugars, long straight-chain fatty acids ($>C_5$), and sulfide, as well as production of both Q-10 and RQ-10. In addition, *Rhodoplanes* species are differentiated from the phenotypically similar *Rhodopseudomonas palustris* by cell size, vitamin requirement, and carbon nutrition. It is quite easy to distinguish *Rhodoplanes* from its nearest phylogenetic neighbors, the *Blastochloris* species, because the latter produce bacteriochlorophyll *b* and have either Q-9 and MK-9 or Q-8 (Q-10) and MK-7 (MK-8) as the major quinones. Major differentiating properties between *Rhodoplanes* species and other phototrophic *Alphaproteobacteria* are shown in Tables BXII.α.168 and BXII.α.169 of the chapter on the genus *Blastochloris* as well as in Tables 3 (pp. 125–126) and 4 (p. 127) in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. The phylogenetic relationships of these bacteria, based on 16S rDNA sequences, are shown in Fig. 2 (p. 128) of that chapter.

Taxonomic Comments

Rhodoplanes roseus was first described as *Rhodopseudomonas rosea* (Janssen and Harfoot, 1991). Later, this species was shown by 16S rDNA sequence analysis and chemotaxonomic information to be different at the generic level from any species of the genus *Rhodopseudomonas*. As a result, *Rhodopseudomonas rosea* was transferred to the new genus *Rhodoplanes* and designated as the type species of this genus, *Rhodoplanes roseus* (Hiraishi and Ueda, 1994b). At the same time, *Rhodoplanes elegans* was described as the second species of this genus. Furthermore, another isolate (strain IL245), classified as *Rhodopseudomonas* sp. (Kawasaki et al., 1993b), is closely related to the two *Rhodoplanes* species at a level of 97% sequence similarity of the 16S rDNA and may represent another species of *Rhodoplanes*. Phylogenetically, *Rhodoplanes* forms a major cluster in the *Alphaproteobacteria* together with the genus *Blastochloris* and the nonphototrophic genus *Ancylobacter*.

Differentiation of the species of the genus *Rhodoplanes*

Two species, *Rhodoplanes roseus* and *Rhodoplanes elegans*, currently comprise this genus. They are phenotypically quite similar to each other, but major differences are noted in budding type, rosette formation, vitamin requirement, and growth at pH 6.0. The average level of genomic DNA–DNA hybridization between *R. roseus* and *R. elegans* is 37% (Hiraishi and Ueda, 1994b). The two species show approximately 98% sequence similarity of their 16S rDNA. General and differential characteristics of the two species are shown in Tables BXII.α.168 and BXII.α.169 of the chapter on the genus *Blastochloris*.

List of species of the genus Rhodoplanes

1. **Rhodoplanes roseus** (Janssen and Harfoot 1991) Hiraishi and Ueda 1994b, 671[VP] (*Rhodopseudomonas rosea* Janssen and Harfoot 1991, 27.)
   ro′se.us. L. adj. *roseus* rose-colored, pink.

   Cells are rod-shaped to elongate-ovoid, 1.0 × 1.8–2.5 μm, motile by means of single polar flagellum. They reproduce by budding without prosthecae and do not form rosettes and clusters. If cells age, they become nonmotile

and encapsulated by slime. Internal photosynthetic membranes are present as lamellar stacks parallel to the cytoplasmic membrane. Phototrophically grown cultures are pink, while aerobic cultures are colorless. Absorption maxima of living cells are at 373–375, 468, 493, 527–530, 591–593, 799–801, and 850–854 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series.

Growth is preferably photoheterotrophic under anoxic conditions in the light. Photoautotrophic growth with thiosulfate, but not sulfide, occurs in the presence of 0.01% yeast extract. Chemotrophic growth is possible under oxic conditions in the dark at full atmospheric oxygen tension and by denitrification under anoxic conditions in the presence of nitrate.

Electron donors and carbon sources used for phototrophic growth are acetate, propionate, butyrate, valerate, lactate, pyruvate, succinate, fumarate, malate, citrate, tartrate, Casamino acids, yeast extract, and peptone. The following organic compounds are not utilized: formate, long-chain fatty acids with more than five carbon atoms, glycolate, malonate, benzoate, arabinose, xylose, rhamnose, fructose, glucose, mannose, galactose, dulcitol, mannitol, sorbitol, glycerol, methanol, ethanol, propanol, alanine, aspartate, asparagine, glutamate, and leucine. Sulfide is growth-inhibitory at 0.2 mM concentration and is not used as a photosynthetic electron donor. Ammonium salts are used as nitrogen sources. Sulfate and thiosulfate are assimilated as sulfur sources. Growth is also stimulated considerably by addition of 0.01% yeast extract. Niacin is required as growth factor.

Mesophilic freshwater bacterium with optimal growth at 30°C, pH 7.0–7.5 (pH range: 6.5–8.0). No growth occurs at pH 6.0 and 8.5 and at 1% NaCl.

Habitat: polluted freshwater lake sediments and wastewater environments.

Major quinone components are Q-10 and RQ-10.

The mol% G + C of the DNA is: 66.8 (HPLC) and 66.0 (T_m).

Type strain: 941, DSM 5909.

GenBank accession number (16S rRNA): D14429, D25313.

2. **Rhodoplanes elegans** Hiraishi and Ueda 1994b, 672[VP]

e' le.gans. L. adj. *elegans* choice, elegant.

Cells are rod-shaped, occasionally slightly curved, 0.8–1.0 × 2.0–3.5 μm, and motile by means of polar or subpolar flagella. They multiply by budding and asymmetric cell division, with a slender prostheca occurring between the mother and daughter cells. If cells age, they form rosette-like clusters. Internal photosynthetic membranes are present as lamellar stacks parallel to the cytoplasmic membrane. Phototrophically grown cultures are pink, while aerobic cultures are colorless. Absorption maxima of living cells are at 373–375, 466, 491, 527–530, 591–593, 799–801, and 854–856 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series.

Growth is preferably photoheterotrophic under anoxic conditions in the light. Photoautotrophic growth occurs with thiosulfate, but not sulfide, in the presence of 0.01% yeast extract. Chemotrophic growth is possible under oxic conditions in the dark at full atmospheric oxygen tension and by denitrification under anoxic conditions in the presence of nitrate.

The following organic compounds are photoassimilated: acetate, propionate, butyrate, valerate, caproate, lactate, pyruvate, succinate, fumarate, malate, citrate, tartrate, Casamino acids, and yeast extract. Not utilized are formate, long-chain fatty acids with more than six carbon atoms, glycolate, malonate, benzoate, arabinose, xylose, rhamnose, fructose, glucose, mannose, galactose, dulcitol, mannitol, sorbitol, glycerol, methanol, ethanol, propanol, alanine, aspartate, asparagine, glutamate, and leucine. Sulfide is growth-inhibitory at 0.2 mM concentration and is not used as an photosynthetic electron donor. Ammonium salts are used as nitrogen sources. Sulfate and thiosulfate are assimilated as sulfur sources. Thiamine and *p*-aminobenzoic acid are required as growth factors.

Mesophilic freshwater bacterium with optimal growth at 30–35°C and pH 7.0 (pH range: 6.0–8.5). No growth occurs at pH 5.5 or 8.5 or at 1% NaCl.

Habitat: activated sludge.

Major quinone components are Q-10 and RQ-10.

The mol% G + C of the DNA is: 69.6–69.7 (HPLC).

Type strain: AS130, ATCC 51906, JCM 9224.

GenBank accession number (16S rRNA): D25311.

Genus XVIII. **Seliberia** *Aristovskaya and Parinkina 1963, 56*[AL]

Jean M. Schmidt and Suzanne V. Kelly

Se.li.be' ri.a. M.L. fem. n. *Seliberia* of Seliber, named for the Russian microbiologist, Professor G.L. Seliber.

Rods, 0.5–0.8 μm in diameter and 1–12 μm in length, with a **helically sculptured** or **furrowed** topography. The ends of the cell may be either blunt or rounded. **Stellate aggregates (rosettes)** of **sessile rods** joined at one pole, and individual, shorter **motile rods (swarmers)** occur in the same culture. An adhesive **holdfast**, secreted at one pole, mediates attachment into rosettes. Growth on appropriate soil extract media may permit formation of round to ovoid **"generative cells"**. Capsules are not produced, although a thin glycocalyx is produced later in the growth cycle. Resting stages are not known. Gram negative. Following **unidirectional polar cell growth**, a shorter motile cell (a **swarmer**) and a longer sessile cell are produced by **asymmetric transverse fission**. A single **subpolar ensheathed flagellum** is characteristically present on the swarmer; **several lateral flagella, not ensheathed,** may also be present. **Strictly aerobic.** Optimal temperature, 25–30°C; maximum ca. 37°C, minimum 15–20°C. Chemoorganotrophic, having an **oxidative type of metabolism**. Catalase and oxidase positive. These organisms live in soil and fresh water environments as autochthonous microflora, often where oligotrophic conditions prevail.

The mol% G + C of the DNA is: 63–66.

Type species: **Seliberia stellata** Aristovskaya and Parinkina 1963, 55.

FURTHER DESCRIPTIVE INFORMATION

Phylogenetic Treatment Limited phylogenetic information on the seliberias is available, due in large part to difficulties encountered in cell lysis for nucleic acid extractions. The analysis of 5S rRNA sequences has placed the genus *Seliberia* in the *Alphaproteobacteria* (Bulygina et al., 1990; Stackebrandt, 1992).

Cell morphology The typical cells are helically structured rods of varying lengths (Figs. BXII.α.236, BXII.α.239, and BXII.α.240). In a growing culture, the shorter cells are motile swarmers; the longer cells are sessile and include the predivisional cells. The rods become very long (10 μm or more in length) when grown on fulvic acid medium (Aristovskaya, 1974); in aquatic environments with very dilute organic nutrient conditions, seliberias also occur as very long helically sculptured rods. In media containing ulmic acid complexes (Aristovskaya, 1974; Schmidt and Swafford, 1979) or when a plentiful supply of organic nutrients is available (Schmidt and Swafford, 1979), the cells are shorter, and the longest cells seldom exceed 5 μm in length. Growth of some strains of *Seliberia stellata* on soil extract media (Aristovskaya and Parinkina, 1963; Aristovskaya, 1964, 1974) may give rise to round or ovoid "generative cells"; production of the round to ovoid generative cells with the type strain of *S. stellata* (ICPB 4130) has not been verified (Schmidt and Starr, 1984).

Cell wall composition The cell wall of *Seliberia stellata* is a bipartite structure with an outer layer of tightly bound protein, but lacking the appearance of an S layer. The outer protein layer is removed from the underlying layer of peptidoglycan with 0.5% KOH, but not with a variety of milder enzymatic and/or detergent treatments. No phospholipid or lipopolysaccharide (LPS) has been found in *Seliberia* cell wall preparations.

Fine structure Ultrastructural features of *Seliberia stellata* are shown in Fig. BXII.α.237.

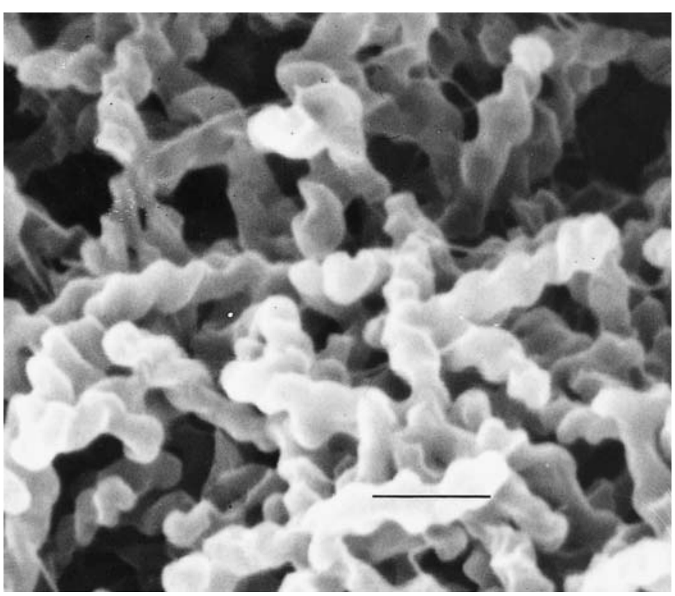

FIGURE BXII.α.236. Scanning electron micrograph of *S. stellata* strain Z/A fixed with 2.0% glutaraldehyde, critical-point dried, and gold-coated, showing the helically sculptured topography of the bacteria. Bar = 1 μm (Courtesy of J.R. Swafford).

Colonial and cultural characteristics On dilute peptone-yeast extract agar, colonies are slow-growing, requiring a week or more of incubation. The colonies are minute (0.5–1.0 mm diameter) and white in color. The colonies may adhere strongly to the agar. On ulmic acid or fulvic acid media, the colonies are also slow-growing and may show some browning, due to presence of iron oxide. In dilute liquid peptone-yeast extract medium, the bacteria adhere tightly to the surface of the growth vessel, and adherence is mediated by the polar holdfast.

Life cycle Cell growth occurs unidirectionally, at the pole of the rod opposite the pole with the secreted holdfast. The end of the predivisional rod that consists of the newly made surface components eventually becomes a motile swarmer as a result of an asymmetric division. The remaining (longer) portion of the predivisional cell retains the surface components of the parent without redistributing them into the zone of new growth. The

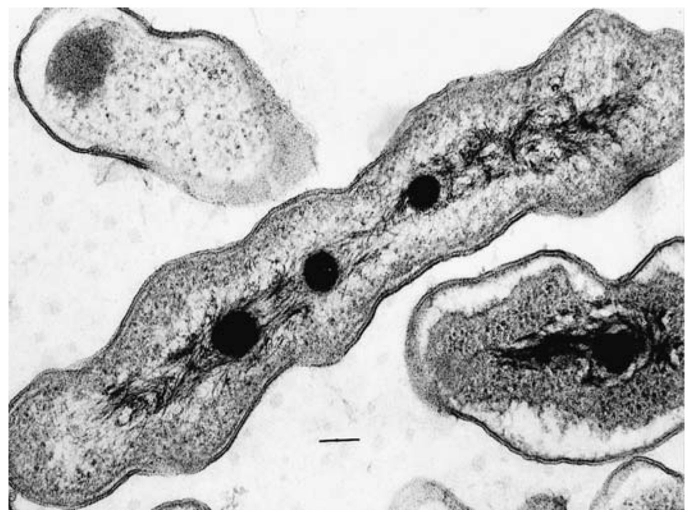

FIGURE BXII.α.237. Thin section of *S. stellata* strain Z/A, prepared with a modification of the Ryter–Kellenberger fixation method (Kellenberger et al., 1958), 1.0% osmic acid in 0.1× buffer for 2 h, and embedded in Spurr resin. The thin cell envelope and wavy outline are characteristic of seliberias. Bar = 0.1μm (Courtesy of J.R. Swafford).

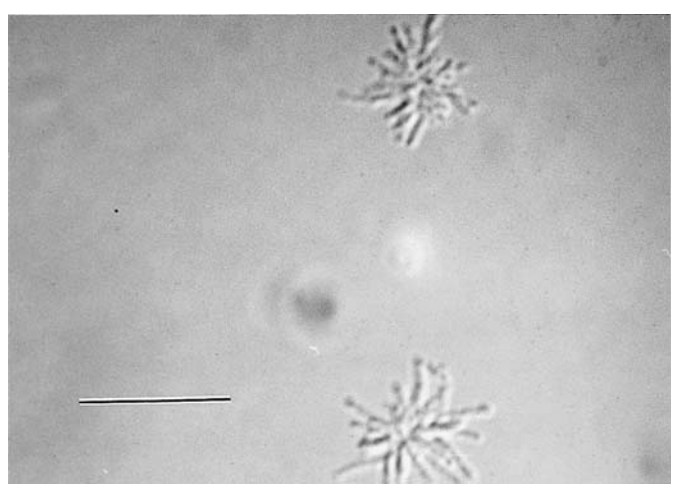

FIGURE BXII.α.238. Nomarski interference contrast light micrograph of *S. stellata* rosettes. Bar = 5 μm (Courtesy of J.R. Swafford).

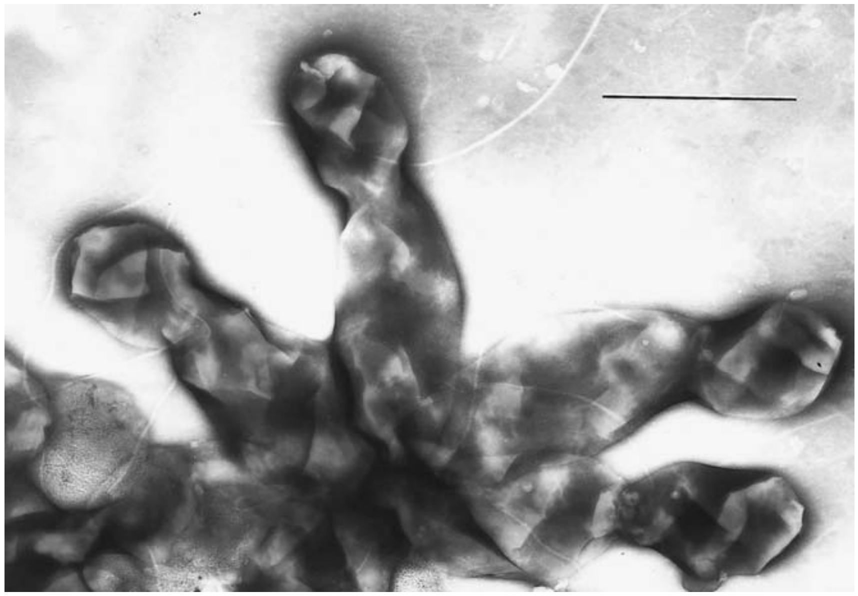

FIGURE BXII.α.239. Phosphotungstate (0.5%) negative stain of an aquatic *Seliberia*-like strain, ICPB 4141, illustrating the asymmetric plane of division. Bar = 1.0 μm.

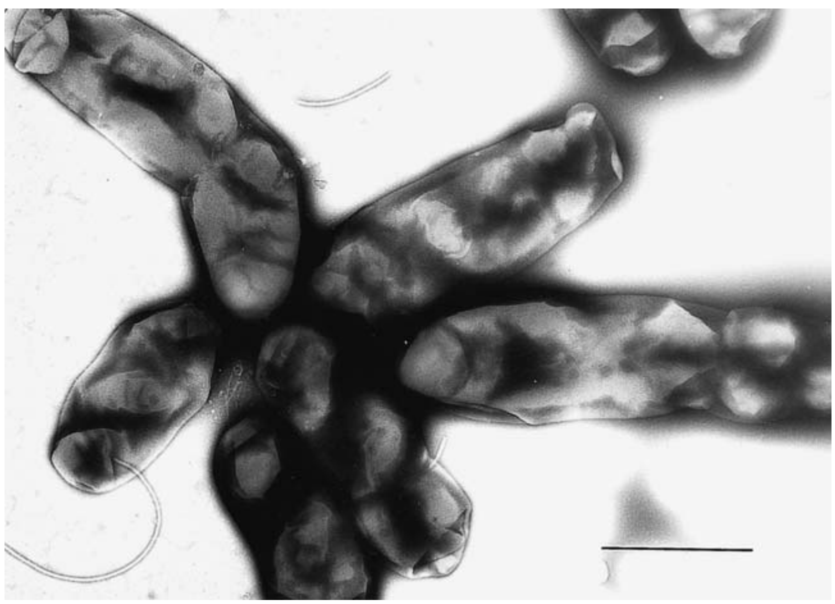

FIGURE BXII.α.240. Phosphotungstate (0.5%) negative stain of a rosette of *Seliberia*-like aquatic strain ICPB 4133. A subpolar flagellum is present. Bar = 1.0 μm (Courtesy of J.R. Swafford).

subpolar ensheathed flagellum of the new swarmer is found at the apical end of the predivisional cell, shortly before its division. The asymmetry perpendicular to the division plane results in unequal division products (Fig. BXII.α.239; Schmidt and Starr, 1984). Swarmer cell production by unidirectional polar growth in the genus *Seliberia* meets two of the major criteria (*de novo* synthesis of the bud surface and transverse asymmetry of division) of accepted definitions of budding (Staley, 1973a; Staley et al., 1981); however, a third feature typical of most budding bacteria, an increasing diameter of the bud during its development (Hirsch, 1974a), is not found in *Seliberia*; the developing daughter cell (swarmer) is (i) not initially narrower than the parent, and (ii) does not increase in diameter (width) during growth (Schmidt and Starr, 1984).

The proportion of cells in stellate aggregates (rosettes) varies in *Seliberia* cultures, but rosettes are readily detectable microscopically under most cultural conditions (Figs. BXII.α.238, BXII.α.240). The stellate aggregates are formed by association of swarmers, which have produced an adhesive holdfast at one pole, with sessile cells–often with those stationary rods located in the immediate vicinity of the predivisional cell that produced the swarmer. In addition, at high cell densities in liquid cultures, polar aggregation of swarmer cells occurs (Schmidt and Starr, 1984), akin to the manner of formation of *Caulobacter* rosettes

(Poindexter, 1964, 1981). The *S. stellata* holdfast consists of a polysaccharide, containing glucose and/or mannose, galactose, *N*-acetylglucosamine, and *N*-acetylgalactosamine (Hood and Schmidt, 1996).

Nutrition and growth conditions Growth of *Seliberia* occurs on dilute organic media, such as yeast extract plus peptone or Casamino acids (Difco), soil extract agar, or pond water agar. Media containing organomineral complexes of either fulvic or ulmic acid with sesquioxides have been used (Aristovskaya and Parinkina, 1963; Aristovskaya, 1974; Schmidt and Swafford, 1981). With these media, aerobic incubation at 25°C gives satisfactory growth.

Metabolism and metabolic pathways Although the genus *Seliberia* has been previously described as facultatively anaerobic (Aristovskaya, 1974), the available type strain (Z/A = ICPB 4130) and all of the several aquatic strains are strictly oxidative; all lack the capacity to carry out anaerobic fermentations. *S. stellata* Z/A possesses glucose dehydrogenase and 6-phosphogluconate dehydrase activities, and can grow aerobically on D-glucuronic acid, suggesting the presence of the Entner–Doudoroff pathway. Strain Z/A also possesses strong NADH oxidase activity, isocitrate dehydrogenase, succinate dehydrogenase, and malate dehydrogenase, consistent with oxidative metabolism. *S. stellata* strain Z/A is a strong denitrifier and can grow anaerobically in the presence of 0.1% $NaNO_3$, indicating a nitrate/nitrite respiration. Most of the aquatic *Seliberia*-like strains are not able to denitrify anaerobically (Schmidt and Swafford, 1979, 1981).

Genetics and molecular data The seliberias have not received much attention, due to difficulties in obtaining DNA preparations, which are related to the problems encountered in obtaining cell lysis. No bacteriophages or plasmids have been reported for the seliberias.

Antigenic structure The outer layer of the cell envelope of the seliberias induces an antibody response in rabbits (Schmidt and Starr, 1984). Indirect fluorescent antibody and agglutination tests done with polyvalent antisera to strain Z/A and to two aquatic *Seliberia*-like strains indicated significant antigenic relatedness among the strains. The two major proteins making up the outer layer of strain Z/A (which lacks LPS) have respective molecular weights of 54–56 kDa and 82–84 kDa. Some information on flagellum-associated proteins is available: strain Z/A, which produces both ensheathed subpolar and nonsheathed lateral flagella, has flagella-associated proteins with molecular weights of 68, 36, and 35 kDa; several aquatic *Seliberia*-like strains which produced only the subpolar ensheathed flagellum gave major flagellar protein values of 56–60 kDa.

Antibiotic Sensitivity Seliberias are quite resistant to low concentrations (10 µg) of most of the common antibiotics; most aquatic *Seliberia*-like strains are inhibited by 100 µg concentrations of ampicillin, penicillin G, vancomycin, chlortetracycline, streptomycin, and rifampin. *S. stellata* strain Z/A is resistant to 100 µg concentrations of ampicillin, penicillin G, and vancomycin.

Pathogenicity No reports of seliberias causing overt or opportunistic infections in humans, animals, or insects have been reported. Their optimal growth temperature range of 25–30°C, poor growth at 37°C, and lack of LPS in their cell wall makes the seliberias unlikely candidates as pathogens of humans or warm-blooded animals.

Ecology The habitats of *Seliberia* include soil and freshwater environments. They have been reported as epiphytes of the cyanobacterium *Nodularia* (Smarda, 1985), and have been found in an activated sludge reactor (Baker et al., 1983). Although seliberias appear to be widely distributed, they have not received much attention from bacteriologists. Seliberias appear to be well suited to conditions of limited nutritional resources, although they can also occur in eutrophic environments.

Enrichment and Isolation Procedures

Specific enrichment procedures for podzol-inhabiting seliberias have not been described, although it has been noted that these bacteria occur frequently in pedoscopes (Aristovskaya and Parinkina, 1963). Seliberias of both aquatic and soil origin can be enriched, nonspecifically, using oligotrophic conditions (Schmidt and Swafford, 1979, 1981). Glass beakers, to which water samples (for example, 200-800 ml of pond, lake, or even tap water) are added, with or without the addition of 0.001–0.005% peptone (Difco), are covered with plastic film to prevent evaporation and incubated for several days to several weeks or months at 24–26°C. To adapt this aquatic enrichment to soil inocula, suspensions of 1 g (or less) of soil are made in 500 ml of filtered pond or tap water to which (i) no nutrients or (ii) very low concentrations of peptone are added (as above, for aquatic sample enrichment). The seliberias usually occur at the air–water interface of the enrichment (in the surface pellicle, if heavy growth has occurred). They may be attached to other microbes or detritus. Seliberias will be easier to isolate subsequently if heavy growth of other, more rapidly growing bacteria has not occurred in the enrichment beaker. Hence, the use of several enrichment beakers with varying concentrations of added nutrients may facilitate the enrichment procedure. Observation of the bacteria at the surfaces of the enrichment, using transmission electron microscopy and negative stains (Schmidt and Swafford, 1992) is useful for determining whether significant numbers of seliberias are present. Use of genus-specific fluorescent dye-labeled oligonucleotide probes in glass slide hybridization reactions for these bacteria has not been reported yet, but it should be feasible once sequences are available.

To obtain pure cultures of seliberias, several types of solid culture media have been used. To isolate seliberias from soil samples, agar media containing dilute organomineral complexes (ulmic or humic acids, or fulvic acid) obtained from soil humus (Aristovskaya and Parinkina, 1961, 1963) have been used successfully. Soil samples thought to contain seliberias are streaked on the ulmic or fulvic acid agar media; after 4–7 d, the slow-growing colonies that show some ferric oxide–caused browning are examined for characteristic morphologic features. The accumulation of ferric hydroxide by seliberias of soil origin is characteristic of their behavior in mixed culture; in pure culture, an atmosphere of about 1% CO_2 stimulates deposition of iron oxide (Aristovskaya and Parinkina, 1963).

Seliberia-like bacteria of aquatic or soil origin may be isolated (from enrichment cultures) by streaking from the liquid enrichment surface onto a dilute organic medium; recipes for two useful media follow. PYE medium: 0.2% peptone (Difco), 0.1% yeast extract, 1.0% Hutner's vitamin-free mineral base (Cohen-Bazire et al., 1957), 1.2% or 1.5% Bacto-agar (Difco), and distilled water. Dilute medium I: 0.02% peptone, 0.01% yeast extract, 1.0% Hutner's mineral base, 1.2 or 1.5% Bacto-agar (Difco), and distilled water; addition of 0.1% glucose (filter-sterilized) is optional (Schmidt and Swafford, 1981). After two weeks or longer of in-

cubation at 25°C, the plates are examined with a dissecting microscope for minute 0.5–1.0 mm diameter white colonies that may adhere to the agar. The selected colonies are transferred to patch plates, reincubated for several days, and then observed with phase-contrast light microscopy for rosette-forming, asymmetrically dividing, rod-shaped bacteria that have a motile stage. Transmission electron microscopy, using negative stains, can be used to check for the helical sculptured topography of the rods (Schmidt and Swafford, 1981). Specific oligonucleotide probes with fluorescent labels may be useful in identification of *Seliberia* colonies or patches.

Maintenance Procedures

Stock cultures grown aerobically on slants of PYE medium in screw-cap test tubes remain viable for several weeks at room temperature (24–26°C). The slant cultures survive several weeks longer at 4°C. Suspensions of cells scraped (with some difficulty) from agar surfaces and suspended in sterile distilled water also survive well for several weeks at room temperature. For longer-term preservation (several years), lyophilization is a satisfactory method.

Procedures for Testing Special Characters

The determination of cellular morphology at a level of resolution attainable by scanning electron microscopy or transmission electron microscopy (negative stains) is a key feature in the identification of seliberias. The helical sculpturing of the bacterial cell surface and the presence of a subpolar sheathed flagellum can be determined with electron microscopy.

Differentiation of the genus *Seliberia* from other genera

At the resolution achievable with light microscopes, seliberias can be confused with various kinds of caulobacters (members of the genera *Caulobacter* or *Asticcacaulis*), because of their occurrence in the same types of natural habitats and preference for aerobic environments, similarities in cell size and apparent rod-like shape, presence of shorter motile and longer sessile cells, and occurrence of rosette arrangements (star-like aggregates) of several to many cells. However, seliberias are not prosthecate, whereas predivisional and mature *Caulobacter* and *Asticcacaulis* cells have at least one prostheca or cellular stalk (Poindexter, 1964, 1981). Prosthecae can be observed with phase contrast high-resolution light microscopy but not without some difficulty since prosthecae are usually 0.2 μm or less in diameter. Other rosette-forming bacteria, which also demonstrate motility, but which typically belong to the genera *Pseudomonas* or *Agrobacterium*, also can be difficult to distinguish from seliberias if only light microscopy is used.

Confirmation that an isolate belongs to the genus *Seliberia* can be established by phenetic characterization, although use of morphological and ultrastructural characteristics as a sole guide to generic assignment is not a desirable situation. Notably, there is still some lack of phylogenetic data for the seliberias, but obtaining phenetic information on the physiology, relationship to oxygen, mol% G + C, and mode of growth and division is useful in defining members of the genus *Seliberia*, distinguishing them from *Caulobacter*, pseudomonads, *Agrobacterium* spp., and other rosette-forming Gram-negative bacteria (Table BXII.α.188). Since the seliberias characteristically exhibit unidirectional polar growth, and their swarmers are generated at the end of the dividing cell (Schmidt and Starr, 1984), this relatively unusual mode of cell division is a useful distinguishing trait.

Taxonomic Comments

The genus *Seliberia*, its single species *Seliberia stellata*, and the closely related but not quite identical aquatic *Seliberia*-like strains have not been examined for 16S rDNA sequences; 5S rRNA analysis has placed this genus in the *Alphaproteobacteria* (Bulygina et al., 1990; Stackebrandt, 1992). Difficulties in achieving cell lysis and DNA extractions have played a role in the delay in acquiring 16S rDNA phylogenetic data and DNA–DNA hybridization data among the phenetically quite similar *Seliberia*-like strains. The DNA–DNA hybridization data among *Seliberia*-like strains are important in determining species-level relationships. Seliberias also should be compared at the molecular level with other *Alphaproteobacteria*, including various species of *Caulobacter*, some pseudomonads, such as *Pseudomonas carboxydohydrogena* (Meyer et al., 1980) due to its morphology, and *Nitrobacter*, a budding bacterium with an unusual cell envelope similar in profile to that of *Seliberia stellata*, to establish the uniqueness of this genus.

Acknowledgments

We thank G.A. Zavarzin, Institute of Microbiology, Academy of Sciences, Moscow, for the culture of *Seliberia stellata* strain Z/A (ICPB 4130). Micrographs were provided by J.R. Swafford. Data on cell wall composition and metabolic pathways were obtained in collaboration with Steven Baker and Michelle Santos.

List of species of the genus Seliberia

1. **Seliberia stellata** Aristovskaya and Parinkina 1963, 55[AL]
stel.la′ ta. L. adj. *stellata* starred.

Colonies on peptone-yeast extract (PYE medium, see Enrichment and Isolation Procedures, above) are smooth, convex, and white. The diameter is 0.5–1.5 mm, with a regular border. On ulmic acid agar, a soil extract medium (Aristovskaya and Parinkina, 1961, 1963), growth is sparse, colonies are less than 1.0 mm in diameter, and light brown. *Seliberia stellata* strain Z/A grows in a chemically defined medium containing an appropriate carbon source, 0.05% ammonium chloride, 1.0% Hutner's vitamin-free mineral base (Cohen-Bazire et al., 1957), and 0.001% phosphate. It grows over a wide pH range, from 4.5 to at least 9.0. No added vitamins are required. *S. stellata* is positive for urease production and starch hydrolysis; it can produce H_2S from cystine; it can reduce nitrate to nitrite under either aerobic or anaerobic conditions; it is unable to liquefy gelatin, utilize citrate, hydrolyze casein, or produce indole, and it gives negative methyl red and Voges–Proskauer reactions. *S. stellata* strain Z/A, the reference strain, can produce both a subpolar, ensheathed, typically single flagellum, and several lateral, ordinary (not ensheathed) flagella. This flagellation is characteristic of its swarmer cells grown on agar-solidified PYE medium at 25°C.

The mol% G + C of the DNA is: 66 (Bd) (strain Z/A).

Type strain: E-37, VKM B-1340.

Other Organisms

Several *Seliberia*-like strains from aquatic (freshwater) sources and a few from soil have been enriched and isolated in pure culture, and these are quite similar to *S. stellata*. Ten strains have been characterized in some detail. A typical aquatic *Seliberia*-like strain (ICPB 4133) is shown in Fig. BXII.α.240. Their description is the same as that for the genus, with the following additional characteristics: the aquatic *Seliberia*-like strains are unable to use any of 60 tested compounds as their sole carbon source; they appear to have complex growth factor requirements. They can be grown on the minimal medium described for *Seliberia stellata* supplemented with 0.001% Vitamin Assay Casamino Acids (Difco) and 0.1% (v/v) Staley's vitamin solution (Staley, 1968). They grow dependably but sparsely on PYE medium (see Enrichment and Isolation Procedures, above; Schmidt and Swafford, 1981).

Growth of aquatic *Seliberia*-like strains is very sparse on all complex media tested. Grown on PYE agar, colonies are white, minute (0.5–1.0 mm diameter), and very adherent to the agar medium. Growth in liquid PYE medium is granular, definitely not well dispersed, with a strong tendency for attachment to the submerged surfaces of glass culture vessels, so long as a shallow (about 1 cm deep) level of liquid medium is maintained. (The growth of *S. stellata* under similar circumstances is well dispersed, with some rosettes visible microscopically, but without the presence of macroscopic granules). The aquatic *Seliberia*-like strains demonstrate an obligate requirement for oxygen and they reduce nitrate under aerobic conditions, but not anaerobically. They do not produce H_2S from cystine. Most of the *Seliberia*-like strains can hydrolyze urea, and all can hydrolyze starch.

All of the aquatic strains produce swarmers with a subpolar ensheathed flagellum, but most have not been found to produce the lateral, ordinary (i.e., not ensheathed) flagella. Two of the aquatic strains, which have been examined with indirect immunoferritin surface labeling during growth, were found to exhibit unidirectional polar cell surface growth, with production of swarmers having *de novo* synthesized surface antigens. *Seliberia stellata* exhibited the same kind of unusual growth and division pattern in similar experiments (Schmidt and Starr, 1984). Nine of 10 aquatic *Seliberia*-like strains cross-react moderately to strongly with *S. stellata* in serological tests (tube agglutination and indirect immunofluorescence tests). The aquatic seliberias are less resistant to common antibiotics than is *S. stellata*.

The mol% G + C of the DNA is: 63–65 (Bd) (aquatic *Seliberia*-like strains).

Genus XIX. **Starkeya** *(ex Starkey 1934) Kelly, McDonald and Wood 2000, 1800[VP]*

Donovan P. Kelly and Ann P. Wood

Star.ke′ ya. M.L. n. *Starkeya* of Starkey; named after Robert L. Starkey, who made important contributions to the study of soil microbiology and sulfur biochemistry.

Short rods, coccoidal or ellipsoidal cells 0.4–0.8 × 0.8–2.0 μm, occurring singly and, occasionally, in pairs. Nonmotile. Colonies grown on thiosulfate agar (with biotin) are small, smooth, circular, round, and opalescent, becoming white with sulfur. Thiosulfate liquid medium (lacking biotin) becomes turbid and sulfur precipitates during static incubation; thiosulfate is incompletely used, and the pH falls from 7.8 to 5.8. This poor development is due to the requirement for biotin exhibited by the type strain. The organism is **facultatively chemolithoautotrophic**, but optimal autotrophic development requires biotin, and op-

timal heterotrophic growth requires yeast extract, biotin, or other additions, such as pantothenate, depending on the organic substrate. Autotrophic growth is also observed with formate when high levels of ribulose 1,5-bisphosphate carboxylase are expressed. Some strains may degrade methylated sulfides. This organism is **strictly aerobic, both autotrophically and heterotrophically**, and is incapable of denitrification. **Oxidizes and grows on thiosulfate and tetrathionate but not on sulfur or thiocyanate.** Ammonium salts, nitrates, urea, and glutamate are used as nitrogen sources. Optimal temperature 25–30°C; growth range 10–37°C (no growth at 5°C or 42°C). Optimal pH 7.0; growth range pH 5.7–9.0. Contains ubiquinone Q-10. Major cellular fatty acids are octadecenoic acid and cyclopropane acid of C_{19}; lacks a major hydroxy fatty acid. The lipopolysaccharide lacks heptoses and has only 2,3-diamino-2,3-dideoxyglucose as the backbone sugar. Member of the *Alphaproteobacteria*. Isolated from soil. Presumably widely distributed.

The mol% G + C of the DNA is: 67.3–68.4.

Type species: **Starkeya novella** (Starkey 1934) Kelly, McDonald and Wood 2000, 1800 (*Thiobacillus novellus* Starkey 1934, 365.)

Further descriptive information

This newly created genus currently contains only one of the former *Thiobacillus* species, *T. novellus*, a facultatively heterotrophic and chemolithoautotrophic, rod-shaped organism in the *Alphaproteobacteria*. The properties, taxonomy, and differentiation of the genera of sulfur-oxidizing, chemolithoautotrophic, Gram-negative, rod-shaped bacteria are summarized in Tables BXII.β.70 and BXII.β.71 and Fig. BXII.β.60 in the chapter on the genus *Thiobacillus* in this *Manual*. *Starkeya* has been shown by 16S rRNA gene sequence analysis and comparison of physiological properties to not be a species of *Paracoccus* (which contains the physiologically comparable species *P. versutus* and *P. pantotrophus*), but rather to be significantly related only to *Ancylobacter* (Kelly et al., 2000). The description given here is based primarily on studies with the type strain, isolated from soil in the 1930s (Starkey, 1934, 1935a, b; Kelly et al., 2000). Another strain, isolated from sewage, has been shown to oxidize methanethiol, dimethylsulfide, and dimethyldisulfide (Cha et al., 1999), properties not yet reported for the type strain. Detailed studies of inorganic sulfur-compound oxidation have been undertaken with *S. novella*, including studies of its unique sulfite:cytochrome *c* oxidoreductase (Southerland and Toghrul, 1983; Toghrol and Southerland, 1983; Kappler et al., 2000) and its thiosulfate-oxidizing system. The latter was initially thought to be a multienzyme complex located exclusively in the cytoplasmic membrane system (Oh and Suzuki 1977), but Kappler et al. (2001) have shown that a periplasmic thiosulfate-oxidizing system not involving a membrane-anchored multienzyme system may also function (C. Dahl, personal communication).

List of species of the genus Starkeya

1. **Starkeya novella** (Starkey 1934) Kelly, McDonald and Wood 2000, 1800^{VP} (*Thiobacillus novellus* Starkey 1934, 365.)
no.vel'la. L. dim. adj. *novella* new.

The species description is the same as the genus description, with the exception that oxidation of methylated sulfides has not been tested with the type strain. Biotin is required by the type strain for good growth on most substrates; yeast extract may be substituted for biotin and, in some cases, the biotin requirement may be replaced by lipoic acid or coenzyme A; good growth on methanol requires pantothenate or yeast extract rather than biotin.

The mol% G + C of the DNA is: 67.3–68.4 (Bd, T_m).

Type strain: ATCC 8093, DSM 506, IAM 12100, IFO 12443, NCIMB 9113.

GenBank accession number (16S rRNA): D32247.

Genus XX. **Xanthobacter** *Wiegel, Wilke, Baumgarten, Opitz and Schlegel 1978, 573*[AL]

Jürgen K.W. Wiegel

Xan.tho.bac'ter. Gr. adj. *xanthos* yellow; M.L. masc. n. *bacter* the equivalent of Gr. neut. n. *bacterion* rod, staff; M.L. masc. n. *Xanthobacter* yellow rod.

Cells are rod shaped, sometimes twisted, 0.4–1.0 × 0.8–6.0 μm. Pleomorphic cells are produced on media containing tricarboxylic cycle-intermediates (especially succinate), **whereas coccoid cells as well as cells up to 10 μm long are produced on media containing an alcohol** as the sole carbon source. Refractile (polyphosphate) and lipid (poly-β-hydroxybutyrate) bodies are evenly distributed in the cells. Resting stages are unknown. Key sporulation genes are absent. Depending on the species and growth conditions, the cells are nonmotile or motile (by peritrichous flagella). **The Gram reaction frequently appears falsely to be positive or variable due to polyphosphate granules; however, ultrastructurally and biochemically, the cell wall is of the negative Gram-type.**[1] **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Optimal temperature, 25–30°C. Optimal pH, 5.8–9.0. Colonies are opaque and slimy (although "slimeless" strains exist) and are **yellow** due to a water-insoluble carotenoid pigment (**zeaxanthin dirhamnoside**). The color intensity depends on the amount of slime produced by individual strains. **Catalase positive.** All strains can grow **chemolithoautotrophically** in mineral media under an atmosphere of H_2, O_2, and CO_2 (7:2:1, v/v) as well as **chemoorganoheterotrophically** on methanol, ethanol, n-propanol, n-butanol, and various organic acids as sole carbon sources. The carbohydrate utilization spectrum is limited, and neither volatile/nonvolatile fatty acids nor gas is produced from carbohydrates such as fructose, glucose, or mannose. Some strains require vitamins. Some strains can utilize substituted thiophenes as sole carbon, energy, and sulfur sources. **When degrading aliphatic epoxides, tested strains contain coenzyme M, which otherwise is a typical coenzyme of the obligate anaerobic methanogenic archaea. N_2 is fixed** in nitrogen-deficient media under heterotrophic or chemolithoautotrophic growth conditions, but by most strains

1. The terms "Gram-type negative" and "Gram-type positive" were proposed by Wiegel (1981) to describe bacteria according to ultrastructural and biochemical Gram characteristics (cell wall structure, presence or absence of indicator compounds such as lipopolysaccharide; Wiegel and Quandt, 1982). The terms are distinct from those referring to the results of the Gram-staining reaction: "Gram-reaction positive", "Gram-reaction negative", or "Gram-reaction variable".

only under a decreased O_2 pressure. The bacteria occur free-living in freshwater (mainly *X. agilis*), wet soil containing decaying organic material (*X. autotrophicus*, *X. flavus*), marine sediments (*X. flavus*), compost of root balls of *Tagetes* (thiophen-utilizing *X. tagetidis*), and associated with the roots of plants including wetland rice (*X. flavus*). *Xanthobacter* can be regarded an associative N_2-fixing bacterium (rice, tagetis, coconut palm). The induction of root or stem nodules has not been observed. 16S rDNA sequence analysis places the members into the class *Alphaproteobacteria*; however, the presently recognized species of *Xanthobacter* are intermixed with the single-species genera *Aquabacter* and *Azorhizobium*, and together they form a distinct cluster.

The mol% G + C of the DNA is: 65–70 (T_m) and 66–68 (Bd).

Type species: **Xanthobacter autotrophicus** (Baumgarten, Reh and Schlegel 1974) Wiegel, Wilke, Baumgarten, Opitz and Schlegel 1978, 580 (*"Corynebacterium autotrophicum"* Baumgarten, Reh and Schlegel 1974, 214.)

Further descriptive information

Colonial characteristics All species of *Xanthobacter* form colonies that are smooth, convex, circular, filiform, opaque, and either yellow, off-white, or—when abundant slime is produced—nearly colorless. Due to the slime formation, especially on nutrient broth agar plates, colonies develop into characteristic colony forms called "fried egg". The main component of the yellow pigment of all strains (the "white" strains contain just minor amounts) has been identified as zeaxanthin dirhamnoside (Hertzberg et al., 1976; J. Wiegel and K. Schmidt, unpublished data). It is water insoluble and is located in the cell wall (Eberhardt, 1971). In *Aquabacter* and *Azorhizobium*, this pigment has not been identified so far; their colonies are creamy white.

Cell morphology The cell shape of *Xanthobacter* depends strongly on the growth conditions, i.e., especially the carbon source, whereas the nitrogen source has a minor effect (Fig. BXII.α.241). Cells under N_2-fixing conditions are only slightly longer than in the presence of ammonia or other sources of combined nitrogen. Cells of both *X. autotrophicus* and *X. flavus* are coccoid when growing on *n*-propanol (Fig. BXII.α.241) and are long, filamentous rods when growing on *n*-butanol. One of the most significant morphological features is the formation of irregular, twisted (especially *X. tagetidis*) (Padden et al., 1997), and branched cells (especially *X. autotrophicus* and *X. flavus*) during growth on tricarboxylic acid cycle intermediates; the intermediates include succinate, which is a good growth substrate and promotes the development of the most irregular cell forms during the late exponential growth phase (Fig. BXII.α.241) (Wiegel and Schlegel, 1976). In contrast to strains of *X. autotrophicus*, *X. flavus*, and *X. tagetidis*, the strains of *X. agilis* (motile under nearly all growth conditions) are only slightly pleomorphic and exhibit branched cell formation only after prolonged incubation (3–7 d) on succinate-containing agar media (Aragno et al., 1977; J. Wiegel, unpublished data). Electron micrographs of ultrathin sections show that the branching cells do not contain septa at the branching points (Fig. BXII.α.242) (Wiegel et al., 1978). Scanning electron micrographs from *X. tagetidis* reveal twisted, nearly fusiliform (i.e., with tapered ends) spirals (Padden et al., 1997). The occurrence of a snapping type of cell division, as was assumed from light-microscopic inspection of *X. autotrophicus*, has not been confirmed by electron-microscopic-studies. The illusion of snapping cell division, as well as of "star formation" (Fig. BXII.α.241), is presumably due to cell aggregation by copious amounts of slime. Surface patterns on the outer cell wall are not observed in electron micrographs. The cells of the exponential growth phase and those grown under heterotrophic conditions are usually larger than those of the early stationary growth phase and those grown under chemolithoautotrophic conditions; the latter are mainly straight or only slightly curved rods (Fig. BXII.α.241).

Cell wall type and Gram-reaction Many strains identified later as strains of *Xanthobacter* were originally described to give a positive or variable Gram reaction (Baumgarten et al., 1974). However, *Xanthobacter* belongs to the negative Gram-type bacterial group, since it contains lipopolysaccharides (Fig. BXII.α.243) (Wiegel and Mayer, 1978; Wiegel, 1981). The impression of a positive Gram-staining reaction is feigned by the content of refractile bodies, which were identified as polyphosphate granules by electron microscopy, as well as by volutin staining (Figs. BXII.α.242 and BXII.α.243). The polyphosphate content of the cells is high (15 mg of phosphate/g dry weight) and even at a low phosphate concentration in the growth medium (0.01 mM) volutin granules do not disappear (Wiegel et al., 1978). Using phosphate limitation or starvation, attempts to obtain cells of *X. autotrophicus* without polyphosphate granules have failed. Large dark bodies, frequently visible in the light microscope, are located at one or both (or in branched cells on several) ends of the cells. Electron microscopy of thin sections of cells (Walther-Mauruschat et al., 1977) indicated that these larger granules are poly-β-hydroxybutyrate granules (Fig. BXII.α.242).

The cell envelope of *X. autotrophicus* has a thin multilayered structure, resembling that of Gram-type negative cells (Fig. BXII.α.242) (Walther-Mauruschat et al., 1977). The peptidoglycan content of the cell wall of the *X. autotrophicus* strains (15–25%) is intermediate compared to that of typical Gram-type positive (30–70%) and Gram-type negative (10%) bacteria. Teichoic acid and teichuronic acid are absent (Schleifer and Kandler, 1972; O. Kandler and F. Fiedler, personal communication), but elevated concentrations of glycine can be present (see below for details).

Compared to other Gram-type negative bacteria the lipopolysaccharide content is relatively low for the strains tested. The lipopolysaccharide was identified both chemically after extraction from autotrophic cells and by the lipopolysaccharide polymyxin B interaction technique using electron microscopy (Wiegel and Mayer, 1978; Wiegel, 1981) (Fig. BXII.α.243). The citrate synthase of *Xanthobacter* species resembles that of Gram-type negative bacteria by having a molecular weight above 250,000 and by being inhibited by NADH (Weitzman and Jones, 1975; Berndt et al., 1976; Weitzman, 1987). All these properties are in agreement with the 16S rDNA sequence analysis placing *Xanthobacter* in the class *Alphaproteobacteria* (Rainey and Wiegel, 1996).

Slime formation The majority of the strains produce copious amounts of slime (Fig. BXII.α.244), which consists mainly of glucose, galactose, mannose, and uronic acid (unidentified; 30% or more of the monomers contain a carboxyl group (Andreesen and Schlegel, 1974; Opitz, 1977). At high C:N ratios, the slime formed can cause gelatinization and solidification of the medium without a significant increase in cell mass. The amount of slime varies with the strain as well as growth conditions. Most strains produce copious amounts of slime during growth on carbohydrates or lactate, but minor amounts are formed during growth on O_2/H_2 or on alcohols. No correlation between slime formation and oxygen tolerance during nitrogen fixation is ob-

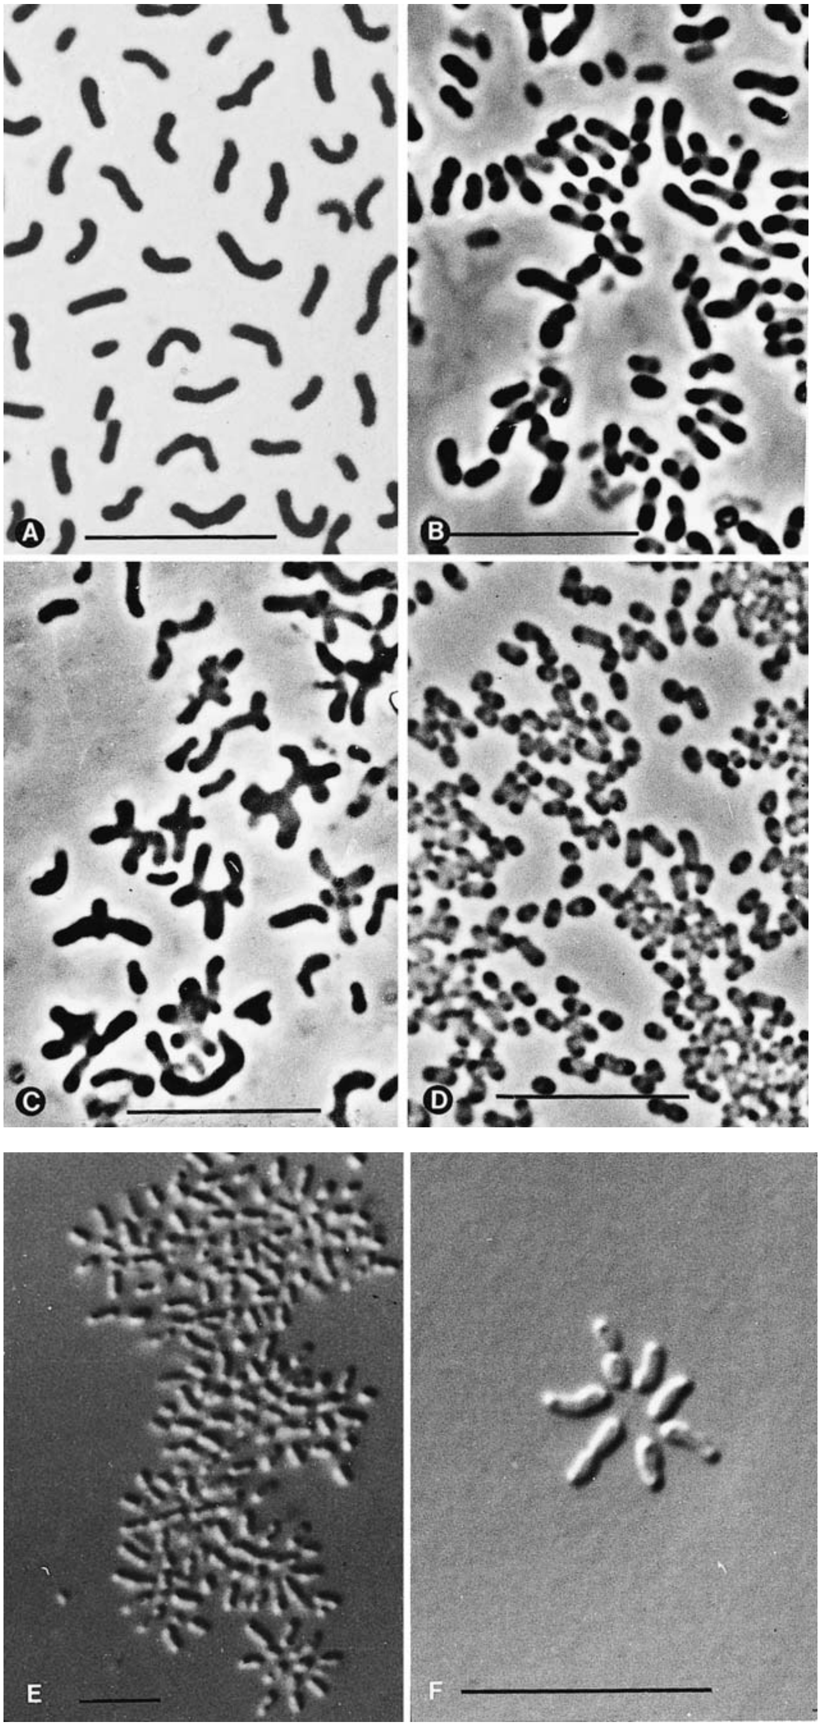

FIGURE BXII.α.241. Cells of *Xanthobacter autotrophicus*. *A*, strain 14g grown on malate in nonagitated liquid culture, showing irregular vegetative cells. *B–D*, strain JW 33 (reference strain). *B*, grown lithoautotrophically under conditions of nitrogen fixation, showing rod-shaped cells and palisade-like formations. *C*, grown in nutrient broth (0.7%) containing 0.1% succinate, showing the typical branched cell formation. *D*, grown on *n*-propanol in the presence of ammonium, showing coccoid cell formation. *E–F*, strain 14g, showing cell aggregation ("star-formation") on nutrient broth medium. This kind of aggregation is only observed after 2–5 h upon transfer into liquid nutrient broth medium under nonagitated growth conditions. All bars = 10 μm. (Parts *A* and *E* reproduced with permission from K. Schneider et al., Archives of Microbiology *93:* 179–193, 1973, ©Springer-Verlag, Heidelberg. Parts *B* and *C* reproduced with permission from J. Wiegel and H.G. Schlegel, Archives of Microbiology *107:* 139–142, 1976, ©Springer-Verlag, Heidelberg. Part *F* reproduced by permission from M. Reh.)

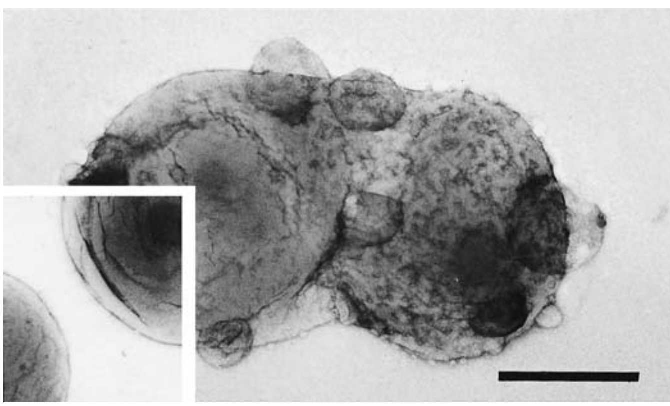

FIGURE BXII.α.243. Demonstration of the presence of lipopolysaccharides in *Xanthobacter autotrophicus.* Negatively stained with 3% uranyl acetate, pH 5. Polymyxin B-treated cell of reference strain JW 33 showing lipopolysaccharide-polymyxin B interactions (bleb formation). The inset shows a control without polymyxin B treatment. Bar = 0.5 µm. (Reproduced with permission from L. Quandt.)

served; however, many of the slime producers grow better than the nonproducers at a high (2–3%) oxygen concentration in the gas atmosphere. Moreover, the majority of the strains produce more slime under N_2-fixing conditions than in the presence of ammonium ions. Beside the motile strains and a very few strains of *X. autotrophicus* that produce traces of slime (e.g., strain JW50), slimeless mutants have been isolated (e.g., mutants of *X. autotrophicus* type strain 7c; Andreesen and Schlegel, 1974), mainly by applying carbon limitation in continuous culture (unpublished results) (Fig. BXII.α.244). The slime becomes soluble at pH values below 4.5 and above 10.5. With alkaline treatment, the slimy cell aggregates can be separated into single cells as needed for isolation purposes (Wiegel and Schlegel, 1976). The slime is somewhat recalcitrant to microbial degradation under aerobic and anaerobic conditions (Andreesen and Schlegel, 1974), but it exhibits useful drag-reducing properties (e.g., reducing frictions in fluids moving through pipes) (Schubert et al., 1986 and personal communication) and could be used as a viscosifier in oil recovery (Kern, 1985; Wan et al., 1988). A different but interesting property is that *Xanthobacter* slime enhanced the efficiency of gene recombination experiments with *Agrobacterium tumefaciens* (Kawai, 1995).

Polyglutamine capsule All of the 20 strains of *X. autotrophicus* and *X. flavus* tested (other species have not been tested) produce an α-polyglutamine capsule that is located between the cell wall and the slime. This polymer is not separated from the cells during an alkaline (pH 11) treatment to solubilize the slime. The glutamine polymer is not found on cells grown under N_2-fixing or chemolithoautotrophic conditions. In contrast to the slime, this polymer is reutilized in the late stationary growth phase and under N-limitation (J. Wiegel, unpublished results). *Flexithrix* is the only other genus known that produces a similar α-polyglutamine capsule (Kandler et al., 1983).

Storage material *Xanthobacter* species deposit poly-β-hydroxybutyrate (PHB) as a reserve material under heterotrophic as well as under chemolithoautotrophic conditions (Fig. BXII.α.242). PHB formation occurred in all tested strains and was analyzed in more details in strains of *X. autotrophicus, X. flavus,* and *X. agilis.* In the stationary growth phase, heterotrophically grown cells contain between 5 and 600 mg PHB/g dry weight of cells, depending on the strain and on the carbon source. Growth on

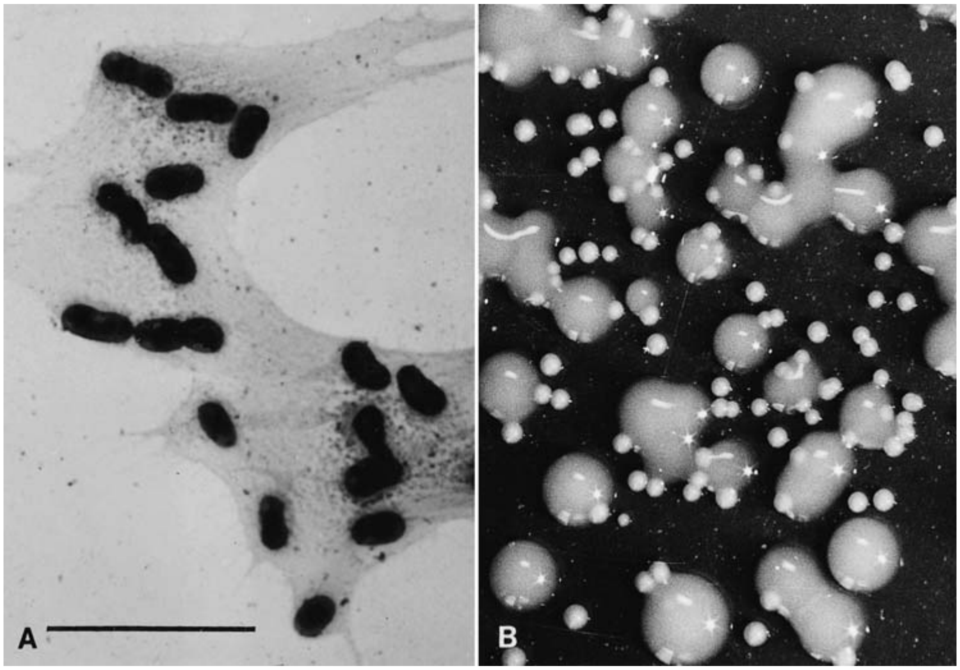

FIGURE BXII.α.244. *A*, Slime production by *Xanthobacter autotrophicus*. Cells and slime of the type strain (DSM 432) stained negatively by uranyl acetate. Bar = 5 μm. (Reproduced with permission from N. Tunail and H.G. Schlegel, Archives of Microbiology *100:* 341–350, 1974, ©Springer-Verlag, Heidelberg.) *B*, Colonies from the wild type (large, slimy colonies) and from the slimeless mutant (small, dark yellow colonies) of DSM 432. (Reproduced with permission from M. Andreesen and H.G. Schlegel, Archives of Microbiology *100:* 351–361, 1974, ©Springer-Verlag, Heidelberg.)

fructose usually results in a high PHB content, whereas growth on succinate results in very low values (less than 15 mg PHB/g dry weight). For example, reference strain *X. autotrophicus* JW33 has 668, 250, and 8 mg PHB/g dry weight when grown on fructose, sucrose, and succinate, respectively (J. Wiegel, unpublished data), based on quantification by spectroscopy after extraction (Jüttner et al., 1975).

Nitrogen fixation and nitrogenase The *Xanthobacter* species described so far are microaerophilic, heterotrophic, and autotrophic (requiring decreased H_2 and O_2 concentrations) N_2-fixing bacteria, as described in the original reports of nitrogen fixation in *X. flavus* (as *"Mycobacterium flavum"* 301) (Federov and Kalininskaya, 1961) and in *X. autotrophicus* (as *"Corynebacterium autotrophicum"*) (Gogotov and Schlegel, 1974; Wiegel and Schlegel, 1976). The nitrogen-fixing system and its relationship to oxygen have been studied mainly with *X. autotrophicus* strain GZ29 (Berndt et al., 1976, 1978) and *X. flavus* strain 301 (Biggins and Postgate, 1969, 1971). The composition of the nitrogenase components of heterotrophically grown cells of strain GZ29 and strain 301 is similar to that of other nitrogenases in regard to metal and sulfur content and amino acid composition. As in other aerobic diazotrophs, the nitrogenase system seems to be loosely associated with membranes. The protection of the nitrogen-fixing system in *Xanthobacter* might be due to some conformational protection for the nitrogenase, the respiration of associated aerobic microorganisms in the natural habitat, or the respiratory activity of *Xanthobacter* itself. The latter possibility seems unlikely, since the respiratory rate of *Xanthobacter* is about one to two orders of magnitude lower than that in *Azotobacter* (Biggins and Postgate, 1971). A possible contribution of slime production to protection against oxygen damage to the nitrogenase could not be demonstrated for *Xanthobacter autotrophicus* (Wiegel, unpublished results). Additional information concerning N_2-fixation in two more well-characterized strains can be summarized as follows:

In *X. autotrophicus* strain GZ29 (Berndt et al., 1976, 1978), the growth rates with ammonium as the nitrogen source and sucrose as the carbon source are highest at an oxygen partial pressure of 0.15 atm, whereas with N_2 as the sole nitrogen source the maximum growth rates occur at 0.014 atm. In the whole cell assay for acetylene reduction, the optimal oxygen partial pressure is 0.0036 atm. Even in the absence of any detectable oxygen, acetylene is reduced linearly for more than 1 h. The acetylene reduction activity has a very narrow pH optimum at 6.8. The nitrogenase is not cold labile. The overall efficiency of nitrogen fixation is 22 mg nitrogen fixed/g of sucrose consumed, but in the early exponential growth phase, values up to 65 mg/g have been found.

In *X. flavus* strain 301 (Biggins and Postgate, 1969, 1971) heterotrophic growth in the presence of ammonium is not dependent on the O_2 partial pressure in the range of 0.01–0.20 atm, but with N_2 as the sole nitrogen source, growth and nitrogen fixation have an optimum at 0.1 atm N_2. The optimal pO_2 for acetylene reduction by whole cells is 0.05 atm. The nitrogenase activity of cell-free extracts stirred under 0.2 atm O_2 decays exponentially, with a half-life of about 5 min. ATP enhances the sensitivity to O_2, presumably because of the formation of an active enzyme conformation. As with nitrogenases from other sources, the enzyme reduces H^+ to H_2, KCN to CH_4, and CH_3NC to CH_4, C_2H_4 and C_2H_6. The optimal concentration of ATP in the cell-free extract for acetylene reduction is 4–8 mM. As in other aerobic diazotrophs, but in contrast to the systems of *Clostridium*

pasteurianum, pyruvate fails to promote acetylene reduction by cell-free extracts.

Ammonium transport Wiegel and Kleiner (1982) postulated that *Xanthobacter* possesses an active ammonium (methyl ammonium) transport system similar to that of other diazotrophs. Methyl ammonium can serve as a sole carbon and nitrogen source (unpublished data). S. Kustu (personal communication) disputes this interpretation and maintains that there is no active ammonium transport system in any bacterium.

Hydrogenase The strains of *X. autotrophicus* studied (e.g., strains 14g, 7c, GZ29) contain a membrane-bound uptake hydrogenase. Like the majority of membrane-bound hydrogenases, this enzyme is not able to reduce NAD directly; instead, it channels electrons into the electron transport chain. A soluble, NAD-reducing hydrogenase is not present (Schneider and Schlegel, 1977). In strain 7c the enzyme is constitutive, and cells grown on various organic substrates and ammonium contain 10–100% of the hydrogenase activity compared to chemolithoautotrophically grown cells (Tunail and Schlegel, 1974). In strain 14g the hydrogenase is a strictly inducible enzyme (Schneider et al., 1973). In strain GZ29 the hydrogenase is apparently a constitutive enzyme; its specific activity (up to 31 mol H_2/h/mg protein in N_2-fixing cells) depends on the oxygen concentration during growth (Berndt and Wölfle, 1979; Pinkwart et al., 1979). Although the enzyme has been solubilized from the membranes and partially purified (Schink and Schlegel, 1980), a detailed description of it is still lacking. Immunological comparison of the membrane-bound hydrogenase of *Alcaligenes eutrophus* strain H16 reveals no relationship to that of *X. autotrophicus* GZ29 (Schink and Schlegel, 1980). Furthermore, an antiserum against the hydrogenase of *X. autotrophicus* strain GZ29 did not react with the membrane extracts of strains 7c, 14g, and 12/60/x. This indicates major differences between the strains. The hydrogenase of the motile strain MA2 is apparently a loosely membrane-bound enzyme that tends to form aggregates and exhibits an unusual high specific activity (Pinkwart et al., 1979, 1982).

Growth conditions The spectrum of carbohydrates utilized by about 80 tested strains of *X. autotrophicus* is normally limited to fructose and/or sucrose and/or—in the presence of traces of yeast extract—mannose. *X. tagetidis* can also grow on galactose and lactose as the sole carbon and energy source. Some strains (*X. autotrophicus* strain 14g and *X. agilis* strains MA2 and SA35 (Jenni and Aragno, 1987)) do not utilize carbohydrates at all, whereas Malik and Claus (1979) reported that strain *X. autotrophicus* DSM 685 could use a wider than normal range of carbohydrates. However, no 16S rRNA sequence or DNA–DNA hybridization data exist on these strains for a definite placement in the proposed species. Some strains of *X. flavus* can utilize a few more sugars, including glucose. Normally *X. autotrophicus*, *X. agilis*, and *X. tagetidis* cannot use glucose, although the pertinent catabolic enzymes are induced during growth on fructose (Opitz, 1977; Padden et al., 1997). However, glucose-utilizing *X. autotrophicus* and *X. flavus* (others not tested) cells appear spontaneously when cultures are incubated for a prolonged time (2–3 weeks) in the presence of glucose. These adapted strains (transport mutants) grow very well on glucose; however, they lose this ability again after growing on other carbohydrates for one or two generations (J. Wiegel, unpublished data). Using the API 20E test, *X. tagetidis* was positive for acetoin production from glucose.

Catabolite repression is exerted by H_2 on the utilization of organic substrates; however, the extent of this effect varies with the organic substrate and the strains studied. Some strains need CO_2/CO_3^{2-} for induction of the enzymes for heterotrophic growth after transition from lithotrophic to organotrophic conditions (Schneider et al., 1973).

The doubling times reported for various strains vary between 1.5 and 5.0 h (heterotrophic conditions) and 3.0 to over 12.0 h (chemolithoautotrophic conditions). Under N_2-fixing conditions, the doubling time is slightly longer (Wiegel and Schlegel, 1976; Berndt et al., 1978).

Traces of yeast extract shorten the lag phase after transition from heterotrophic to lithotrophic conditions. Many strains of *X. flavus* and three strains of *X. autotrophicus* are reported to require biotin (Aragno, 1975). High cell yields during mass culture under autotrophic conditions are obtained when oxygen levels are raised to match the increasing growth. For example, for autotrophic growth with ammonium as the nitrogen source, an O_2 level of 5–8% (v/v) is usually optimum; at optical densities higher than 1.0 (at 600 nm), 10–15% O_2 is sufficient, and at optical densities higher than 2.5 (at 600 nm), 20% O_2 in the gas atmosphere is required for good growth. The oxygen-resistant strain, *X. autotrophicus* Y38, requires nickel for optimal growth (Nakamura et al., 1985).

For strain *X. autotrophicus* GZ29, intact cells are able to reduce acetylene under anaerobic assay conditions, indicating the presence of a fermentative energy regenerating system. So far, however, growth has not been observed under anaerobic conditions and no strict anaerobic metabolic activity has been ascertained (Berndt et al., 1976; Arzumanyan et al., 1997). The finding of a typical methanogenic cofactor, coenzyme M, in *Xanthobacter*, suggests that this issue needs to be revisited, although the proposed role of the cofactor is in the carboxylation of aliphatic epoxide in the aerobic alkene utilization pathway (Allen et al., 1999; Krum and Ensign, 2000; Sauer and Thauer, 2000).

The typical pH for growth is between 6.5 and 8.0, with the optimum around 7.5 for most strains. Although usually no acids are formed from carbohydrates or alcohols, the formation of acidic slime and the consumption of ammonium ions cause the pH of the medium to decrease. This decrease has to be counterbalanced by adding alkali to maintain optimal growth. During growth on organic acids, the pH shift is small, but depending on the slime production of the strain used, it can be in either the acidic or alkaline direction.

Antibiotics Tested strains of *Xanthobacter autotrophicus* and *X. flavus* are sensitive to the following antibiotics at 100 μg/ml of growth medium: penicillin (MIC ~1 μg/ml), novobiocin, and polymyxin B. They are resistant to erythromycin and bacitracin at 200 μg. Violet red-bile medium (Oxoid), deoxycholate medium (Oxoid), and tellurite agar (selective for coryneform bacteria) support growth of the majority of the isolated strains. Both *Xanthobacter* species grow on mineral medium supplemented with an appropriate carbon source and 10^{-5} M crystal violet. However, the colonies formed are red instead of the blue color that is characteristic of other Gram-negative bacteria (Wiegel et al., 1978).

In contrast, *X. tagetidis* is resistant to 1 U penicillin and 5 μg/ml tetracycline but sensitive to 25 μg/ml of ampicillin and 30 μg/ml of chloramphenicol (Padden et al., 1997).

Metabolic pathways Carbohydrates and gluconate are degraded via the Entner–Doudoroff pathway, as has been shown for *X. autotrophicus* strains by determining enzyme activities after growth on various substrates (Tunail and Schlegel, 1972, 1974;

Schneider et al., 1973). In addition, radiorespirometric studies indicate that the pentose phosphate pathway is concomitantly used to a significant degree (Opitz and Schlegel, 1978). *X. autotrophicus* Py2 utilizes an ATP-utilizing acetone carboxylase when growing on acetone (Sluis et al., 1996).

C_1-carbon utilization CO_2 is mainly fixed via the ribulose bisphosphate pathway (Bowien and Schlegel, 1981; Lehmicke and Lidstrom, 1985; Meijer et al., 1991; Meijer 1994; Shively et al., 1998). The key enzyme, ribulose bisphosphate carboxylase, is inducible. In addition, phosphoenolpyruvate carboxylase activity occurs. Radiorespirometric experiments with $^{14}CO_2$ or $^{14}CH_3OH$ as substrates yielded radioactive malate. Other experiments suggest that methanol is presumably utilized via CO_2 and the ribulose bisphosphate cycle (Opitz, 1977). Methanol is oxidized to CO_2 via a methanol dehydrogenase, which is of the normal type (mol. wt. of about 120,000) stimulated by NH_4^+ and contains 2 mol of the coenzyme pyrroloquinoline quinone (PQQ) (J. A. Duine, personal communication). The glucose-6-phosphate dehydrogenase is allosterically inhibited by phosphoenolpyruvate (PEP) (Tunail and Schlegel, 1972; Opitz and Schlegel, 1978). The triose phosphate isomerase is the same enzyme that is formed during chemolithoautotrophic and heterotrophic growth (Meijer et al., 1997).

Carbon monoxide is not oxidized to CO_2 by *X. autotrophicus* or *X. flavus* strains (others not tested) and cannot serve as an energy or carbon source for lithotrophic growth (O. Meyer, personal communication). Thiosulfate can substitute for H_2 as a substrate for lithotrophic growth and provide energy for CO_2-fixation (Friedrich and Mitrenga, 1981; J. Wiegel, unpublished data, six strains of *X. autotrophicus* tested).

Alkene utilization and epoxide formation The use of various alkenes such as ethene, propene, butene, and 1,3-butandien through oxidation by monooxygenases has been studied in detail on the physiological and biochemical level mainly in *X. autotrophicus* strain Py2. The oxidation leads to the formation of epoxides, which then are further metabolized by epoxide hydrolases, and carboxylases (Swaving and deBont, 1998, and older literature cited therein). The use of *Xanthobacter* strains for the commercial removal of propene from waste gas has been proposed (Reij and Hartmans, 1996).

Chloroalkenes and haloaromatic compounds Much work has been done on the haloalkene and haloaromatic compounds degradation by *Xanthobacter* strains, mainly with *X. autotrophicus* GJ10 and on chlorobenzenes with *X. flavus* 14p1 (Spiess et al., 1995; Spiess and Gorisch, 1996; Sommer and Gorisch, 1997). A novel dehalogenase has been found and purified and the crystal structure elucidated. Strain GJ10 contains two dehalogenating enzymes one for haloalkenes and the other for halogenated carboxylic acids (Prince, 1994). Strain *X. autotrophicus* Py2 has a novel pathway for degradation of epichlorohydrin. This strain also degrades trichloroethylene during growth on propene (Reij et al., 1995) as does *X. autotrophicus* GJ10 (Inguva and Shreve, 1999).

Genetics Intraspecific gene transfer has been detected in crosses involving the strains GZ29, GZ27, and JW50 of *X. autotrophicus*, which produce only traces of slime. Strain GZ29 was used to study the transfer more closely. The involvement of a defective generalized transducing bacteriophage as well as conjugational gene transfer have been described (Wilke and Schlegel, 1979; Wilke, 1980). A plasmid has also been identified in strain GJ10 (Bergeron et al., 1998). The bacteriophage CA3 was detectable only by its transducing activity and by electron microscopy; it did not form plaques. The genetic markers (resistance, auxotrophy, pigmentation) were transducible at frequencies of about 10% per marker and per phage particle. No cotransduction of markers was detected. Mating experiments on agar plates have revealed a recombination system requiring direct cell contact. It allowed the transfer of large chromosomal segments at low frequency. All partners used functioned as donors as well as recipients. Two groups of closely linked markers have been found (Wilke, 1980). In addition, an electrotransformation system that is also applicable to other strains has been developed for *X. autotrophicus* GJ10. Transformation rates up to 2×10^6 cells transformed per μg DNA were obtained (Swaving et al., 1996; Swaving and deBont, 1998). A triparental mating system was used to express the dehalogenase in other *Xanthobacter* strains including type strain 7c (Wilke, 1980; Janssen et al., 1989). For *X. autotrophicus* strain Py2, mutants defective in epoxyalkane degradation were complemented with DNA fragments (Swaving et al., 1995).

Cytochromes, ubiquinones, and fatty acids *X. autotrophicus* (only strain 14g has been investigated) contains cytochromes *a*, *b* (two different ones), *c*, and *o*, irrespective of the growth conditions. The amounts of cytochromes *a*, *b*, and *c* type were 0.03, 0.4–0.52, and 0.36 μmol/g of particle protein, respectively (Bernard et al., 1974). Ubiquinones Q-10 (major), Q-9, and Q-8 are present in *X. autotrophicus* and *X. flavus* (Collins and Jones, 1981; Urakami et al., 1995a, and unpublished data). The cellular fatty acids are high in $C_{18:1}$ and include $C_{18:0}$, $C_{16:0\ 3OH}$, and, in *X. agilis*, cyclo $C_{19:0\ cyclo\ \omega7c}$ (Urakami et al., 1995a; Wiegel, unpublished results) (Table BXII.α.189). Menaquinones have not been found in these species (Wiegel et al., 1978). *X. autotrophicus* and *X. flavus* contain the coenzyme pyrroloquinoline quinone after growth on methanol (J.A. Duine, personal communication).

Ferredoxin *Xanthobacter flavus* (previously called *"Mycobacterium flavum"* 301) contains a $[4Fe–4S]_2$- and a [4Fe–4S]-ferredoxin. It is likely that the latter is a [3Fe–3S]-ferredoxin. *X. autotrophicus* GZ29 contains two different $[4Fe–4S]_2$-ferredoxins (Bothe and Yates, 1976; Berndt et al., 1978; Yates et al., 1978; M.G. Yates, personal communication). The ferredoxin of *X. autotrophicus* GZ29 exhibits EPR features in the oxidized as well as in the reduced state, which is in contrast to the ferredoxins of *Azotobacter vinelandii* and *X. flavus*. Thus, it is possible that *X. autotrophicus*, at least strain GZ29, contains ferredoxins unique among N_2-fixing bacteria. Additional strains need to be analyzed before conclusions regarding generic diversity can be drawn. There is no evidence for the presence of constitutive flavodoxins in *X. flavus* 301 (Bothe and Yates, 1976) or in *X. autotrophicus* GZ29. In the latter strain, the ferredoxins probably serve as direct electron donors for the nitrogenase (Schrautemeier, 1981).

Habitats The type strain of *X. autotrophicus*, strain 7c, was isolated from black mud of a pond near Göttingen during enrichments for propane-oxidizing bacteria (Siebert, 1969). However, strain 7c and all other strains tested do not utilize propane. Typical strains of *X. autotrophicus* and *X. flavus* can be specifically isolated from wet soil and mud containing organic material including wetland rice fields (Oyaizu-Masuchi and Komagata, 1988; Reding et al., 1991). A highly specific isolation procedure is based on the ability to fix nitrogen under chemolithoautotrophic growth conditions and specific colony morphology and color on succinate-containing nutrient broth plates after an alkaline treatment (Wiegel and Schlegel, 1976). Yellow colonies containing

[a]Data from Reding (1991). Samples were prepared and analyzed by Microbial ID Inc. (Newark, DE).

[b]Value given is the sum of $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, and $C_{18:1\ \omega12t}$.

branched cells (Fig. BXII.α.241) are probably strains of *Xanthobacter*. Thus, it appears that *Xanthobacter* is ubiquitous in sediment and wet soil samples—including from wet rice fields and marine mud samples—containing organic material.

Strains from *X. autotrophicus* and *X. flavus* can be isolated as associative nitrogen-fixing microaerophiles from rice roots (Reding et al., 1991) and grass roots (Wiegel, unpublished data). *X. tagetidis* was isolated from soil around the roots and roots of the marigold plant (*Tagetes*), suggesting that it is also an associative nitrogen-fixing species (Padden et al., 1997). *X. agilis* has been isolated from the water column of a Swiss lake (Aragno, 1975). Roots of coconut palms (*Cocos nucifera*) contained 10^3 cells per g dry weight (R. Prabhu, personal communication). One *X. flavus* strain originated from a marine sediment sample (Lidstrom-O'Connor et al., 1983; Meijer et al., 1990). *X. autotrophicus* and *X. flavus* isolates have also been found as members of a wood degrading community in wooden pipelines (2-m diameter) from hydroelectric power plants (Line, 1997). Another unusual environment in which *Xanthobacter* has been identified by 16S rDNA assay is in the accessory nidamental glands (ANG) of female cuttlefish and in the myopsid squids, where it occurs as a symbiont (Grigioni et al., 2000).

Pathogenicity No clinical reports of infections of humans or animals by *Xanthobacter* species have been published. In various laboratory settings, however, pathological effects have been observed. This includes the killing of embryos in normally pregnant mice by intraperitoneal injection of 2×10^8 cells of *X. autotrophicus* per g body weight (Manna and Sadhukhan, 1991). In addition, *X. flavus* has exhibited cytological effects and chromosomal aberrations in mouse and human cell cultures (Manna and Sadhukhan, 1992, 1993). No plant pathogenic effects have been reported.

Maintenance Procedures

All strains of *Xanthobacter* can be readily maintained autotrophically on minimal media containing vitamins and 0.02% yeast extract. Cultures grown chemolithoautotrophically can be kept at 2–5°C in liquid medium for about 10 months and in sealed agar slants for more than 15 months; in the presence of 60% (v/v) glycerol, they can be stored for at least 3 years at −20°C. Cultures in liquid nutrient broth or on nutrient agar plates tend to lose viability within 30 d at 4–25°C. For long-term preservation, the cultures are lyophilized in the presence of skim milk with 10% (wt/wt) honey; they have been kept in this form for more than 20 years without significant loss of viability (Malik, 1975, personal communication).

Differentiation of the genus *Xanthobacter* from other genera

Originally two main phenotypic characters were considered to be definitive for *Xanthobacter*: (a) nitrogen fixation under heterotrophic conditions as well as under chemolithoautotrophic conditions (with H_2 serving as the electron donor for respiration), and (b) the presence of the egg-yolk yellow color due to zeaxanthin dirhamnoside. However, nitrogen fixation with H_2 utilization also occurs in several other diazotrophic bacteria (e.g., *Rhizobium*, *Azotobacter*, and *Azospirillum*). Thus, besides determining the relatedness of new isolates to *Xanthobacter* based on the comparison of 16S rDNA sequences, the following special characteristics should be tested before strains are assigned to the genus *Xanthobacter*:

Chemolithoautotrophic growth on $H_2 + CO_2 + O_2$.
Microaerophilic N_2-fixation.
Pleomorphic cells when grown in nutrient broth containing TCA cycle intermediates.
The presence of zeaxanthin dirhamnoside (tested as described by Wiegel (1986)).
Since the Gram reaction (even with the modified procedures) is often doubtful with these species, other methods such as the polymyxin B-lipopolysaccharide interaction (Wiegel and Mayer, 1978; Wiegel and Quandt, 1982), Fig. BXII.α.243 should be used to determine the Gram-type (Wiegel, 1981).
The mol% G + C of the DNA should be in the range 65–70. See phylogenetic comments below for a differentiation from the closely related (based on 16S rDNA sequence analysis) *Aquabacter* and *Azospirillum*.

Xanthobacter strains were originally described as *Mycobacterium* and as *Corynebacterium* (coryneform bacteria) because of their pleomorphic cell shape, their tendency to exhibit a positive Gram staining reaction, their high mol% G + C value, and the impression of a "snapping-type" or "palisade" cell formation. However, in contrast to *Arthrobacter* and coryneform bacteria, snapping occurs because of the presence of adhesive slime and not because of the rupture of connective cell walls (Figs. BXII.α.241 and BXII.α.244). Moreover, *Xanthobacter* is a Gram-type negative organism (Wiegel, 1981). The main carotenoid, zeaxanthin dirhamnoside, separates recognized *Xanthobacter* from other yellow-pigmented chemolithotrophic or N_2-fixing bacteria of other genera. Zeaxanthin has also been found in some strains of *Flavobacterium* that have a high mol% G + C value; however, members of this group neither fix N_2 nor grow chemolithoautotrophically, and do not show pleomorphism similar to that of *Xanthobacter*

(Oyaizu-Masuchi and Komagata, 1988). The high mol% G + C of *Xanthobacter*, its pleomorphism (on succinate–nutrient broth media), and the ability to utilize short aliphatic alcohols are further properties that separate this genus from many other hydrogen-oxidizing bacteria.

Taxonomic Comments

Xanthobacter belongs to the *Alphaproteobacteria* (Rainey and Wiegel, 1996), in agreement with its previous assignment to the fourth RNA superfamily of the Gram-type negative bacteria (De Smedt et al., 1980). Before 16S rDNA sequence analysis was completed, the genus *Xanthobacter* was regarded as a well-defined genus with easily recognizable traits (see above). However, 16S rDNA sequence analysis places two other organisms—*Azorhizobium caulinodans* (Dreyfus et al., 1988) and *Aquabacter spiritensis* (Irgens et al., 1991)—among the species of *Xanthobacter*, thereby converting the well-defined genus to a cluster—the *Xanthobacter–Azorhizobium–Aquabacter* cluster. The placement of *Azorhizobium* is in agreement with a previously published rRNA cistron similarity dendrogram (De Ley, 1992). *Azorhizobium caulinodans* differs from all *Xanthobacter* species by its absence of the characteristic yellow color, failure to grow on carbohydrates, methanol, or methylamine, and by its inability to fix CO_2; moreover, unlike *Xanthobacter*, it shows nodulation of plant stems. *Aquabacter spiritensis* (Irgens et al., 1991) differs from *Xanthobacter* by containing gas vacuoles, showing no sugar or methanol utilization, failing to grow under autotrophic conditions, and by an absence of pleomorphic cell shapes. For both *Aquabacter* and *Azorhizobium*, zeaxanthin dirhamnoside or a precursor thereof has not been demonstrated, although the organisms probably have not been carefully analyzed for its presence. Since *Aquabacter* and *Azorhizobium* apparently do not share several of the key properties used to define the genus *Xanthobacter*, it is presently not quite clear how to solve the problem of their taxonomy. To make a better decision on what defines this phylogenetic group beside its relatedness on the 16S rDNA sequence level, the author suggests waiting until more novel and unusual strains and 16S rDNA sequences have been described. One possibility is that, based on the 16S rDNA sequence data, all isolates including the strains presently named *Azorhizobium* or *Aquabacter* and similar strains might be combined as species in an emended genus *Xanthobacter*, since this genus name would have seniority. Another possibility is that *X. agilis*, *X. flavus*, and *X. tagetidis* might be transferred to new genera. At present, an assignment of novel strains to the genus *Xanthobacter*, *Aquabacter*, and *Azorhizobium* should definitely include 16S rDNA sequence analysis and if possible DNA–DNA hybridization data to aid in solving this question.

Two not validly published *Blastobacter* species were reassigned to two novel *Xanthobacter* species *X. viscosus* 7d and *X. aminoxidans* 14d (Doronina and Trotsenko, 2003). Both strains were originally isolated from activated sludge and exhibited yellow branching cells and other typical characteristics of *Xanthobacter* species. However, cells reproduced by budding, thus requiring an emendation of the *Xanthobacter* genus description to include this feature. Closest neighbors in the 16S rDNA based phylogenetic tree are *X. autotrophicus* and *X. flavus*, respectively. The creation of *X. aminoxidans* based on DNA–DNA hybridization data requires a reevaluation of the *X. flavus* strains including H4-14 with respect to the type strain *X. flavus* 301, since the differences in the 16S rDNA values of the strains are small.

Differentiation of the species of the genus *Xanthobacter*

Characteristics useful for the differentiation of the four species currently recognized in the genus *Xanthobacter* are listed in Table BXII.α.190. Because the designated type strain of the type species *X. autotrophicus* strain 7c is a relatively atypical strain, the reference strain *X. autotrophicus* JW33 (DSM 1618) should be used for comparative studies (Wiegel et al., 1978). However, alkane oxidation and dehalogenation capabilities and thiophene carboxylic acid utilization have not been studied for either of these two strains.

TABLE BXII.α.190. Differential characteristics of the species of the genus *Xanthobacter*[a]

Characteristic	*X. autotrophicus*	*X. agilis*	*X. flavus*	*X. tagetidis*
Cell morphology: pointed ends, twisted	−	−	−	+
Highly pleomorphic on nutrient broth agar + succinate	+	−	+	+
Motility under autotrophic growth conditions	−	+	−	+
Vitamins required for growth (biotin, riboflavin)	d	−	+	−
Sensitivity to chloramphenicol	−	+	−	+
Autotrophic growth at 37°C	+	−	+	+
Growth on nutrient broth	+	−	+	+
Growth on glutamine as carbon source	+	−	−	nd
Growth on citrate	+	−	d	+

[a]For symbols, see standard definitions; nd, not determined.

List of species of the genus Xanthobacter

1. **Xanthobacter autotrophicus** (Baumgarten, Reh and Schlegel 1974) Wiegel, Wilke, Baumgarten, Opitz and Schlegel 1978, 580[AL] (*"Corynebacterium autotrophicum"* Baumgarten, Reh and Schlegel 1974, 214.)
au.to.tro'phi.cus. Gr. pref. *auto* self; Gr. n. *trophos* one who feeds; M.L. masc. adj. *autotrophicus* self feeding, referring to the ability of the organism to use CO_2 as a sole carbon source.

The characteristics are as described for the genus and as listed in Tables BXII.α.190 and BXII.α.191. The morphology is depicted in Fig. BXII.α.241.

Habitat: soil, mud, and water. Widely distributed in nature.

The mol% G + C of the DNA is: 69–70 (T_m) (Wiegel et al., 1978); 65–68 (T_m) (De Smedt et al., 1980); 66–68 (Bd) (M. Aragno, unpublished data).

Type strain: 7c, ATCC 35674, CIP 105432, DSM 432.

GenBank accession number (16S rRNA): X94201.

Additional Remarks: The type strain is atypical of the species, and reference strain DSM 1618 (strain JW33; Wiegel and Schlegel, 1976; Wiegel et al., 1978) should be used for comparative purposes. Reference strains T101 and T102 (ATCC7000551/2) degrade toluene and were isolated from a drainage ditch (Wilmington MA, USA). Strain GJ10 (DSM 3874; ATCC 43050) degrades haloalkanes including dichloromethane (Janssen et al., 1985). Other well-characterized strains can be obtained from the authors who described them.

2. **Xanthobacter agilis** Jenni and Aragno 1988, 136[VP] (Effective publication: Jenni and Aragno 1987, 257.)
a'gi.lis. L. adj. *agilis* quick, agile, indicating motility.

The general characteristics are as described for the genus and as listed in Tables BXII.α.190 and BXII.α.191. The morphology of *X. agilis* differs somewhat from that of *X. autotrophicus*, *X. flavus*, and *X. tagetidis* in that the branched-cell morphology on succinate-NB medium is much less pronounced and can be observed only after prolonged incubation.

At the time of its description, *Xanthobacter* species were described as nonmotile; this description was changed later (Reding et al., 1992; Reding and Wiegel, 1993) However, *X. agilis* strains are motile under nearly all growth conditions and exhibit a faster movement than that of other species.

Several strains were isolated from a freshwater lake in Switzerland (Jenni and Aragno, 1987). The type strain was isolated from the water column of a small lake in Neuchatel (Switzerland).

The mol% G + C of the DNA is: 68–69 (T_m).

Type strain: SA35, ATCC 43847, DSM 338, LMG 16336.

GenBank accession number (16S rRNA): X94198.

3. **Xanthobacter flavus** Malik and Claus 1979, 286[AL]
fla'vus. L. adj. *flavus* yellow.

The characteristics are as described for the genus and as listed in Tables BXII.α.190 and BXII.α.191. The properties of *X. flavus* are somewhat similar to those of *X. autotrophicus*, except the nitrogenase system of *X. flavus* 301 differs considerably from *X. autotrophicus* strain GZ29 (Berndt et al., 1978) and all *X. flavus* used to require the addition of biotin to the culture medium. However, non–biotin-requiring strains have been isolated more recently and identified as *X. flavus* by 16S rDNA sequence analysis. The DNA–DNA hybridization values (T_m) between the type strains of *X. flavus* and *X. autotrophicus* is about 25%. Furthermore, in comparison with *X. autotrophicus*, the type strain 301 exhibits a higher sensitivity to oxygen under autotrophic conditions. The range of carbohydrates that can be used is no longer regarded as a valuable property for differentiating these two species as previously proposed (Malik and Claus, 1979).

Isolated from turf podozol soil in the U.S.S.R, rice patty sediments, marine sediments, sewage in the Netherlands, and wetland rice roots.

The mol% G + C of the DNA is: 68–69 (T_m).

Type strain: 301, ATCC 35867, DSM 3770; IFO 14759, NCIB 10071.

GenBank accession number (16S rRNA): X94199.

Additional Remarks: Reference strains include rice root isolate JW-KR2 (ATCC 51492); strain 14p1 (DSM 10330), which degrades 1,4-dichlorobenzene and was isolated from contaminated soil by Sommer and Gorisch (1997); and strain H4-14 of Meijer et al. (1990). The type strain, 301, was misclassified by Federov and Kalininskaya (1961) as *"Mycobacterium flavum"* strain 301.

4. **Xanthobacter tagetidis** Padden, Rainey, Kelly and Wood 1997, 400[VP]
ta.ge.ti'dis. M.L. n. *tagetidis* of *Tagetes* the marigold genus of flowering plants.

The main characteristics are as described for the genus and as listed in Tables BXII.α.190 and BXII.α.191. The main properties of *X. tagetidis* are similar to those of the other species in respect to the characteristic yellow color of zeaxanthin dirhamnoside, pleomorphism on succinate-NB medium, production of copious amounts of slime while growing on carbohydrates, and restricted utilization of carbohydrates. Although they grow poorly, the wild type strains are able to grow more readily on glucose than most other strains tested belonging to the other three species. It can be specifically isolated from soil around the roots of marigold plants (*Tagetes patula* and *T. erecta*). *X. tagetidis* is so far the only *Xanthobacter* species that can utilize substituted thiophenes. Whether or not the ability to grow on substituted thiophenes is restricted only to *X. tagetidis* (Padden et al., 1997, 1998) or also can be found among strains belonging to the other species is presently unknown. Similar to *X. agilis*, *X. tagetidis* is motile under most growth conditions.

To date, two strains were described that were isolated from sludge (strain DSM 11602) and from soil around marigold plants (strain TagT2C), respectively, in England. The type strain was isolated from composted root balls of *T. patula*.

The mol% G + C of the DNA is: 68–69 (T_m).

Type strain: TagT2C, ATCC 700314, DSM 11105.

GenBank accession number (16S rRNA): X99469.

Additional Remarks: Several strains with properties other than described above have been isolated and are under investigation. However, several of them, although biochemically well studied, have not been deposited in a culture collection or assigned a species name at this time.

TABLE BXII.α.191. Other characteristics of the species of the genus *Xanthobacter*[a]

Characteristic	*X. autotrophicus*	*X. agilis*	*X. flavus*	*X. tagetidis*

Other Organisms

1. *"Xanthobacter methylooxidans"*

   The species name *"X. methylooxidans"* has been proposed for the facultatively methylotrophic bacterial strain 32P (Doronina et al., 1996c). It is characterized by a high content of *cis*-vaccenic (55–75%) and lactobacillic (13–17%) acids. It does not require vitamins, forms indole, ammonia, and hydrogen sulfide, liquefies gelatin, and utilizes formate, methylamine, dimethylformamide, dimethylacetamide, and dimethyl sulfoxide as carbon and energy sources. The oxidation of methanol proceeds with the participation of the corresponding dehydrogenases via formaldehyde and formate to CO_2, which is assimilated via the ribulose bisphosphate pathway. Strain 32P oxidizes H_2 and fix N_2. The DNA–DNA hybridization values of strain 32P with type strains belonging to the genus *Xanthobacter* (*X. agilis* DSM 3770, *X. flavus* DSM 338, and *X. autotrophicus* DSM 432) did not exceed 25%; this, together with its phenotypic peculiarities, allowed strain 32P to be classified as a "new species", however, without being validly described and named).

   The mol% G + C of the DNA is: 69.5 (T_m).

   Deposited strain: 32P.

2. Several isolates have been described either as strains without attributing them to a genus, but that resemble *Xanthobacter* strongly in their properties, or were just described as strains of *Xanthobacter* but without assignment to a species. Many autotrophically isolated strains of *X. autotrophicus* from various habitats can be obtained from J. Wiegel. The others strains below should be available from the corresponding authors; unfortunately, the strains have not been deposited in public culture collections. Some of the early isolated and interesting strains are:

   a. Sixteen strains isolated on alkenes (De Bont and Leijten, 1976)
   b. *"Mycobacterium butanitrificans"* (Coty, 1967)
   c. Group IV, 10 strains (Kouno and Ozaki, 1975)
   d. Strains N61 and N63 (Jensen and Holm, 1975)
   e. Strains PY 2 (Ensign, personal communication: *X. autotrophicus*; one of the best studied strains in respect to carbon metabolism; containing coenzyme M) PY10, By2 (van Ginkel and DeBont, 1986; van Ginkel et al., 1986) utilizing alkanes under epoxide formation
   f. Strain 124X (ATCC 49450), degrading 4-hydroxyphenylacetate (Van den Tweel et al., 1986) and styrene (Hartmans et al., 1989)
   g. Strain MAB2 (ATCC 48876) (Villarreal et al., 1991) and patent strain NW11 (ATCC 53272), (Robinson and Stipanovic, 1989) polysaccharide producing strains for use in oil recovery
   h. Strain 25a (Meijer et al., 1990)
   i. Strain Cimw 99 (Smith et al., 1991) degrading 3-chloro-2-methylproprionic acid
   j. Strain CP (Ditzelmüller et al., 1989) degrading chlorophenols and 2,4-dichlorophenylacetic acid

Family IX. **Methylobacteriaceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Meth.yl.o.bac.te.ri.a' ce.ae. M.L. neut. n. *Methylobacterium* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Methylobacteriaceae* the *Methylobacterium* family.

The family *Methylobacteriaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Methylobacterium* (type genus) and *Microvirga*. *Microvirga* was proposed after the cut-off date for inclusion in this volume (June 30, 2001) and is not described here (see Kanso and Patel (2003).

Chemoorganotrophic; *Methylobacterium* is facultatively methylotrophic. Form pink colonies.

Type genus: **Methylobacterium** Patt, Cole and Hanson 1976, 228 emend. Green and Bousfield 1983, 876.

Genus I. **Methylobacterium** *Patt, Cole and Hanson 1976, 228^AL emend. Green and Bousfield 1983, 876*

PETER N. GREEN

Meth.yl.o.bac.te' ri.um. M.L. n. *methyl* the methyl radical; Gr. n. *bacterion* a small rod; M.L. neut. n. *Methylobacterium* methyl bacterium.

Rods 0.8–1.2 × 1.0–8.0 µm that occasionally branch and/or exhibit polar growth. Form pink to orange-red colonies on methanol salts agar. Stain Gram negative to Gram variable; Gram-negative cell wall type. Motile by means of a single polar, subpolar, or lateral flagellum. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Mesophilic. Chemoorganotrophic and facultatively methylotrophic**, able to grow with formaldehyde (often at micromolar concentrations), formate, and methanol; some strains grow on methylated amines. Widely distributed in nature.

The mol% G + C of the DNA is: 68.0–72.4.

Type species: **Methylobacterium organophilum** Patt, Cole and Hanson 1976, 228.

FURTHER DESCRIPTIVE INFORMATION

Morphology and cell structure All *Methylobacterium* strains are rods (0.8–1.2 × 1.0–8.0 µm) that occur singly or occasionally in rosettes (Heumann, 1962; Patt et al., 1974). They are often branched or pleomorphic, especially in older stationary-phase cultures (Fig. BXII.α.245). There is some evidence to suggest that they exhibit polar growth or a budding morphology (L.B. Perry, unpublished observations). All strains are motile by a single polar, subpolar or lateral flagellum, although some strains are not vigorously motile. Cells often contain large sudanophilic inclusions (poly-β-hydroxybutyrate) and sometimes volutin granules. They are Gram negative, although many strains stain as Gram variable. Representative strains have a multilayered cell wall structure and the type of citrate synthase (Green and Bousfield, 1982) characteristic of Gram-negative bacteria.

Cultural features Most strains grow slowly but a few grow poorly or not at all on nutrient agar. After 7 d incubation at 30°C, colonies on GP agar are 1–3 mm in diameter and pale pink to bright orange-red, whereas colonies on MMS agar are a more uniform pale pink. The pigment is nondiffusible, nonfluorescent, and is a carotenoid (Ito and Iizuka, 1971; Downs and Harrison, 1974, Urakami et al., 1993). In static liquid media, most strains form a pink surface ring and/or pellicle.

The optimal growth temperature for all *Methylobacterium* strains is in the range 25–30°C. Some strains will grow at 15°C or less, and some will grow at or above 37°C. Although growth is optimal around neutrality, some strains can grow at pH 4 and some at pH 10.

Pigments All strains contain carotenoid pigments that have absorption maxima at 465, 495, and 525 nm (Urakami et al., 1993). Sato (1978), Sato and Shimizu (1979), and Nishimura et al. (1981) have shown that strains of *Methylobacterium* can form bacteriochlorophyll *a* under specific cultural conditions, suggesting a common link with the phototrophs in their ancestry.

Metabolism and methylotrophy All strains are strict aerobes and are catalase and oxidase (often weakly) positive. They are chemoorganotrophs and facultative methylotrophs, capable of growth on a variety of C_1 compounds. All grow on formaldehyde (often at micromolar concentrations), formate, and methanol; some grow on methylated amines. Only one species (*M. organophilum*) is reported to have utilized methane as sole carbon and energy source, but the ability has since been lost by the type (and only) strain. Methane assimilability in this organism was thought to be plasmid borne and easily lost if cultures were not maintained on an inorganic medium in a methane atmosphere (R.S. Hanson, personal communication). This led Green and Bousfield (1983) to emend the genus description of *Methylobacterium* to exclude methane assimilation as a key taxonomic criterion. Representative *Methylobacterium* strains have been reported to assimilate C_1 compounds via the icl(-) serine pathway (the type of serine C_1-assimilatory pathway used by these organisms) (Quayle, 1972; Bellion and Spain, 1976) and to have a complete tricarboxylic acid cycle when grown on complex organic substrates.

Growth factors are not required by any strain although growth of some strains is stimulated by calcium pantothenate. Most strains do not degrade or hydrolyze casein, starch, gelatin, cellulose, lecithin, or DNA. Urease is produced by all strains, and some strains have weak lipolytic activity. The enzymes β-galactosidase, L-ornithine decarboxylase, L-lysine decarboxylase, and L-arginine dihydrolase are not produced. Indole (except for *M. thiocyanatum*) and H_2S are also not produced. The methyl red and Voges–Proskauer tests are negative, although some strains reduce nitrate to nitrite.

Carbon and nitrogen sources The following compounds were used as carbon sources by most (≥95%) strains of *Methylobacterium*: glycerol, malonate, succinate, fumarate, α-ketoglutarate, DL-lactate, DL-malate, acetate, pyruvate, propylene glycol, ethanol, methanol, and formate. Some strains (see Green and

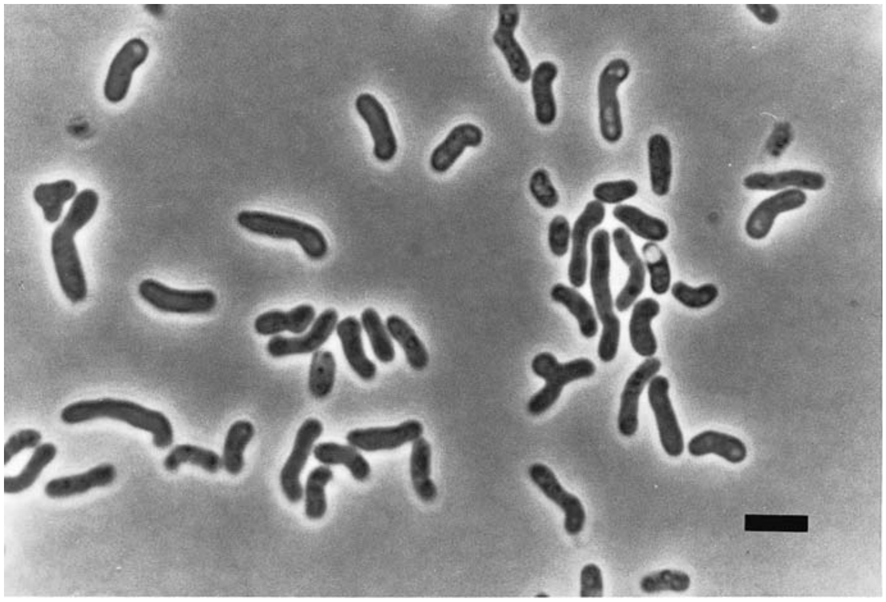

FIGURE BXII.α.245. Phase-contrast micrograph of *Methylobacterium* spp. Bar = 2 μm.

Bousfield, 1982; Urakami et al., 1993, and Table BXII.α.192) can also utilize L-arabinose, D-xylose, D-fucose, D-glucose, D-galactose, D-fructose, L-aspartate, L-glutamate, adipate, pimelate, sebacate, azelate, suberate, D-tartrate, citrate, citraconate, saccharate, monomethylamine, dimethylamine, trimethylamine, trimethylamine-*N*-oxide, ethanolamine, butylamine, formamide, *N*-methylformamide, dimethylglycine, betaine, tetramethylammonium hydroxide (TMAH), *N,N*-dimethylformamide (DMF), chloromethane, and dichloromethane. None of the strains appear to use any of the disaccharides or sugar alcohols examined (except for glycerol) (Green and Bousfield, 1982) or any of the following as sole carbon and energy source: propionate, DL-arginine, L-valine, glycine, geraniol, tryptamine, histamine, putrescine, *m*-hydroxybenzoate, testosterone, sarcosine, phenol, thiourea, tetramethyl urea, hexane, or benzene. Oxidative production of acid from sugars was variable among strains Urakami et al. (1993).

Ammonia, nitrate, and urea can serve as nitrogen sources (Urakami and Komagata, 1984). *M. thiocyanatum* can utilize thiocyanate or cyanate as sole source of nitrogen for growth (Wood et al., 1998).

Fatty acid composition The fatty acid composition of *Methylobacterium* strains is comprised largely (around 70–90%) of $C_{18:1}$ acid with small amounts of $C_{16:1}$, $C_{19:0\ cyclo}$, and $C_{14:0\ 3OH}$ hydroxy acid. Some strains contain hopanoids and small amounts of squalene. Phospholipids of all strains included large amounts of cardiolipin (diphosphatidylglycerol), phosphatidylethanolomine, phosphatidylcholine, and a small amount of phosphatidylglycerol (Urakami et al., 1993). The major isoprenoid quinone components are ubiquinones with 10 isoprene units (Urakami and Komagata, 1979). DNA base composition is 68.0– 72.4 mol% G + C (Hood et al., 1987).

Antibiotic sensitivity Most strains are sensitive to the chemotherapeutic agents kanamycin, gentamicin, albamycin T, streptomycin, framycetin, and especially the tetracyclines, whereas most are resistant to cephalothin, nalidixic acid, penicillin, bacitracin, carbenicillin, colistin sulfate, polymyxin B, and nitrofurantoin.

Habitats and sources Being ubiquitous in nature and a common airborne organism, strains of *Methylobacterium* spp. are found in a wide variety of environmental, industrial, and even occasionally clinical environments, mainly as part of a transient flora or as chance contaminants. Their ability to scavenge trace amounts of nitrogen and to resist a certain degree of desiccation contributes to their survival in hostile environments. Some strains have been shown to exhibit resistance to gamma irradiation 10–40 times higher than that exhibited by many other Gram-negative bacteria (Ito and Iizuka, 1971). *M. thiocyanatum* (Wood et al., 1998) has been shown to tolerate high (≥50 mM) thiocyanate or cyanate. Other *Methylobacterium* strains have not been tested for this feature.

Enrichment and Isolation Procedures

Because of the ability of *Methylobacterium* spp. to grow on methanol as sole carbon and energy source, and because of their characteristic pigmentation, these organisms are relatively easy to isolate. Methanol mineral salts (MMS)[1] medium is a suitable selective medium for *Methylobacterium.*

Although many *Methylobacterium* strains can grow between 5°C and 37°C, all grow well at 30°C, and thus 25–30°C can be used for all isolation and subsequent growth experiments. These organisms are fairly slow growers, often taking 2–3 d at 30°C to produce clearly visible colonies or confluent growth, and often taking more than 7 d for colonies to reach their maxim size of 1–3 mm in diameter. Growth is sometimes more luxuriant, with

1. Methanol mineral salts medium consists of (per liter water): K_2HPO_4, 1.20 g; KH_2PO_4, 0.62 g; $CaCl_2{\cdot}6H_2O$, 0.05 g; $MgSO_4{\cdot}7H_2O$, 0.20 g; NaCl, 0.10 g; $FeCl_3{\cdot}6H_2O$, 1.0 mg; $(NH_4)_2SO_4$, 0.5 mg; $CuSO_4{\cdot}5H_2O$, 5.0 mg; $MnSO_4{\cdot}5H_2O$, 10.0 mg; $Na_2MoO_4{\cdot}2H_2O$, 10.0 mg; H_3BO_3, 10.0 mg; $ZnSO_4{\cdot}7H_2O$, 70.0 mg; $CoCl_2{\cdot}6H_2O$, 5.0 mg. The medium is sterilized by autoclaving at 121°C for 20 min and cooled to 50°C. A filter-sterilized vitamin solution (Colby and Zatman, 1973) is added if required, along with 0.1–0.2% v/v sterile methanol. The pH of the medium is adjusted to pH 7.0. A solidified medium (MMS agar) is prepared by the addition of 1.5–2% Oxoid purified agar before autoclaving. No *Methylobacterium* strain isolated to date has been shown to have an obligate requirement for vitamins or other added growth factors.

[g]Most strains which utilize sebacate can also utilize pimelate, suberate, azelate, and adipate.

[h]Nutrient agar, e.g., Oxoid cm55.

a deeper pigmentation, on Glycerol–Peptone (GP) agar[2]. Although this medium is useful for subculturing stocks of pure *Methylobacterium* spp., it is less suitable for enrichment than the MMS medium, as other rapidly growing heterotrophs present in the sample can overgrow the pink-pigmented facultative methylotrophic (PPFM) bacteria. The use of certain antibiotics in selective media (see Further Descriptive Information, this chapter) can also be considered, as can the use of individual carbon sources, for the isolation of specific groups or species of *Methylobacterium*.

If MMS agar is used as a selective medium, the vast majority of the pink colonies which reach diameters of more than 1 mm will be strains of PPFM organisms. Pink methylotrophic yeasts are not uncommon, but bacterial pink methylotrophs other than *Methylobacterium* species are rare. Growth of PPFM organisms in liquid media is almost always characterized by a surface ring and/or thin pellicle, indicative of their aerobic nature.

When attempting to isolate PPFM strains from leaf surfaces, a leaf impression technique, using one of the above media, is recommended. Homogenization of whole leaves or embedding of leaves in molten agar are alternatives, although they are not as successful as the impression technique.

If fungal contamination is a problem with samples from particular habitats when attempting to isolate strains of PPFM, 20 μg/ml of cycloheximide can be added to the medium.

Maintenance Procedures

Strains of *Methylobacterium* can be maintained short term (2–4 weeks) on GP or methanol salts agar. For long-term preservation organisms can be stored at −70°C or in/over liquid nitrogen, using either of the above liquid growth media supplemented with 10% v/v glycerol; alternatively, the organisms can easily be lyophilized. Strains isolated on methane and dichloromethane must be maintained on a salts medium containing these compounds as sole carbon source or their ability to utilize these substrates may be lost.

Procedures for Testing Special Characters

Because the nine species of *Methylobacterium* are differentiated mainly by the pattern of compounds they utilize as sole carbon and energy source, care should be taken to standardize such tests since they are notoriously difficult to duplicate between laboratories. All carbon utilization tests shown in Table BXII.α.192 were carried out as described by Green and Bousfield (1982), who used faintly turbid suspensions of cells that had been thrice washed in sterile saline, to inoculate media. All tests were read only after 14 days incubation at 30°C, and growth was compared to a negative control with no added carbon source. This long incubation time was necessary to allow for slow growth on certain compounds. Tests for biochemical, physiological, and morpho-

2. Glycerol–Peptone Agar consists of (g/l): agar, 15.0; glycerol, 10.0; peptone (Difco), 10.0. The pH is adjusted to pH 7.0.

logical features as well as calculations of DNA base ratios are described by Green and Bousfield (1982) and Green (1992).

Taxonomic Comments

Many of the strains which comprise the genus *Methylobacterium* have a checkered taxonomic history (Green and Bousfield, 1981) and based on their Gram variability, occasional cellular pleomorphism, and flagellar arrangements were previously included in the following genera: *Bacillus*, *Vibrio*, *Pseudomonas*, *Flavobacterium*, *"Protaminobacter"*, *Mycoplana*, *Protomonas*, and *Methylobacterium*. Taxonomic studies (Wolfrum et al., 1986; Hood et al., 1987, 1988; Urakami et al., 1993) have shown the genus to be heterogeneous, with 12 validly published species to date (Green, 1992; Urakami et al., 1993; Wood et al., 1998; Doronina et al., 2000b; McDonald et al., 2001), as well as several unassigned strains representing centers of genetic variation which may equate to new taxa. Recent DNA–rRNA homology studies by Dreyfus et al. (1988) have placed *Methylobacterium* in the rRNA superfamily IV of De Ley (1978), along with other members of the *Agrobacterium*–*Rhizobium* complex.

Differentiation of the species of the genus *Methylobacterium*

Species within the genus *Methylobacterium* are differentiated mainly by the pattern of compounds they utilize as sole carbon and energy source (see Table BXII.α.192).

List of species of the genus Methylobacterium

1. **Methylobacterium organophilum** Patt, Cole and Hanson 1976, 228[AL]
or.ga.no′phi.lum. Gr. n. *organo* organ, living bodies; Gr. adj. *philos* loving; Gr. adj. *organophilus* intended to mean preferring complex carbon sources.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. Originally reported as being able to utilize methane as sole source of carbon and energy (Patt et al., 1974), but this feature has subsequently been lost (Green and Bousfield, 1982). The type strain was isolated from lake sediment.
The mol% G + C of the DNA is: 70.5 (T_m); 71.1 (Bd).
Type strain: XX, ATCC 27886, DSM 760, NCIMB 11278.
GenBank accession number (16S rRNA): D32226.

2. **Methylobacterium aminovorans** Urakami, Araki, Suzuki and Komagata 1993, 510[VP]
a.mi.no′vo.rans. N.L. n. *aminus* amine; L. part. adj. *vorans* devouring, digesting; N.L. part. adj. *aminovorans* amine digesting.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from soil.
The mol% G + C of the DNA is: 68.0 (HPLC).
Type strain: TH15, JCM 8240, NCIMB 13343.

3. **Methylobacterium chloromethanicum** McDonald, Doronina, Trotsenko, McAnulla and Marrell 2001, 121[VP]
chlo.ro.me.tha′ni.cum. N.L. n. *chloromethanicum* chloromethane utilizing.

Characteristics are those given for the genus and/or the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from soil at the Nizhekamsk petrochemical factory, Tatarstan, Russia.
The mol% G + C of the DNA is: 64.4 (T_m).
Type strain: CM4, NCIMB 13688.
GenBank accession number (16S rRNA): AF198624.

4. **Methylobacterium dichloromethanicum** Doronina, Trotsenko, Tourova, Kuznetsov and Leisinger 2000c, 1953[VP] (Effective publication: Doronina, Trotsenko, Tourova, Kuznetsov and Leisinger 2000b, 216.)
di.chlo.ro.meth.an′ic.um. M.L. n. *methanum* methane; L. pref. *di* two; M.L. adj. *dichloromethanicum* dichloromethane utilizing.

Characteristics are those given for the genus and/or the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from activated sludge.
The mol% G + C of the DNA is: 67.1 (T_m).
Type strain: DM4, DSM 6343.
GenBank accession number (16S rRNA): AF227128.

5. **Methylobacterium extorquens** (Bassalik 1913) Bousfield and Green 1985, 209[VP] (*Protomonas extorquens* (Bassalik 1913) Urakami and Komagata 1984, 198; *Bacillus extorquens* Bassalik 1913, 258.)
ex.tor′quens. L. part. adj. *extorquens* twisting out.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from earthworm excreta in 1949 by L. Janota-Bassalik. Bassalik's original strain is no longer extant.
The mol% G + C of the DNA is: 69.4 (Bd).
Type strain: ATCC 43645, DSM 1337, NCIMB 9399.
GenBank accession number (16S rRNA): L20847, D32224.

6. **Methylobacterium fujisawaense** Green, Bousfield and Hood 1988, 124[VP]
fu.ji.sa′wa.en.se. N.L. neut. adj. *fujisawaense* coming from the Fujisawa region of Japan.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192.
The mol% G + C of the DNA is: 70.8–71.8 (Bd).
Type strain: 0-31 (Kouno and Ozaki 1975), ATCC 43884, DSM 5686, NCIMB 12417.

7. **Methylobacterium mesophilicum** (Austin and Goodfellow 1979) Green and Bousfield 1983, 876[VP] (*Pseudomonas mesophilica* Austin and Goodfellow 1979, 377.)
me.so.phi′li.cum. Gr. n. *meson* the middle; Gr. adj. *philikos* friendly; N.L. neut. adj. *mesophilicum* friendly to the middle, because of its preference for moderate temperatures.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from *Lolium perenne* leaves.
The mol% G + C of the DNA is: 69.9 (Bd).
Type strain: A47, ATCC 29983, DSM 1708, NCIMB 11561.
GenBank accession number (16S rRNA): D32225.

8. **Methylobacterium radiotolerans** (Ito and Iizuka 1971) Green and Bousfield 1983, 876[VP] (*Pseudomonas radiora* Ito and Iizuka 1971, 1568.)
ra.di.o.to′le.rans. Eng. pref. *radio* pertaining to radiation; L. part. adj. *tolerans* tolerating; N.L. part. adj. *radiotolerans* tolerating radiation.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from rice grains.

The mol% G + C of the DNA is: is 72.3 (Bd).

Type strain: 0-1, ATCC 27329, DSM 1819, NCIMB 10815.

GenBank accession number (16S rRNA): D32227.

9. **Methylobacterium rhodesianum** Green, Bousfield and Hood 1988, 124^VP^
rho' de.si.an.um. M.L. neut. adj. *rhodesianum* named after the British taxonomist Muriel Rhodes–Roberts.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from a fermentor operating with formaldehyde as sole carbon source.

The mol% G + C of the DNA is: 69.8–71.2 (Bd).

Type strain: *Pseudomonas* strain 1, ATCC 43882, DSM 5687, NCIMB 12249.

GenBank accession number (16S rRNA): L20850.

10. **Methylobacterium rhodinum** (Heumann 1962) Green and Bousfield 1983, 876^VP^ (*Pseudomonas rhodos* Heumann 1962, 342.)
ro.di' num. N.L. neut. adj. *rhodinum* rosy, because of its pink color.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated by Heumann (1962) from *Alnus* rhizosphere.

The mol% G + C of the DNA is: 71.8 (Bd).

Type strain: ATCC 14821, DSM 2163, NCIMB 1942.

GenBank accession number (16S rRNA): L20849, D32229.

11. **Methylobacterium thiocyanatum** Wood, Kelly, McDonald, Jordan, Morgan, Khan, Murrell and Borodina 1999, 341^VP^ (Effective publication: Wood, Kelly, McDonald, Jordan, Morgan, Khan, Murrell and Borodina 1998, 157.)
thio.cy.an.a' tum. M.L. n. *thiocyanatum* using thiocyanate.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. Able to tolerate high (≥50 mM) thiocyanate and/or cyanate and utilize these compounds as sole nitrogen source for growth. The type strain was isolated from soil in the rhizosphere of *Allium aflatunense*.

The mol% G + C of the DNA is: 69.8–71.0 (T_m).

Type strain: ALL/SCN-P, ATCC 700647, DSM 11490.

GenBank accession number (16S rRNA): U58018.

12. **Methylobacterium zatmanii** Green, Bousfield and Hood 1988, 124^VP^
zat.ma' ni.i. M.L. gen. n. *zatmanii* named after the British biochemist L.J. Zatman.

Characteristics are those given for the genus and for the carbon utilization spectra shown in Table BXII.α.192. The type strain was isolated from a fermentor operating with formaldehyde as sole carbon source.

The mol% G + C of the DNA is: 69.4–70.3 (Bd).

Type strain: 125, ATCC 43883, DSM 5688, NCIMB 12243.

GenBank accession number (16S rRNA): L20804.

Family X. **Rhodobiaceae** *fam. nov.* *

George M. Garrity, Julia A. Bell and Timothy Lilburn

Rho.do.bi.a' ce.ae. M.L. n. *Rhodobium* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Rhodobiaceae* the *Rhodobium* family.

The family *Rhodobiaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains *Rhodobium* (type genus).

Grow phototrophically in the light and chemotrophically in the dark. Photosynthetic membranes present as lamellar stacks. Require NaCl for growth.

Type genus: **Rhodobium** Hiraishi, Urata and Satoh 1995d, 230.

Genus I. **Rhodobium** *Hiraishi, Urata and Satoh 1995d, 230^VP^*

Johannes F. Imhoff and Akira Hiraishi

Rho.do' bi.um. Gr. n. *rhodon* the rose; Gr. n. *bios* life; M.L. n. *Rhodobium* red life.

Cells are ovoid to rod shaped, motile by means of polar, subpolar or randomly distributed flagella; and cells multiply by budding and asymmetric cell division. Rosette formation is rare. **Gram negative and belong to the *Alphaproteobacteria*.** Phototrophically grown cells contain **internal photosynthetic membranes as lamellar stacks parallel to the cytoplasmic membrane**. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. **Straight-chain saturated and monounsaturated $C_{18:1}$ and $C_{18:0}$ are the major components of cellular fatty acids, with the former being predominant. Ubiquinones and menaquinones with 10 isoprene units (Q-10 and MK-10) are present as major quinones.**

Preferred growth is photoheterotrophically under anoxic conditions in the light with simple organic substrates as carbon and electron sources. **Chemotrophic growth is possible under oxic conditions in the dark.** Dark fermentative growth may also be possible. Growth factors are required. **Mesophilic, marine bacteria that require NaCl for growth** and grow at seawater salinity and also at slightly higher salt concentrations.

The mol% G + C of the DNA is: 61.5–65.7.

Type species: **Rhodobium orientis** Hiraishi, Urata and Satoh 1995d, 230.

Further descriptive information

Cells of *Rhodobium* multiply by budding or asymmetric cell division, and show polar growth (Fig. BXII.α.246), as do other species of phototrophic bacteria in the alpha-2 *Proteobacteria*. They

**Editorial Note:* As this subvolume went to press, *Roseospirillum* was moved from the Family *Rhodobiaceae* to the Family *Rhodospirillaceae*. Placement in either family is tentative.

form sessile buds, but prosthecae between mother and daughter cells, which are characteristic for other phototrophic budding bacteria, are only found in *R. orientis*. Rosette-like cell aggregates are occasionally found in *R. orientis* (Fig. BXII.α.246) but not in *R. marinum*. In particular, *R. marinum* contains very active and agile motile cells.

A quantitative analysis of the carotenoids of *R. marinum* revealed that spirilloxanthin and rhodovibrin constituted 65% and 24%, respectively, of the total content, whereas anhydrorhodovibrin, monodemethylated spirilloxanthin, and lycopene were minor components (Imhoff, 1983). Absorption spectra of living cells or membrane preparations of *R. orientis* show major absorption maxima at around 800 and 870 nm, suggesting that the core light-harvesting complex (LH I), together with the photosynthetic reaction center and a peripheral light-harvesting complex (LH II), are present. Cells and membrane preparations of *R. marinum*, however, exhibit an absorption maximum at 883 nm and have very low absorption at 800 nm, similar to *Rhodospirillum rubrum*. This is due to the presence of LH I as the only antenna complex. The core antenna complex of *R. marinum* consists of 24 polypeptides with 24 bacteriochlorophyll *a* molecules, and the B880 complex exhibits a six-fold symmetry of the ring-like structure (Meckenstock et al., 1994).

Major polar lipid components of *R. marinum* are phosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, cardiolipin, and an ornithine lipid. Also unusually high proportions of a sulfolipid, most probably sulfoquinovosyl diglyceride, and an unidentified aminolipid are produced (Imhoff, 1983).

Based on 16S rDNA sequence information, *Rhodobium* species represent a deeply branching line of descent in the group of bacteria known as the alpha-2 *Proteobacteria*, where they are most closely related to representatives of *Rhizobium* and *Sinorhizobium*. 16S rDNA sequence analysis indicates that *R. orientis* and *R. marinum* share 93% similarity, a relatively low value for two species of the same genus. In addition, *R. marinum* has a shorter length of 16S rDNA than *R. orientis*. This is due to a 21-base deletion in the conserved region of the 16S rRNA between positions 1256 and 1281 (according to the *Escherichia coli* numbering system), like the deletion found in the bacteria known as the alpha-2 group of the *Proteobacteria*. This sequence deletion is a good marker for differentiation of *R. marinum* from *R. orientis* and other species of the group of bacteria known as the alpha-2 *Proteobacteria*.

Rhodobium species occur in marine and hypersaline environments as their natural habitats. Strains of *R. orientis* have been isolated from tidal pools and coastal seashore of Japan. *R. marinum* appears to be one of the most common species of phototrophic purple bacteria in marine environments. Strains of this species have been isolated from diverse sites in the world, including a splash water pond at the Adriatic shore near Split (Yugoslavia), Solar Lake (Sinai), an intertidal flat near Inverary in Scotland (Imhoff, 1983), a microbial mat at Laguna Guerrero Negro in Mexico (Mangels et al., 1986), and surface seawater at the coast of Japan (A. Hiraishi, unpublished).

As with other members of the purple nonsulfur bacteria (PNSB), growth with limited concentrations of ammonium salts or amino acids as nitrogen sources leads to extensive H_2 photoevolution due to nitrogenase activity.

Enrichment and Isolation Procedures

The methods and media used routinely for the cultivation of phototrophic PNSB (Imhoff, 1988; Imhoff and Trüper, 1992) can be employed for isolation and enrichment of *Rhodobium* species, if NaCl is added at appropriate concentrations. Media with 3–5% NaCl and pH 6.8–7.0 are suitable for *Rhodobium* species (Imhoff and Trüper, 1976; Imhoff, 1983; Hiraishi et al., 1995d).

Maintenance Procedures

Cultures are well preserved in liquid nitrogen, by lyophilization, or at −80°C in a mechanical freezer.

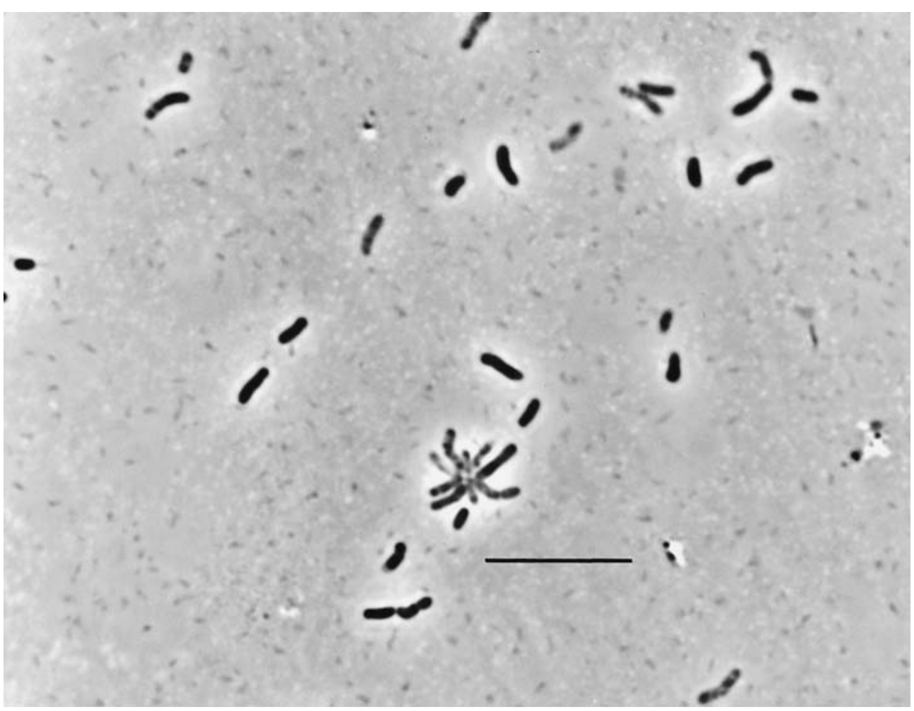

FIGURE BXII.α.246. Phase-contrast photomicrograph showing general cell morphology of *Rhodobium orientis* (strain MB 312). Bar = 10 μm.

Differentiation of the genus *Rhodobium* from other genera

The genus *Rhodobium* consists of species of the PNSB that are truly marine or slightly halophilic bacteria, multiply by budding or asymmetric cell division, and contain internal photosynthetic membrane systems of the lamellar type. In these respects, *Rhodobium* species are similar to other bacteria in the group of phototrophic bacteria belonging to the alpha-2 *Proteobacteria*, such as *Rhodoplanes*, *Blastochloris*, and *Rhodopseudomonas*. The genus *Rhodobium* is differentiated from the latter genera by its phylogenetic position, natural habitats, and chemotaxonomic characteristics. Major differentiating properties between *Rhodobium* and other phototrophic alpha-2 *Proteobacteria* are shown in Tables 3 (pp. 125–126) and 4 (p. 127) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. The phylogenetic relationships of these bacteria based on 16S rDNA sequences are shown in Fig. 2 (p. 128) of that same chapter.

Taxonomic Comments

At present, the genus *Rhodobium* consists of two species, *R. orientis* and *R. marinum*. After tentative assignment to *Rhodopseudomonas palustris* (Imhoff and Trüper, 1976), primarily based on morphological and physiological characteristics, the latter species was described as *Rhodopseudomonas marina* (Imhoff, 1983). Later, phylogenetic analysis based on 16S rDNA sequences revealed that this species was far distant from *Rhodopseudomonas palustris*, the type species of the genus *Rhodopseudomonas*, but closely related to new isolates from marine environments (Hiraishi et al., 1995d). These new isolates were assigned to the new genus *Rhodobium* and described as the type species of this genus, *Rhodobium orientis*, and *Rhodopseudomonas marina* was transferred to this genus as *Rhodobium marinum* (Hiraishi et al., 1995d).

Mangels et al. (1986) isolated a N_2-fixing marine strain of PNSB and designated it "*Rhodopseudomonas marina* var. *agilis*". Upon reinvestigation, no differences in physiological properties and 16S rDNA sequence between the type strain of *Rhodobium marinum* and "*Rhodopseudomonas marina* var. *agilis*" were found (Hiraishi et al., 1995d), confirming the phenotypic and genotypic coherency of the two organisms at the species level. Therefore, " var. *agilis*" isolates should be considered as strains of *Rhodobium marinum.*

Differentiation of the species of the genus *Rhodobium*

Major differentiating properties between *Rhodobium* species are shown in Tables BXII.α.193 and BXII.α.194.

List of species of the genus Rhodobium

1. **Rhodobium orientis** Hiraishi, Urata and Satoh 1995d, 230[VP]
o.ri.en′ tis. L. part. adj. *orientis* of the orient.

Cells are ovoid to rod-shaped, 0.7–0.9 × 1.5–3.2 µm, motile by means of polar, subpolar, and randomly distributed flagella; cells multiply by budding and asymmetric cell division (Fig. BXII.α.246). Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane (Fig. BXII.α.247). Phototrophically grown liquid cultures are pink-to-red, whereas aerobically grown or denitrifying cultures are faintly pink or colorless. Absorption maxima of living cells are at 377, 468, 500, 530, 591, 802, and 870 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series.

Preferred mode of growth is photoheterotrophically in the light. Photoautotrophic growth with thiosulfate, but not sulfide, as the electron donor occurs in the presence of 0.01% yeast extract. Chemotrophic growth occurs under oxic conditions in the dark at the full oxygen tension of air, and by denitrification under anoxic dark conditions with nitrate as a terminal electron acceptor. Good growth is possible with acetate, lactate, pyruvate, succinate, fumarate, malate, fructose, glucose, peptone, and yeast extract as carbon sources. Moderate growth occurs with butyrate, valerate, caproate, xylose, mannitol, and sorbitol. Formate, propionate, caprylate, citrate, tartrate, benzoate, arabinose, galactose, mannose, glycerol, methanol, ethanol, and Casamino acids are not utilized. Ammonium salts are used as nitrogen sources. Sulfate and thiosulfate are assimilated. Hydrolytic activities against starch, gelatin, casein, and Tween 80 are absent. Poly-β-hydroxybutyrate granules are formed as a storage material. Growth is stimulated considerably by addition of 0.05% yeast extract. Biotin and *p*-aminobenzoic acid are required as growth factors. Mesophilic, marine bacterium with optimal growth at 30–35°C, pH 7.0–7.5 (pH range: 6.0–8.5), and in the presence of 4–5% NaCl (salinity range: 2–8% NaCl). No growth in the absence of NaCl.

Habitat: tidal seawater pools and similar marine environments.

Major quinone components are Q-10 and MK-10.

The mol% G + C of the DNA is: 65.2– 65.7 (HPLC).

Type strain: MB312, ATCC 51972, DSM 11290, JCM 9337.

GenBank accession number (16S rRNA): D30792.

2. **Rhodobium marinum** (Imhoff 1984b) Hiraishi, Urata and Satoh 1995d, 320[VP] (*Rhodopseudomonas marina* Imhoff 1984b, 270.)
ma.ri′ num. L. adj. *marinum* of the sea, marine.

Cells are ovoid to rod-shaped, 0.7–0.9 × 1.0–2.5 µm, multiply by budding cell division without prostheca, and are highly motile by means of randomly distributed flagella. Rosette formation is not observed. Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. Phototrophically or fermentatively grown liquid cultures are pink-to-red, whereas aerobically grown cultures are faintly pink or colorless. Absorption maxima of living cells are at 375, 483, 516, 533, 590, 803, and 883 nm, with only a low absorption maximum around 800 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the dominant component.

Cells preferably grow photoheterotrophically under anoxic conditions in the light. Growth under microoxic dark conditions is also possible. Photoautotrophic growth with sulfide as a photosynthetic electron donor is poor, but the addition of 0.01% yeast extract enhances growth and sulfide tolerance. No photoautotrophic growth occurs with thio-

TABLE BXII.α.193. Differential characteristics of the species of the genus *Rhodobium*[a]

Characteristic	*Rhodobium orientis*	*Rhodobium marinum*
Cell diameter (µm)	0.7–0.9	0.7–0.9
Type of budding	Sessile	Sessile

[a] +, positive in most strains; −, negative in most strains; +/−, variable in different strains; nd, not determined; (+), weak growth or microaerobic growth only; (APS), via adenosine-5′-phosphosulfate; (PAPS), via 3′-phosphoadenosine-5′-phosphosulfate; (biotin) biotin is required by some strains; Q-10, ubiquinone 10; MK-10, menaquinone 10; RQ-10, rhodoquinone 10. Bd, buoyant density.

sulfate as the electron donor. Fermentative growth in the dark occurs with fructose as substrate. Denitrification is not possible. All or most strains use the following compounds as electron donors and carbon sources: acetate, propionate, butyrate, valerate, caproate, lactate, pyruvate, succinate, fumarate, malate, ascorbate, fructose, glucose, sucrose, mannitol, sorbitol, ethanol, propanol, and Casamino acids. Weak growth occurs with formate, galactose, and glycerol. Benzoate, tartrate, and methanol are not utilized. Sulfate is assimilated and, in addition, thiosulfate, tetrathionate, cysteine, methionine, glutathione, sulfite, and sulfide can serve as assimilatory sulfur sources. Ammonia, glutamate, aspartate, alanine, and urea serve as nitrogen source. Hydrolytic activities against starch, gelatin, casein, and Tween 80 are absent. Growth is stimulated considerably by adding 0.01% yeast extract.

Mesophilic marine bacterium with optimal growth at 25–30°C, pH 6.9–7.1, and 1–5% NaCl. No growth in the absence of NaCl.

Habitats: marine and moderately hypersaline waters and coastal sediments.

Major quinone components are Q-10 and MK-10.

The mol% G + C of the DNA is: 61.5–64.1 (T_m), 62.4–64.1 (HPLC).

Type strain: BN 126, ATCC 35675, DSM 2698.

GenBank accession number (16S rRNA): D30790.

Class II. **Betaproteobacteria** *class. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Be.ta.pro.te.o.bac.te′ ri.a. Gr. n. *beta* name of second letter of Greek alphabet; Gr. n. *Proteus* ocean god able to change shape; Gr. n. *bakterion* a small rod; M.L. fem. pl. n. *Betaproteobacteria* class of bacteria having 16S rRNA gene sequences related to those of the members of the order *Spirillales*.

The class *Betaproteobacteria* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the class contains the orders *Burkholderiales*, *Hydrogenophilales*, *Methylophilales*, *Neisseriales*, *Nitrosomonadales*, *"Procabacteriales"*, and *Rhodocyclales*.

Type order: **Burkholderiales** *ord. nov.*

Order I. **Burkholderiales** *ord. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Burk.hol.de.ri.a′ les. M.L. fem. n. *Burkholderia* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Burkholderiales* the *Burkholderia* order.

The order *Burkholderiales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the families *Burkholderiaceae*, *Oxalobacteraceae*, *Alcaligenaceae*, and *Comamonadaceae*.

Order is phenotypically, metabolically, and ecologically diverse. Includes strictly aerobic and facultatively anaerobic chemoorganotrophs; obligate and facultative chemolithotrophs; nitrogen-fixing organisms; and plant, animal, and human pathogens.

Type genus: **Burkholderia** Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398 (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1268) emend. Gillis, Van, Bardin, Goor, Hebbar, Willems, Segers, Kersters, Heulin and Fernandez 1995, 286.

Family I. **Burkholderiaceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Burk.hol.de.ri.a′ ce.ae. M.L. fem. n. *Burkholderia* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Burkholderiaceae* the *Burkholderia* family.

The family *Burkholderiaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Burkholderia* (type genus), *Cupriavidus*, *Lautropia*, *Limnobacter*, *Pandoraea*, *Paucimonas*, *Polynucleobacter*, *Ralstonia*, and *Thermothrix*. *Limnobacter* was proposed after the cutoff date for inclusion in this volume (June 30, 2001) and is not described here (see Spring et al. (2001).

Family is phenotypically, metabolically, and ecologically diverse. Includes both strictly aerobic and facultatively anaerobic chemoorganotrophs and obligate and facultative chemolithotrophs.

Type genus: **Burkholderia** Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398 (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1268) emend. Gillis, Van, Bardin, Goor, Hebbar, Willems, Segers, Kersters, Heulin and Fernandez 1995, 286.

Genus I. **Burkholderia** *Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398[VP] (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1268) emend. Gillis, Van, Bardin, Goor, Hebbar, Willems, Segers, Kersters, Heulin and Fernandez 1995, 286**

NORBERTO J. PALLERONI

Burk.hol.de′ ri.a. M.L. fem. n. *Burkholderia* named after W.H. Burkholder, American bacteriologist who discovered the etiological agent of onion rot.

Cells single or in pairs, **straight or curved rods**, but not helical. Dimensions, generally 0.5–1 × 1.5–4 μm. Motile by means of one or, more commonly, **several polar flagella**. One species (*Burkholderia mallei*) lacks flagella and is nonmotile. Do not produce sheaths or prosthecae. No resting stages are known. **Gram negative.** Most species **accumulate poly-β-hydroxybutyrate (PHB) as**

**Editorial Note:* The literature search for the chapter on *Burkholderia* was completed in January, 2000. During the course of unavoidable publication delays, a number of new species were described or reclassified after the chapter was completed. It was not possible to include these species in the text or to include their characteristics in the comparative tables. The reader is encouraged to consult the studies listed in the Further Reading section.

carbon reserve material. Chemoorganotrophs. Have a strictly **respiratory type of metabolism with oxygen as the terminal electron acceptor**. **Some species can exhibit anaerobic respiration with nitrate.** Strains of some of the species (*B. cepacia*, *B. vietnamiensis*) are able to fix N_2. Catalase positive. A wide variety of organic compounds can be used as sources of carbon and energy for growth. Although hydroxylated fatty acids are present in the lipids of members of other genera of aerobic pseudomonads, species of *Burkholderia* are **characterized by the presence of hydroxy fatty acids of 14, 16, and 18 carbon atoms ($C_{14:0\ 3OH}$ and $C_{16:0}$, and $C_{16:0\ 2OH}$, $C_{16:1}$, and $C_{18:1}$)**. **The most characteristic of these acids is the $C_{16:0\ 3OH}$.** Two different ornithine lipids are present in strains of some of the species. Over one-half of the species are **pathogenic for plants or animals (including humans)**. The genus belongs to the ribosomal RNA similarity group II, which can be differentiated from other groups of aerobic pseudomonads by rRNA/DNA hybridization experiments or by rDNA sequencing.

The mol% G + C of the DNA is: 59–69.6.

Type species: **Burkholderia cepacia** (Palleroni and Holmes 1981) Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398 (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1271) (*Pseudomonas cepacia* Palleroni and Holmes 1981, 479.)

Further descriptive information

Cell morphology The cells of the genus *Burkholderia* correspond in their general characteristics to those of other aerobic pseudomonads: Gram-negative rods, straight or slightly curved, with rounded ends, usually motile when suspended in liquid. Motility is due to several polar flagella, but a single flagellum per cell has been reported for *B. andropogonis*, *B. glathei*, and *B. norimbergensis*.* The single flagellum of *B. andropogonis* is sheathed (Fuerst and Hayward, 1969a). One species, *B. mallei*, is nonmotile and lacks flagella (Redfearn et al., 1966).

Intracellular granules The cells of species of the genus accumulate granules of carbon reserve material (poly-β-hydroxybutyrate, PHB, which may be part of a copolymer with poly-β-hydroxyvalerate, PHA). Proteins ("phasins") have been found to be associated with the granules (Wieczorek et al., 1996). Only *B. pseudomallei* and some strains of *B. mallei* use extracellular PHB for growth (Ramsay et al., 1990). All species able to accumulate PHB can use the intracellular polymer when needed; however, in the description of some species, the statement "can use PHB" has been included, without indicating whether the PHB was endo- or extracellular.

The colonies of most species of the genus are smooth, but those of the human pathogen *B. pseudomallei* often have a rough surface.

Lipids The first detailed analysis of the fatty acids of aerobic pseudomonads, using both saprophytic and phytopathogenic strains, demonstrated the possibility of establishing a correlation with the phylogenetic subdivision of the genus *Pseudomonas*, as classically defined, on the basis of rRNA–DNA hybridization (Oyaizu and Komagata, 1983). Years later, the results of this survey were confirmed and extended (Stead, 1992). The results of these investigations firmly established the fact that members of rRNA similarity group II of Palleroni et al. (1973), which includes the genus *Burkholderia*, have a fatty acid composition containing $C_{14:0\ 3OH}$ and $C_{16:0}$, and $C_{18:1\ 2OH}$. Most strains also contained $C_{16:0\ 2OH}$ and $C_{16:1}$. Even though hydroxylated fatty acids are present in the lipids of members of other groups, group II including *Burkholderia* is the only one having hydroxylated fatty acids of 14, 16, and 18 carbon atoms (Table BXII.β.1). A recent evaluation of the taxonomic significance of fatty acid composition emphasizes the diagnostic value of the above results (Vancanneyt et al., 1996), confirming earlier findings on this approach for the characterization of major phylogenetic groups within the pseudomonads (Wollenweber and Rietschel, 1990).

Ornithine-containing lipids in *Pseudomonas aeruginosa*, *P. putida*, and *B. cepacia* represent from 2–15% of the total of extractable lipids. The amino acid was not found in the phospholipids that amount to more than 80% of all the extractable lipids (Kawai et al., 1988). An analysis of the polar lipids and fatty acids of *B. cepacia* has shown that the only significant phospholipids in this species are phosphatidyl-ethanolamine and bis(phosphatidyl)-glycerol. These characteristics, taken together with the unusual lipid profiles of *B. cepacia*, can be used as markers of chemotaxonomic importance (Cox and Wilkinson, 1989a).

A striking feature of the cellular composition of *B. cepacia* is the range of polar lipids, which include two forms (with and without 2-OH fatty acids) of phosphatidyl-ethanolamine and ornithine amide lipids. Variations in the lipid composition, as well as in pigmentation and flagellation, were observed as the consequence of changes in growth temperature and limiting oxygen, carbon, phosphorus, and magnesium supplies in the medium. Phosphorus limitation appears to be the only nutritional factor that results in a composition with polar lipids represented only by ornithine amide lipids (Taylor et al., 1998).

Interestingly, the 3-hydroxylated fatty acid of 10 carbon atoms is a component of the lipids of *B. gladioli* but not of those of *B. cepacia*, as indicated by lipid analysis performed on *B. gladioli* strains isolated from respiratory tract infections in cystic fibrosis patients (Christenson et al., 1989).

Differentiation of the plant pathogenic species of *Burkholderia* can be done by a direct colony thin-layer chromatographic

TABLE BXII.β.1. Fatty acid and ubiquinone composition of the genus *Burkholderia* (rRNA group II) and of aerobic pseudomonads of other rRNA groups[a,b]

[b]Data taken from Oyaizu and Komagata (1983) and Stead (1992).

**Editorial Note:* Since submission of this manuscript, *Burkholderia norimbergensis* was reclassified as *Pandoraea norimbergensis* by Coenye et al. (2000). Readers are advised to review the chapter in that genus for additional details.

method. Only minor uncertainties have been noticed with respect to the composition of aminolipids (Matsuyama, 1995).

The general qualitative profile of hydroxylated fatty acids indicated above is constant for a given species, although at least in one case (*B. glumae*) a subdivision of strains into two types is possible based on differences in composition. One of the subgroups, which included the type strain, had a composition that was similar to the bulk of rRNA similarity group II. The other was represented by strains that had significant amounts of the $C_{10:0\ 3OH}$ fatty acid, and was unique in rRNA similarity group II in having the $C_{12:0\ 3OH}$ fatty acid (Stead, 1992). For some of the components of the fatty acid profile, significant quantitative variations can be observed among the strains of different species of *Burkholderia*.

In contrast to the hydroxylated fatty acids, which have their origin in lipid A, the more abundant, nonhydroxylated fatty acids are mainly located in the cytoplasmic membrane. Their value as taxonomic markers is significant at the species level and less at the higher level of the RNA similarity groups. All strains of group II have $C_{16:0}$, $C_{16:1\ cis}$, and $C_{18:1\ cis}$ nonhydroxylated fatty acids (Stead, 1992). The investigations of Komagata and his collaborators have established that Q-8 is the quinone characteristic of group II (Oyaizu and Komagata, 1983).

Hopanes have been detected in the composition of cells of *B. cepacia* (Rohmer et al., 1979), but the value of these compounds as chemotaxonomic markers is not known because later studies apparently did not include strains of other species of the group. This point perhaps warrants further attention.

Flagella Motility can be observed in young cultures of strains of all species of *Burkholderia*, with the exception of *B. mallei*, which lacks flagella. Cells of the latter species do not even show twitching motility on the surface of solid media (Henrichsen, 1975a). Motility in liquid is due to one or, more commonly, several polar flagella. A single flagellum per cell has been reported for *B. andropogonis*, *B. glathei*, and *B. norimbergensis* (see descriptions in the list of species at the end of this chapter). The best-known example is that of *B. andropogonis*, whose single flagellum is sheathed (Fuerst and Hayward, 1969a) (Fig. BXII.β.1).

SDS-polyacrylamide gel electrophoresis has been used for the characterization of the flagellins of different species of aerobic pseudomonads. Based on flagellin composition, *B. cepacia* strains have been divided into two groups. Group I has flagellin of molecular weight 31,000, whereas group II flagellin ranges from 44,000–46,000. Type I was serologically uniform, while group II was heterologous. The flagellin types of *B. cepacia* appear to be analogous to the two major flagellin types of *P. aeruginosa*, and they could be used as molecular epidemiological tools (Montie and Stover, 1983).

The methodology for the isolation of *B. pseudomallei* flagellin and its characterization has been described. Electrophoretic analysis under denaturing conditions results in monomer protein bands with an estimated M_r of 43,000 (Brett et al., 1994). O-polysaccharide-flagellin conjugates in this species have been described with respect to their structural and immunological characteristics (Brett and Woods, 1996).

Pili (fimbriae) Peritrichous pili have been identified years ago in *B. cepacia* (Fuerst and Hayward, 1969b). They are thought to facilitate adherence to mucosal epithelial surfaces (Kuehn et al., 1992; Sajjan and Forstner, 1993). Twitching motility is correlated with the presence of polar fimbriae, a correlation that is supported by the fact that this type of motility is absent from *B. cepacia*, which has no polar fimbriae (Henrichsen, 1975a). No fimbriae have been observed in *B. andropogonis* (Fuerst and Hayward, 1969b).

One or more of five morphologically distinct classes of pili can be present in the cells of *B. cepacia*. Some of the types have been identified in cells of epidemically transmitted strains, and others in environmental isolates (Goldstein et al., 1995; Sajjan et al., 1995). The role of a 22-kDa pilin in binding *B. cepacia* to the mouth epithelial cells has been described (Sajjan and Forstner, 1993). Further details on fimbriae will be given in the section on pathogenesis for humans and animals.

Composition of cell envelope The earliest data on the cell wall composition of *B. cepacia* were obtained in S. Wilkinson's laboratory, where it was found that the major components, myristic, 3-hydroxymyristic, and 3-hydroxypalmitic acids, were indications that members of this group had a different composition than other species of aerobic pseudomonads. These results are in agreement with those of fatty composition of whole cells (Samuels et al., 1973). The core polysaccharide contains glucose, rhamnose, and heptoses, but at most a very low phosphorus content. The lipopolysaccharide (LPS) has a low content of 3-deoxy-D-manno-2-octulosonic acid (KDO), and the side chain is basically a mannan. One added peculiar feature is the presence of an acid-labile amino sugar phosphate presumably associated with the lipid A.

The results have been confirmed, at least in part, by Manniello et al. (1979). Analyses of *B. cepacia* performed by these workers revealed the presence of rhamnose, glucose, heptose, and hexosamine, but no KDO, and the phosphorus content was found to be about one-third of that of *P. aeruginosa*. The presence of KDO in the LPS of *B. cepacia*, however, was later confirmed (Straus et al., 1990).

A method of extraction of LPS from *B. pseudomallei* has been described. As in the case with *B. cepacia*, the link between the inner core and lipid A is stable to acid hydrolysis (Kawahara et al., 1992). The LPS of clinical strains of this last species was composed of two polymers made of different repeating units, but both polymers contained D-rhamnose and D-galactose residues (Cerantola and Montrozier, 1997).

Five major outer membrane proteins have been isolated from several strains of *B. pseudomallei*, with M_r values ranging from 17,000–70,000. One of the proteins associated with the peptidoglycan acts as a porin through which small saccharides may diffuse (Gotoh et al., 1994b).

Outer membrane proteins of *B. cepacia* and *B. pseudomallei* that are inducible by phosphate starvation appear to be similar to the *E. coli* PhoE porin protein. The latter does not have the binding sites for anions and phosphate that are present in the analogous proteins from *Pseudomonas* species (Poole and Hancock, 1986).

One porin of *B. cepacia* is an oligomer composed of two proteins. The purified 81-kDa whole protein (OpcPO) upon heating gives a major 36-kDa protein (OpcP1) and a minor one (OpcP2) of 27 kDa. The association of these two components is noncovalent (Gotoh et al., 1994a). Recently, the major porin protein, (OpcP1), was partially sequenced, and the information was used for cloning the gene. Its sequence showed an open reading frame of a length in agreement with that of OpcP1 (Tsujimoto et al., 1997).

Additional information about porins and other components of the cell envelopes may be found in the sections on antibiotic susceptibility and antigenic structure.

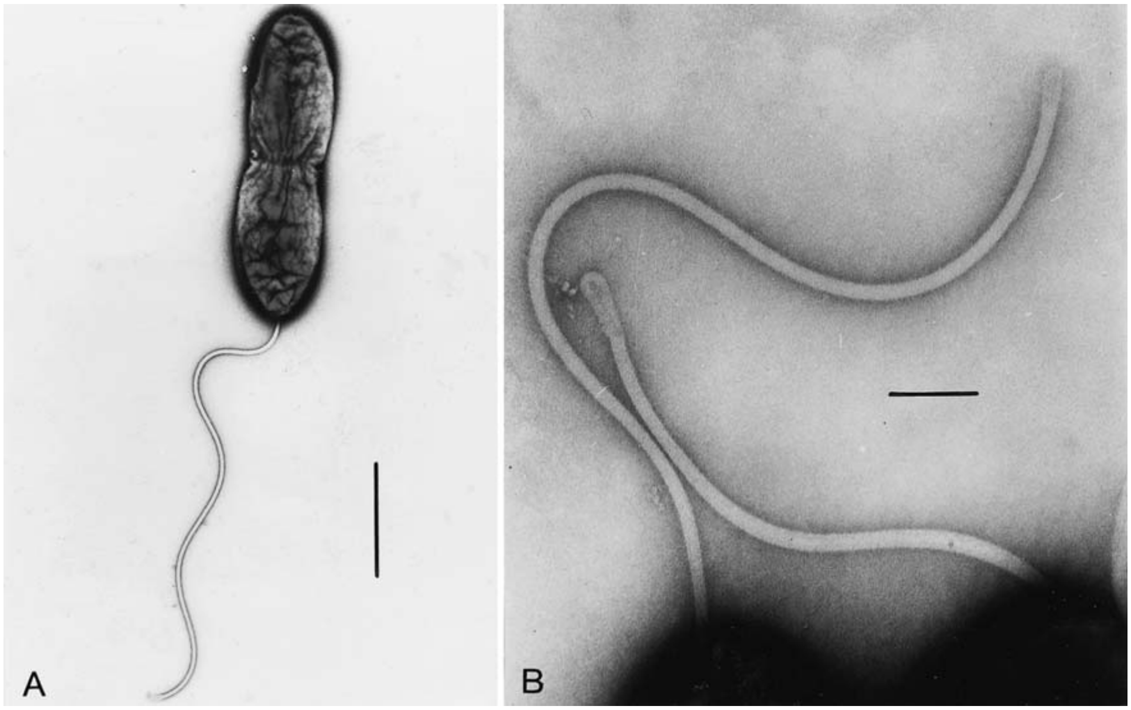

FIGURE BXII.β.1. *A*, *B. andropogonis* (syn. *"Pseudomonas stizolobii"*), with single-sheathed polar flagellum. Negative staining, 1% uranyl acetate, 0.4% sucrose. Bar = 1 μm. *B*, sheathed flagella of *B. andropogonis*. Same treatment as in *A*. Bar = 0.2 μm. (Courtesy of Dr. J.A. Fuerst.)

Pigmentation Pigmentation is by no means a universal character of *Burkholderia*. Some *B. cepacia* strains are not pigmented, whereas others produce phenazine pigments of a bewildering variety of colors when grown on solid chemically defined media containing different carbon sources. Pigmented strains of the species can be subdivided into two types on the basis of their pigmentation: some are yellow on glucose yeast extract peptone agar and others are various shades of brown, red, violet, and purple (Morris and Roberts, 1959). Morris and Roberts isolated the pigment from a purple-pigmented strain and demonstrated that its basic structure was that of a phenazine. In fact, two phenazine pigments—one yellow and the other purple—may be synthesized, both of which are water-soluble under neutral or alkaline conditions. A single strain can produce both types, only one type, or none. Because the pigments are soluble in water, both the colonies and the medium appear pigmented. Growth on King A medium[1] often enhances pigment production.

In the author's experience, pigment production in *Burkholderia* is, as in many other cases, a striking but not very reliable taxonomic character, because pigment biosynthesis often requires conditions that cannot be precisely controlled.

Nutrition and growth conditions The strains of *Burkholderia* species grow in media of minimal composition, without the addition of organic growth factors. Occasionally, strains are isolated from nature that grow extremely slowly but are stimulated by addition of complex organic mixtures such as yeast extract. Some of the fluorescent plant pathogens of the genus *Pseudomonas* fall in this category, and the phenomenon has also been observed for some *B. caryophylli* strains (Palleroni, 1984).

The ability to grow in media of very simple and chemically defined composition stimulated research on the nutritional versatility of the aerobic pseudomonads—among them, species later to be assigned to the genus *Burkholderia*. These studies have revealed a remarkable variety of organic compounds that can serve individually as carbon and energy sources for strains of some species (*B. cepacia*, *B. pseudomallei*). The types of compounds used for growth are the basis of the vast phenotypic information now available for many strains (Redfearn et al., 1966; Stanier et al., 1966; Ballard et al., 1970). One of the simplest chemically defined media used for nutritional studies is the one recommended for the hydrogen pseudomonads (Palleroni and Doudoroff, 1972).[2]

The nutritional investigations revealed that some strains of *B. cepacia* could utilize any of a list of 100 organic compounds (two-thirds of the list of tested substrates) (Stanier et al., 1966). Later work performed in various laboratories has enlarged the list considerably. This remarkable metabolic versatility of the species was unknown to plant pathologists, and its discovery rapidly converted *B. cepacia* into a fascinating subject for biochemical research. A sample of the nutritional properties of *Burkholderia* species is presented in Table BXII.β.2, and some of these properties, together with general characteristics of taxonomic importance, are summarized in Table BXII.β.3. Comparisons of nutritional properties of some related species are also to be found in later sections (Tables BXII.β.5 and BXII.β.7). To the remarkable metabolic versatility of *B. cepacia* we have to add the ability to fix N_2 that is exhibited by some of the strains (Bevivino et al., 1994;

1. Medium of King et al. (1954) (g/l distilled water): Bacto-peptone (Difco), 20.0; Bacto Agar (Difco), 15.0; glycerol, 10.0; K_2SO_4, 10.0; $MgCl_2$, 1.4; pH 7.2.

2. Medium of Palleroni and Doudoroff (1972) (g/l 0.33 M Na-K phosphate buffer, pH 6.8): NH_4Cl, 1.0; $MgSO_4 \cdot 7H_2O$, 0.5; ferric ammonium citrate, 0.05; $CaCl_2$, 0.005. The first two ingredients are added to the buffer and sterilized by autoclaving. The ferric ammonium citrate and $CaCl_2$ are added aseptically from a single stock solution that has been sterilized by filtration.

[a]For symbols see standard definitions; ±, slow. The + or − superscripts of the d symbol refer to the result obtained with the type strain, when known.

[b]Data from Gillis et al. (1995), Viallard et al. (1998), and Palleroni (1984).

[c]Carbon compounds used by all strains (with few exceptions; see Gillis et al., 1995) are fructose, fumarate, galactose, gluconate, glucose, mannose, glycerol, *m*-inositol, mannitol, sorbitol, acetate, DL-glycerate, DL-lactate, L-malate, pyruvate, succinate, D-α-alanine, L-α-alanine, DL-aminobutyrate, L-aspartate, L-glutamate, L-serine, L-proline, *p*-hydroxybenzoate. Carbon compounds not used by any strain: glycogen, methyl-mannoside, D-melezitose, inulin, starch, D-turanose, aesculin, creatine, 3-aminobenzoate, D-mandelate, phthalate, isophthalate.

Tabacchioni et al., 1995). This ability is also present in a closely related taxon, *B. vietnamiensis* (Gillis et al., 1995).

Temperature for growth Usually a temperature of 30°C is used for growth of all strains of the genus. Many of them, however, can grow well at 37°C and even at 40°C. Additional information on temperature relationships will be given in the section dealing with the description of individual species.

Oxygen relationships All strains grow well under aerobic conditions. Some species (*B. mallei*, *B. pseudomallei*, *B. caryophylli*, *B. plantarii*, *B. vandii*) can also use nitrate as the terminal electron acceptor under anaerobic conditions. The original description of *B. vietnamiensis* (Gillis et al., 1995) indicates that the strains are able to reduce nitrate to nitrite, suggesting that this is the final stage of the reduction process. However, *B. vietnamiensis* is described elsewhere as a denitrifier. In view of this, the species was omitted from Table 4, which presents the general properties of denitrifying aerobic pseudomonads. In spite of this, denitrification was included among the general properties useful as differential characteristics for *Burkholderia* species.

Metabolism and metabolic pathways Knowledge of many areas of the general metabolism of species of the genus *Burkholderia* is scanty and fragmentary. The following refers to some aspects of the general metabolism of the genus, with the exclusion of the catabolism of aromatic compounds, which will be treated in a second part.

Extensive nutritional information is available on a large num-

[a]For symbols see standard definitions. The denitrifying pseudomonads *P. azotoformans*, *P. mucidolens*, and *P. nitroreducens* have not been included in this table.

ber of carbon substrates used individually as sole sources of carbon and energy for *B. cepacia*, *B. gladioli*, *B. caryophylli*, *B. pseudomallei*, and *B. mallei* (Redfearn et al., 1966; Stanier et al., 1966; Ballard et al., 1970; Palleroni and Holmes, 1981; Palleroni, 1984). In some of these reports, the information refers to names that are synonyms of some of the above (*"Pseudomonas marginata"* for *B. gladioli*, and *"Pseudomonas multivorans"* for some of the strains of *B. cepacia*). The information has been summarized in several tables in this chapter.

For *B. vietnamiensis* and *B. andropogonis*, a source of information on nutritional spectra useful for a comparison with other species of the genus, is given by Gillis et al. (1995). Less extensive surveys have been performed with *B. glumae*, *B. vandii*, and *B. cocovenenans* (Azegami et al., 1987; Urakami et al., 1994; Zhao et al., 1995).

As mentioned in the section on nutrition, some of the *Burkholderia* species are extremely versatile from the metabolic standpoint. This is particularly true of *B. cepacia*, the most versatile of all known aerobic pseudomonads, but *B. pseudomallei* and *B. gladioli* are similarly remarkable for their capacity of living at the expense of any of a long list of organic compounds as sole source of carbon and energy. Unfortunately, these species also have an infamous reputation as direct or opportunistic human and animal pathogens, and investigations on the saprophytic activities of some of the species are sparse because of the danger of handling the organisms in the laboratory.

All species of the genus *Burkholderia* that have been examined are able to accumulate PHB as a carbon reserve material, which they can degrade when nutrients in the medium become exhausted. However, use of exogenous PHB is an uncommon property among the aerobic pseudomonads. In *Burkholderia*, only *B. pseudomallei* and some strains of *B. mallei* are capable of degrading extracellular PHB (Redfearn et al., 1966; Stanier et al., 1966).

Table BXII.β.5 summarizes data on arginine utilization and the occurrence of arginine deiminase in some representative members of the various rRNA similarity groups of aerobic pseudomonads. Interestingly, *B. cepacia*—a member of RNA group II that is notorious for its nutritional versatility and for the diversity of its catabolic pathways—can degrade arginine only through the use of the succinyl transferase pathway, although it can use 2-ketoarginine and agmatine, the products of arginine oxidase and arginine decarboxylase, respectively (Stalon and Mercenier, 1984; Vander Wauven and Stalon, 1985).

In a survey of lysine catabolic pathways in the pseudomonads,

TABLE BXII.β.5. Arginine utilization and deiminase system in some aerobic pseudomonads

Organisms	RNA group	Arginine utilization	Arginine deiminase
Fluorescent saprophytic *Pseudomonas* species	I	+	+
Burkholderia cepacia, B. gladioli	II	+	–
B. mallei, B. pseudomallei	II	+	+
Ralstonia solanacearum, R. pickettii	II	–	–
Comamonas, Hydrogenophaga, Acidovorax	III	–	–
Brevundimonas	IV	–	–
Stenotrophomonas, Xanthomonas	V	–	–
Stenotrophomonas, Xanthomonas	V	–	–

it has been reported that *B. cepacia* and *P. aeruginosa* use the pipecolate pathway and not the so-called oxygenase pathway. *P. aeruginosa* can also use the cadaverine pathway, but this is not operative in *B. cepacia* (Fothergill and Guest, 1977; Palleroni, 1984). These facts are summarized in Table 1 (BXII.γ.108, p. 334) of the genus *Pseudomonas* in Volume 2, Part B.

N_2 fixation has been detected in strains of *B. cepacia* isolated from plant rhizospheres (Bevivino et al., 1994; Tabacchioni et al., 1995). A different set of nitrogen fixing strains studied in another laboratory was found to be closely related to this species, and was assigned the new species name *B. vietnamiensis* (Gillis et al., 1995).

Some miscellaneous activities of interest of the lesser-known species of the genus include the following. An α-terpineol dehydratase—capable of converting the citrus compound limonene to α-terpineol—was partially solubilized from a particulate fraction obtained from *B. gladioli* cells (Cadwallader et al., 1992). A lipase from *B. glumae* has been purified and some of its properties have been described (Deveer et al., 1991; Cleasby et al., 1992). Cloning and sequencing of a lipase gene of *B. cepacia* (*lipA*) have been performed, and its expression is dependent on a second gene (*limA*) (Jorgensen et al., 1991).

In cells of *B. caryophylli*, a D-threo-aldolase dehydrogenase that catalyzes the oxidation of L-fucose and the "unnatural" sugars L-glucose, L-xylose, and D-arabinose, has been purified and characterized. It is inhibited by D-glucose and other natural aldoses (Sasajima and Sinskey, 1979). Some enzymatic activities of species other than *B. cepacia* may be of environmental importance. Thus, *B. pseudomallei* is capable of breaking the C-P bond in the utilization of the herbicide *N*-(phosphonomethyl)-glycine, which is known by the empirical name glyphosate. The genes controlling this activity have been cloned and sequenced (Peñaloza-Vazquez et al., 1995). Similarly, the phytopathogen and human opportunistic pathogen *B. gladioli* was found to be able to form and cleave C-P bonds (Nakashita et al., 1991; Nakashita and Seto, 1991). In a more general way, it has been suggested that *B. gladioli* probably participates in the degradation of some xenobiotic compounds in the environment (Cadwallader et al., 1992).

Several siderophores are produced by species of *Burkholderia*. In iron-deficient media, *Pseudomonas aeruginosa*, *P. fluorescens*, and *B. cepacia* synthesize salicylic acid, a compound of particular interest because of its siderophore capacity (Visca et al., 1993) and the fact that it is a precursor of another siderophore, pyochelin. Interestingly, salicylate is used as a source of carbon and energy by many strains of *Burkholderia* and of many other aerobic pseudomonads. An iron-binding compound produced by the great majority of *B. cepacia* strains isolated from the respiratory tract was named azurechelin and is capable of releasing Fe from transferrins (Sokol et al., 1992). Later, however, azurechelin was found to be salicylic acid (Visca et al., 1993).

Pyochelin production was found in half of 43 strains of *B. cepacia* isolated from cystic fibrosis patients. The siderophore has in its structure one molecule of salicylic acid and two molecules of cysteine (Cox et al., 1981). A siderophore of a linear hydroxamate/hydroxycarboxylate type, was discovered in *B. cepacia* and also found in *B. vietnamiensis*. It was named ornibactin and functions as a specific iron-transport system equivalent to that of the pyoverdin system of fluorescent pseudomonads. In the composition of ornibactins, there is a peptide, an amine, and acyl groups of different lengths (Stephan et al., 1993a, b).

In nature, these siderophores are often successful in competing for iron with siderophores of various other sources (Yang et al., 1993). Thus, pyochelin allows *B. cepacia* to grow in the presence of transferrin (Sokol, 1986).

In low Fe-content medium, *B. cepacia* excretes both pyochelin and a low molecular weight compound (1-hydroxy-5-methoxy-6-methyl-2(1H)-pyridinone), which received the name of cepabactin. The structure resembles that of a cyclic hydroxamate, and it can also be considered a heterocyclic analogue of catechol (Meyer et al., 1989). The compound is related to synthetic hydroxy-pyridinones. Cepabactin had already been described as chelator (Winkler et al., 1986) and was known to have antibiotic properties (Itoh et al., 1979).

At least three different siderophores—ornibactins, pyochelin, and cepabactin—can be produced by a single *B. cepacia* strain. Other strains produce either two siderophores—ornibactins plus pyochelin or ornibactins plus cepabactin—and still other strains produce only pyochelin. In a survey of strains from a collection, 88% of the strains produced ornibactin, 50% pyochelin, and 14% cepabactin (J.M. Meyer, personal communication).

A recently identified member of the siderophore group produced by a strain of *B. cepacia* is cepaciachelin, a catecholate compound. The producing strain appears to be a unique example of a pseudomonad able to synthesize both hydroxamate and catecholate siderophores (Barelmann et al., 1996).

In summary, the variety of siderophores that *B. cepacia* is able to synthesize demonstrates once again the remarkable biochemical versatility of strains of this species.

All 84 strains of *B. pseudomallei* included in a study were found to produce a siderophore of approximately 1000 molecular weight. The compound, called malleobactin (Yang et al., 1991a), permitted cell growth in the presence of EDTA and of transferrin, and can trap iron from transferrin (at all pH values tested) and from lactoferrin. *B. cepacia* can use malleobactin as an iron-scavenging compound. However, pyochelin and azurechelin (salicylic acid) are more effective in trapping cell-derived iron as well as protein-bound iron (Yang et al., 1993).

Media with limiting phosphate concentrations enhance the production of a particular OM protein (OprP) of *Pseudomonas aeruginosa*. This protein is believed to be involved in phosphate transport and is only produced by species of *Pseudomonas*. Under similar conditions, both *B. cepacia* and *B. pseudomallei* produce proteins of a size similar to the PhoE protein of *Escherichia coli* and other enteric bacteria (Poole and Hancock, 1986).

Metabolism of aromatic and halogenated compounds For many years this subject has attracted the attention of biochemists because of the striking ability of prokaryotes to degrade aromatic compounds that are resistant to chemical attack and are not readily metabolized by other organisms. In recent years, this in-

terest has increased due to concern for chemically polluted environments and the obvious convenience of favoring these degradative activities as part of bioremediation strategies.

The first edition of this *Manual* included information on basic catabolic activities of the aerobic pseudomonads on simple aromatic compounds because of their obvious taxonomic implications (Palleroni, 1984). Much research has since been done on the catabolism of many aromatic compounds that include benzoate and derivatives, polycyclic aromatic hydrocarbons, biphenyl (particularly the halogenated derivatives), metabolic intermediates such as the halogenated catechols, and some important herbicides (24D and 245T). This field of research now contains a multitude of references, of which only a selected minority will be discussed here.

The investigations of Ornston and his collaborators on the biochemistry of degradation of aromatic compounds are of particular interest because the corresponding pathways were also analyzed for their phylogenetic implications. The β-ketoadipate pathway has taken center stage in these investigations. Natural selection has adopted many permutations in the distribution of its components, their regulation, and the genetic makeup, all of which have been highlighted in an excellent review (Harwood and Parales, 1996). Immunological cross-reaction was observed between the enzymes of one of the species (*Pseudomonas putida*) and the corresponding enzymes of other fluorescent *Pseudomonas* species. Cross-reaction, however, was also detected between the γ-carboxymuconolactone decarboxylases of *P. putida* and *B. cepacia* (Patel and Ornston, 1976). Although the results suggested that the interspecific transfer of the structural gene for the enzyme was not common among pseudomonads, it nevertheless seemed to have occurred between these two distantly related species. The cross-reaction did not extend to other enzymes of the two species, including the salicylate hydroxylases, which are structurally different, and for which an explanation based on convergent evolution has been proposed (Kim and Tu, 1989).

As mentioned in a description of the metabolism of *para*-hydroxybenzoate (POB), *B. cepacia* is able to convert *meta*-hydroxybenzoate (MOB) to gentisate by the action of a 6-hydroxylase (Yu et al., 1987). Interestingly, this finding relates to an earlier report on the formation of gentisate from MOB by *Comamonas acidovorans*, which is a member of the *Betaproteobacteria* in which *Burkholderia* is located (Wheelis et al., 1967). A description of the induction of the hydroxylase from *B. cepacia* has been published (Wang et al., 1987).

The genetic organization and sequence of genes of the α and β subunits of protocatechuate 3,4-dioxygenase of *B. cepacia* has been investigated, and there is extensive similarity to genes of other *Pseudomonas* species, although this similarity does not extend to the promoter sequences (Zylstra et al., 1989b). The pattern of induction of this and other enzymes of the POB metabolism has been examined (Zylstra et al., 1989a).

As a member of a microbial community, *B. cepacia* was the most competitive member among other aerobic pseudomonads in the degradation of toluene (Duetz et al., 1994). A novel pathway of toluene catabolism was described for this organism, with the participation of toluene monooxygenase, which is able to hydroxylate toluene, phenol, and cresol, and also to catalyze the degradation of trichloroethylene (TCE) (Shields et al., 1991). Cometabolism of TCE and toluene has been described (Landa et al., 1994). A constitutive strain was selected for the degradation of TCE (Shields and Reagin, 1992). Degradation of TCE by *B. cepacia* using the toluene monooxygenase system is expressed at higher capacity than the toluene dioxygenase systems present in other organisms (for instance, *P. putida*) (Leahy et al., 1996).

The toluene 2-monooxygenase from *B. cepacia* is a three-component system capable of oxidizing toluene to *o*-cresol and this to 3-methylcatechol. The catabolic features of this system resemble those of soluble methane monooxygenase from methanotrophic bacteria (Newman and Wackett, 1995). For the activity of toluene 2-monooxygenase on TCE, all its protein components and NADH are required. All protein components were modified during TCE oxidation, but reducing compounds such as cysteine protected the enzyme (Newman and Wackett, 1997).

Phthalate oxygenase is an enzyme specific for phthalate and closely related compounds. The system of *B. cepacia*, which requires the contribution of phthalate oxygenase reductase for efficient catalytic activity, is similar to other bacterial oxygenase systems. The *B. cepacia* enzyme can be isolated in large quantities and its stability is higher than that from other sources (Batie et al., 1987).

B. cepacia strains grow on fluorene and degrade this compound by a mechanism analogous to naphthalene catabolism. The system has wide specificity, and the range of substrates includes many other polycyclic aromatic compounds (Grifoll et al., 1995). But in spite of the remarkable catabolic versatility of the species, there are some limitations to the range of susceptible substrates. Thus, strains isolated on phenanthrene from polyaromatic hydrocarbon (PAH)-contaminated soils had limited capacity to use higher PAHs (Mueller et al., 1997).

For more than a decade, the degradation of the halogenated herbicides 2,4-dichlorophenoxyacetic acid and 2,4,5-trichlorophenoxyacetic acid (245T) by *B. cepacia* has been the object of attention by researchers, among them, A. Chakrabarty and his group (Haugland et al., 1990). In fact, *B. cepacia* grows luxuriantly on 245T. Although initially this species is not able to use phenoxyacetate, it can acquire this property by long selective pressure. Gene activation in the mutants seems to be due to translocation of insertion elements (Ghadi and Sangodkar, 1994). Polychlorinated phenols are produced in the degradation, and they are further metabolized by *B. cepacia* to the corresponding hydroquinones (Tomasi et al., 1995). The cloning, mapping, and expression of genes controlling the degradation by strains of this species have been under investigation (Sangodkar et al., 1988).

The study of spontaneous *B. cepacia* mutants unable to degrade 245T has permitted the identification of insertion sequences that facilitate or are required for growth at the expense of 245T (Haugland et al., 1991). The rapid evolution of the degradative pathway for this herbicide probably has been possible by insertion elements (such as IS1490) that play a central role in the transcription of 245T genes in *B. cepacia* (Hubner and Hendrickson, 1997). A 1477 bp sequence was repeated several times in a *B. cepacia* strain chromosome, and by the location it was concluded that genes involved in 245T degradation were actually recruited from foreign sources (Tomasek et al., 1989). Originally, foreign gene recruitment such as the mechanism postulated by Lessie and Gaffney (1986), may have been responsible for the acquisition of 245T degradation capacity. Better knowledge of the evolution of these pathways may facilitate the job of developing strains with enhanced degradative capacity (Daubaras et al., 1996a).

B. cepacia competes effectively in the microflora for the degradation of the herbicide 2,4-dichlorophenoxyacetic acid (24D) (Ka et al., 1994a). The enzyme that cleaves 3,5-dichlorocatechol in this pathway has been purified (Bhat et al., 1993). To monitor

a strain in the degradation of 24D, a reporter gene system containing *luxAB* and *lacZY* was integrated into the chromosome of the strain, which thus could be readily identified in the community (Masson et al., 1993).

Oxygenase TftAB, capable of converting 245T to 2,4,5-chlorophenol, is an enzyme of wide specificity, since it can give phenolic derivatives of several other related compounds (Danganan et al., 1995). Two proteins, TftA1 and TftA2, characterized in the pathway, were sequenced and found to have similarity to BenA and BenB of the benzoate 1,2-dioxygenase system of *Acinetobacter calcoaceticus*, and to XylX and XylY from the equivalent system in *Pseudomonas putida* (Danganan et al., 1994). The *B. cepacia* enzyme that degrades 2,4,5-trichlorophenol, the intermediate in 245T catabolism, has been characterized and found to consist of two components (Xun, 1996).

1,2,4-trihydroxybenzene, another intermediate in 245T degradation, is a substrate for the enzyme hydroxyquinol 1,2-dioxygenase. The enzyme is specific, and it is a dimeric protein of 68 kDa (Daubaras et al., 1996b).

Environmental strains of *B. cepacia* are active in the degradation of polychlorinated biphenyls. As in other examples of aerobic metabolism of haloaromatic compounds, dehalogenation often occurs after ring cleavage (Arensdorf and Focht, 1995). *In vitro* constructed hybrids of *B. cepacia* could carry out total degradation of 2-Cl, 3-Cl, 2,4-dichloro-, and 3,5-dichlorobiphenyl (Havel and Reineke, 1991).

Chlorocatechols are key intermediates in the metabolism of haloaromatic compounds, and they are metabolized through reactions resembling those for catechol. A 2-halobenzoate 1,2-dioxygenase, a two-component system of *B. cepacia* strain 2CBS has a very broad specificity (Fetzner et al., 1992). However, in *B. cepacia* isolated from enrichment on 2-chlorobenzoate and in mutants blocked in different steps of the pathway, the 2,3-dioxygenase of the *meta* pathway predominated over the 1,2-dioxygenase (or *ortho*) system (Fetzner et al., 1989).

The dioxygenases and the cycloisomerases involved in the modified *ortho* pathways resemble the enzymes of pathways for nonhalogenated compounds, while the diene-lactone hydrolases needed in a later step are quite different (Schlomann et al., 1993). The results of work done on systems isolated from *Alcaligenes* and *B. cepacia* suggest that the hydrolases of the modified pathway may have been recruited from a different preexisting pathway, which was already operating before the start of industrial synthesis of halogenated compounds (Schlomann, 1994). When plasmid TOL is introduced into *B. cepacia* strains, these strains are able to grow with 3,4- and 3,5-dichlorotoluene, thus bypassing dead-end routes of chlorocatechols degradation (Brinkmann and Reineke, 1992).

The results of the experiments that have been briefly discussed in the preceding paragraphs often point to the high similarity among some components of peripheral metabolic pathways among organisms that are rather distantly related, suggesting horizontal transfer of the corresponding genetic determinants. One additional case is the high similarity between the genes coding for the *cis*-biphenyl dihydrodiol dehydrogenases of *P. putida* (gene *bphB*) and that of *B. cepacia* (Khan et al., 1997), and also between the *bphC* genes of both species, which code for the 2,3-dihydroxybiphenyl 1,2-dioxygenase (Khan et al., 1996b). On the other hand, in spite of having almost identical amino acid sequences, the biphenyl dioxygenase of *B. cepacia* (gene *bphA1*) and that of *Pseudomonas pseudoalcaligenes* have markedly different substrate ranges, the one for *B. cepacia* being wider (Kimura et al., 1997).

Additional details on the metabolism of aromatic compounds may be found in the section on plasmids.

Genetic characteristics The genome of a strain of *B. cepacia* (ATCC 17616) consists of three replicons whose respective sizes are 3.4, 2.5, and 0.9 Mb, which, together with the 170-kb cryptic plasmid present in the strain, gives an overall estimate for genome size of approximately 7 Mb (Cheng and Lessie, 1994). The three large replicons had ribosomal RNA genes, as well as the insertion elements previously described by Lessie and collaborators. Studies on mutants and the associated reductions in size of the replicons provide a convenient framework for genetic analysis of this strain.

The genome of another strain of *B. cepacia* (ATCC 25416) was analyzed and found to contain four circular replicons of sizes 3.65, 3.17, 1.07, and 0.2 Mb (Rodley et al., 1995). The values total 8.1 Mb. Again the interpretation is that the genome is made of three chromosomes and a large plasmid, because of the presence of ribosomal RNA genes only in the three large replicons. An interesting additional observation is the fact that multiple chromosomes are not confined to *B. cepacia* but also are found in other members of rRNA similarity group II (*B. glumae*, *Ralstonia pickettii*, and *R. solanacearum*) (Rodley et al., 1995). A very useful review that highlights the remarkable genomic complexity and plasticity of *B. cepacia* has been published (Lessie et al., 1996).

A *recA* gene has been identified in *B. cepacia* that is able to complement a *recA* mutation in *E. coli*, also restoring UV and methylmethane sulfonate resistance and proficiency in recombination (Nakazawa et al., 1990). Additionally, an SOS box related to LexA-regulated promoters and −10 and −35 consensus sequences have been detected in *B. cepacia*. The predicted RecA protein sequence shows 72% similarity with that of *P. aeruginosa*.

Transposable elements that activate gene expression in *B. cepacia* have been identified by Lessie and his collaborators (Scordilis et al., 1987). This opened a new horizon on insertional activation and on the significance of a high frequency of genomic rearrangements that presumably are related to the remarkable versatility of the species (Gaffney and Lessie, 1987; Lessie et al., 1996).

In spite of all these developments, at present there is incomplete knowledge of gene expression and of regulatory mechanisms in species of *Burkholderia* because of the lack of an appropriate gene exchange system. In the absence of a conventional bacterial genetic system, some alternatives have been developed. One of the proposed methods of genetic analysis is based on transposon mutagenesis and complementation of mutations by means of cloned genes. In a particular application, a shuttle plasmid was constructed that could be used for cloning genes of *B. cepacia* involved in protease production (Abe et al., 1996).

Studies on population genetics have been carried out on a population of *B. cepacia* isolated from a southwestern stream in the United States, to examine the allelic variation in a group of loci using multilocus enzyme electrophoresis. The studies showed a low degree of association between the loci, or extensive genetic mixing. This evidence of frequent recombination (and consequent low levels of linkage disequilibrium) indicates that the structure of the population was not clonal (Wise et al., 1995).

The topology of a 23S rRNA phylogenetic gene tree agrees with the 16S rRNA tree (Höpfl et al., 1989).

Plasmids A cryptic 170-kb plasmid that was discovered in *B. cepacia* ATCC 17616 has been the subject of much research. Derivatives of this strain carried versions of the plasmid containing various insertion sequences in different combinations. These elements, inserted in the broad host range plasmid RP1, served as probes to examine the extent of the reiteration of the various components in the genome of the organism. The results indicated a high frequency of genomic rearrangements, mainly the result of replicon fusions promoted by the insertion elements, that could help explain the remarkable biochemical versatility of the species (Barsomian and Lessie, 1986; Gaffney and Lessie, 1987).

Derivatives of a nonconjugative *Pseudomonas* plasmid (pVS1), carrying genes for mercury and sulfonamide resistance as well as segments required for stability and for mobilization by plasmid RP1, have been established in *B. cepacia* (Itoh et al., 1984). Some further constructions based on pVS1 could be used as cloning vectors (Itoh and Haas, 1985).

In many instances, the degradation of toxic compounds and environmental pollutants is controlled by genes located in plasmids. Some of them already have been mentioned, and only brief reference to some additional instances will be made here. A 50-kb plasmid is responsible for the degradation of *para*-nitrophenol by *B. cepacia*, following an oxidative route with the production of hydroquinone and nitrite. The plasmid can be conjugationally transferred (Prakash et al., 1996). A 70-kb plasmid in *B. cepacia* strain 2CBS carries a gene cluster with the determinant of an enzyme able to catalyze double hydroxylation of 2-halobenzoates with release of halogenide and CO_2 and producing catechol (Haak et al., 1995). A catabolic plasmid involved in the degradation of 4-methyl-*o*-phthalate was described and named MOP (Saint and Ribbons, 1990). Finally, a fragment of a plasmid involved in the catabolism of 4-methylphthalate in *B. cepacia* was sequenced and two open-reading frames were discovered, one of which encoded a permease that belongs to a group of symport proteins found in both pro- and eucaryotes. Information on this system could be used to improve the degradative capability for bioremediation purposes (Saint and Romas, 1996).

The novel pathway of toluene degradation mentioned in the section on metabolism of aromatic compounds is inducible and the corresponding genes are located in a plasmid. A strain of *B. cepacia* was found to carry two plasmids, one of 108 kb (named TOM) containing the genes for a toluene monooxygenase pathway that was expressed constitutively. The same strain also contained a small plasmid of less than 70 kb (Shields et al., 1995).

A new plasmid (pMAB1) with genes controlling the degradation of 24D in *B. cepacia* was characterized, and spontaneous negative mutants were isolated under nonselective conditions. Instead of the original 90-kb plasmid, these mutants had a smaller one (70-kb) or had lost it altogether. The activity could be regained by reintroducing the larger plasmid by electroporation. The 70-kb plasmid lacked a region that included the gene *tfdC* encoding the 3,5-dichlorocatechol 1,2-dioxygenase, whose sequence was identical with that of a well-characterized 24D degradative plasmid (pJP4) of *Alcaligenes eutrophus.* The similarity did not extend to the rest of the plasmids (Bhat et al., 1994). Another *B. cepacia* plasmid (pBS1502) was found to be able to control the early dehalogenation of 2,4-dichlorobenzoate (Zaitsev et al., 1991). There is also a report of the presence of a catabolic plasmid named MOP carrying genes involved in the catabolism of phthalate derivatives (Saint and Ribbons, 1990), and a small (2-kb) plasmid was implicated in the degradation of phenylcarbamate herbicides (Gaubier et al., 1992).

Plasmid analyses in combination with other typing techniques have been proposed for epidemiological studies on nosocomial infections by *B. cepacia* (Yamagishi et al., 1993). Early studies based on agarose gel electrophoresis of *B. cepacia* extracts demonstrated the presence of one or more plasmids in several strains of *B. cepacia* of plant and clinical origin. The plasmid composition, together with bacteriocin production and sensitivity, and pectolytic activity, could have applications in epidemiological studies (González and Vidaver, 1979).

Strains of *B. cepacia* from clinical and pharmaceutical origin carried large plasmids (146–222 kb) containing antibiotic resistance genes (Lennon and DeCicco, 1991). The nonconjugative *B. cepacia* plasmid pVS1 contained Hg and sulfonamide resistance genes, and a segment required for mobilization by RP1 (Itoh et al., 1984).

Bacteriophages Most cultures of *B. pseudomallei* from collections have shown spontaneous phage production (Denisov and Kapliev, 1991). From the strains from a collection, 14 pure lines of bacteriophages belonging to two morphological types were isolated. The specificity of these phages was studied, and it was found that some strains of the host undergo poly-lysogeny, which was inferred from the fact that phages of different morphological types could be isolated from single strains (Denisov and Kapliev, 1995).

A generalized transducing phage was isolated from a lysogenic strain of *B. cepacia*, and half of more than 100 strains of the species were sensitive to it (Matsumoto et al., 1986).

Strain Berkeley 249 (ATCC 17616) of *B. cepacia*, which has been studied very intensively in Lessie's laboratory, carries an organic solvent-sensitive phage (Cihlar et al., 1978). Its sensitivity is attributed to alteration of a tail component provoked by the solvent. Results obtained by using other *B. cepacia* strains as hosts imply the occurrence of host restriction and modification systems. The phage has a head of 55 nm in diameter, a broad contractile tail of 15×145 nm, and double-stranded DNA of a molecular weight of about 3×10^{7}.

Many years ago a bacteriophage lytic for a wide range of aerobic pseudomonads was isolated and tested against strains of different species, among which was *"Pseudomonas multivorans"* (later identified as a synonym of *B. cepacia*) (Kelln and Warren, 1971). *B. cepacia* was insensitive; the phage was lytic only for species of rRNA similarity group I (*Pseudomonas sensu stricto*) and not for members of other rRNA groups.

Bacteriocins Early work performed on *B. cepacia* strains isolated from plants and from clinical specimens showed that the two groups could be differentiated by bacteriocin production patterns, onion maceration tests, and hydrolysis of pectate at low pH, thus suggesting the usefulness of these characteristics in epidemiological studies (González and Vidaver, 1979). Additional differences between strains from the two sources have been recorded (Bevivino et al., 1994) and will be discussed below (see Ecology, Habitats, and Niches).

A number of *B. cepacia* bacteriocins ("cepaciacins") were defined in work done on a collection of 34 strains isolated from plant rhizospheres and human patients (Dodatko et al., 1989a). One of the cepaciacins consisted of protein and carbohydrate in a 3:1 molecular ratio. The bacteriocin was thermolabile, stable within a narrow range of pH values, and it was destroyed by

proteolytic action. UV irradiation or mitomycin C stimulated its biosynthesis (Dodatko et al., 1989b).

A typing scheme has been described based on bacteriocin susceptibility and production by *B. cepacia* strains using six producer strains and a set of eight indicator strains (Govan and Harris, 1985). The majority of strains of a large collection were typed into a total of 44 combinations, and the typing scheme was found to be useful for the possibility of its application to epidemiological studies.

Antigenic structure The LPS structure of different *B. pseudomallei* strains is quite homogeneous. Antibodies prepared with material from one strain react with all others (Pitt et al., 1992). In agreement with the degree of their phylogenetic relationships, cross-reactions are observed with *B. mallei* and, to a lesser extent, with *B. cepacia*.

Many features of the biological activity of LPS isolated from *B. pseudomallei* cells have been described, and the strong mitogenic activity that it has toward murine splenocytes has been attributed to unusual chemical structures in the inner core attached to lipid A (Matsuura et al., 1996). In addition, information is available about the identification, isolation, and purification of an exopolysaccharide of this species. As in the instance described above, the compound having a molecular mass of >150 kDa did not show cross-reactivity with any of the species of all the *Pseudomonas* rRNA similarity groups, with the exception of the closely related species *B. mallei* (Steinmetz et al., 1995).

Purification to homogeneity of flagellin from several *B. pseudomallei* strains gave monomer flagellin bands of M_r 43,400 Da. Passive immunization studies showed that a specific antiserum could protect animals from challenge by a *B. pseudomallei* strain of different origin (Brett et al., 1994).

Two monoclonal antibodies were found to be highly specific for *B. pseudomallei* when tested by indirect enzyme-linked immunosorbent assay and immunoblotting against whole-cell extracts of other *Burkholderia* species, fluorescent pseudomonads, and *E. coli*. One of the antibodies could agglutinate all 42 *B. pseudomallei* strains included in the study, thus providing a tool for rapid identification of the species using primary bacterial cultures from clinical specimens (Pongsunk et al., 1996).

Of the serological typing schemes devised for *B. cepacia*, the one most widely used is that proposed by Werneburg and Monteil (1989). Originally, the scheme described procedures for the preparation, adsorption, and titration of O and H rabbit sera, and it could define seven O (O1 to O7) and five H antigens (H1, H3, H5, H6, and H7) for the slide agglutination test and the agglutination and immobilization test, respectively (Heidt et al., 1983). The scheme later was supplemented with new serotypes, using strains of a different geographical origin, to make a total of 9 O and 7 H antigens (Werneburg and Monteil, 1989). Other immunological typing schemes have been proposed (Nakamura et al., 1986).

Wilkinson and his collaborators have studied the composition of the O-specific polymers from the LPS of *B. cepacia* strains belonging to groups O1 (Cox and Wilkinson, 1990b), O3, O5 (Cox and Wilkinson, 1989b), O7 (Cox and Wilkinson, 1990a), and O9 (Taylor et al., 1994a). The O9 group has repeating units that are also present in *Serratia marcescens*. In the same laboratory it has been discovered that the O antigen of the LPS of *B. cepacia* serotype E (O2) is composed of two different trisaccharide repeating units in a 2:1 ratio (Beynon et al., 1995), and that the same O specific polymer is found in the two related species *B. cepacia* and *B. vietnamiensis*.

Interestingly, the lipopolysaccharides extracted from *B. cepacia* and *B. gladioli* have a higher endotoxic activity and provoke a higher cytokine response than that from *Pseudomonas aeruginosa* (Shaw et al., 1995). This adds to the importance to the human pathogenic propensities of *P. gladioli*, an example of a plant pathogen of medical importance similar to that of *B. cepacia*. Plant-associated *B. gladioli* can be differentiated from other pathogenic and symbiotic bacterial species by a rapid slide agglutination test using polyclonal antisera conjugated to protein-rich *Staphylococcus aureus* whole cells (Lyons and Taylor, 1990).

Cross-reactivity of *P. aeruginosa* antipilin monoclonal antibodies with heterogeneous strains of *P. aeruginosa* and *B. cepacia* has been reported (Saiman et al., 1989).

Antibiotic susceptibility For obvious reasons, most information on antibiotic susceptibility of species of the genus *Burkholderia* refers to only a few species of medical importance (*B. pseudomallei*, *B. cepacia*, *B. gladioli*).

All strains of *B. cepacia* that have been tested are sensitive to sulfonamides and novobiocin. Most are also sensitive to trimethoprim plus sulfamethoxazole, and to minocycline and chloramphenicol (Santos Ferreira et al., 1985). Both *B. cepacia* and *B. gladioli* are resistant to a wide variety of antibiotics (ticarcillin by itself or mixed with clavulanic acid; cefsulodin, imipenem, aminoglycosides, colistin, and fosfomycin) (Baxter et al., 1997). A catechol-containing monobactam (BMS-180680) was quite active (MIC90, 1 μg/ml; MIC90 is a minimum concentration which inhibits 90% of the strains tested) (Fung-Tomc et al., 1997).

Eighty percent of a collection of strains of *B. cepacia* was tested for inhibition by ceftazidime (Tabe and Igari, 1994). A number of quinolone analogs and derivatives (trovafloxacin, ciprofloxacin, ofloxacin, levofloxacin, sparfloxacin, clinafloxacin, ceftazidime) were active on several Gram-negative, nonfermentative species, including *B. cepacia*. In comparison, the MIC for imipenem on *B. cepacia* and on *Stenotrophomonas maltophilia* was very high (Visalli et al., 1997).

In a comparison of the activity of many antibiotics against *B. pseudomallei*, a quinolone (tosufloxacine) and a tetracycline derivative (minocycline) appeared to be the most active (Yamamoto et al., 1990).

For years, the oral maintenance treatment of melioidosis has depended on the combined action of amoxicillin and the β-lactamase inhibitor clavulanic acid (Suputtamongkol et al., 1991). Biapenem, one of several carbapenem antibiotics tested against *B. pseudomallei*, was the most active against strains that showed a diminished susceptibility to third-generation cephalosporins (Smith et al., 1996).

Several resistance mechanisms operate in different species of *Burkholderia*. Resistance to cationic antibiotics in *B. cepacia* has been attributed to their ineffective binding to the outer membrane as a consequence of the low number of phosphate and carboxylate groups in the LPS, and the presence of protonated aminodeoxypentose (Cox and Wilkinson, 1991). The involvement of the outer membrane of *B. cepacia* in the resistance to polymyxin and aminoglycosides may also be related to a particular arrangement in the structure of the outer membrane, in which cation-binding sites on LPS are protected from polycations (Moore and Hancock, 1986).

An important factor in the antibiotic resistance in these organisms is porin permeability (Parr et al., 1987; Burns et al., 1996). However, a different interpretation is that resistance may not be a direct consequence of permeability of the porins, but

instead may be related to the low number of porins per cell. A β-lactam-resistant mutant of *B. cepacia* and resistant strains of this species isolated from cystic fibrosis cases owe their resistance to a low porin content. These strains had reduced amounts of a 36-kDa outer membrane protein and did not express a 27-kDa outer membrane protein that can be a major porin or a major component of the porin complex of the cells (Aronoff, 1988). According to this view, the most common resistance mechanism in *B. cepacia* is the low porin-mediated outer membrane permeability, combined with multiple drug resistance due to an efflux pump system (Burns et al., 1996).

It may be of interest to mention here that growth in the presence of salicylate or other weak acids can induce resistance to antibiotics in *B. cepacia*, because these compounds have been found to be inhibitors of porin formation (Burns and Clark, 1992).

A number of β-lactams are susceptible to hydrolysis by a β-lactamase of *B. cepacia*, a metalloenzyme of type I that is induced by imipenem (Baxter and Lambert, 1994). A significant degree of similarity was found between the chromosomal β-lactamase of *B. cepacia* strain 249 and the enzymes of *Pseudomonas aeruginosa* and *E. coli*. Interestingly, in spite of differences in the mol% G + C content of the DNA of these organisms, the codon usage in *B. cepacia* resembled that of *E. coli* (Proenca et al., 1993).

The multiple resistance gene *oprM* of *P. aeruginosa* is part of a highly conserved efflux system. A gene homologous to *oprM* was identified in *B. cepacia* (Burns et al., 1996). Moreover, an intragenic probe hybridized the genomic DNA of several fluorescent pseudomonads and, in addition, the DNA of *B. pseudomallei* (Bianco et al., 1997). A lucid review is available on the participation of multidrug efflux pumps in the resistance of Gram-negative organisms to antibiotics (Nikaido, 1996).

The fusaric acid resistance gene of *B. cepacia* has been cloned and sequenced (Utsumi et al., 1991).

Antibiotic production Antifungal antibiotics have been identified in strains of *B. cepacia*. Cepacidine A, composed of two related forms, cepacidine A1 and A2, is a cyclic peptide and xylose connected to a 5,7-dihydroxy-3,9-diaminooctadecanoic acid (Lee et al., 1994a; Lim et al., 1994). Two antibiotics previously discovered and described under the names cepacin A and B are not related to the cepacidines. The cepacins showed good antistaphylococcal activities (MICs of 0.2 and 0.05 μg/ml for cepacin A and B, respectively), but no significant activity against Gram-negative bacteria (Parker et al., 1984).

Another antifungal antibiotic is pyrrolnitrin (Jayaswal et al., 1993). The producing organism was named *Pseudomonas pyrrocinia* (Imanaka et al., 1965), now *Burkholderia pyrrocinia*. The antibiotic is also produced by *B. cepacia* and by some strains of *Pseudomonas chlororaphis* (Elander et al., 1968). A study by Burkhead et al. (1994) has examined the conditions of pyrrolnitrin by *B. cepacia* in culture and in the wounded areas of potatoes colonized by the organism.

Some compounds related to pyrrolnitrin (amino-pyrrolnitrin, and monochloroamino-pyrrolnitrine) also have antifungal properties (McLoughlin et al., 1992). The antibiotic activity of *B. cepacia* has been reported to antagonize the pathogenic activity of the sunflower wilt fungus (McLoughlin et al., 1992) and to be a suppressor of maize soil-borne disease (Hebbar et al., 1992). The influence of some environmental factors on the antagonism of *B. cepacia* toward *Trichoderma viride* has been analyzed (Upadhyay et al., 1991), as well as some morphological alterations and inhibition of conidiation of plant pathogenic fungi (Upadhyay and Jayaswal, 1992). A compound having both hemolytic activity and antifungal action was characterized and given the name cepalycin (Abe and Nakazawa, 1994).

Transposon mutagenesis could eliminate pyrrolnitrin production ability. However, the mutation failed to be complemented by the cloned gene because of difficulties encountered in mobilizing the carrier cosmids from *E. coli* to *B. cepacia* mutants (Jayaswal et al., 1992).

A group of eight cyclic peptides of antifungal activity, the xylocandins, has been isolated from *B. cepacia* and characterized (Bisacchi et al., 1987). A mixture of two of the forms (A1 and A2) showed potent anticandidal and antidermatophytic activities *in vitro* (Meyers et al., 1987).

The antagonistic activity of *B. cepacia* is not limited to antifungal activity. Of practical importance is the finding that metabolites produced by strains of this species can antagonize plant pathogenic agents such as *Ralstonia solanacearum* (Aoki et al., 1991).

Toxoflavin, an azapteridine antibiotic produced by *B. cocovenenans*, was identified more than 30 years ago (Lauquin et al., 1976). The production of toxoflavin is inhibited by the combined action of 2% NaCl and acidity (pH 4.5) in the medium (Buckle and Kartadarma, 1990). A monobactam antibiotic (MM 42842) is also produced by *B. cocovenenans*. It is related to a previously described antibiotic named sulfazecin. In addition, the *B. cocovenenans* strain synthesizes bulgecin, an antibiotic also produced by other aerobic pseudomonads (Box et al., 1988; Gwynn et al., 1988).

Tropolone, which is known to have antibacterial and antifungal activities (Lindberg, 1981), is produced by *B. plantarii* cultures (Azegami et al., 1987).

Plant pathogenicity Many species of the genus *Burkholderia* are pathogenic for animals or plants. Phytopathogenic pseudomonads are located in three of the five RNA similarity groups. One of them is rRNA group II, in which *Burkholderia* and *Ralstonia* are allocated. The various symptoms produced in plants by the phytopathogenic pseudomonads are tumorous outgrowth, rot, blight or chlorosis, and necrosis, which are caused by alteration of the normal metabolism of plant cells by pathogenicity factors excreted by the bacteria. These factors include enzymes capable of degrading components of plant tissues, toxins, and plant hormones.

The phytopathogenic species of the genus *Burkholderia* mainly produce rots, due to active pectinolytic enzymes and cellulases (Gehring, 1962; Hildebrand, personal communication). Further details on symptoms and on the list of hosts attacked by each species will be given in the section of species descriptions at the end of this chapter.

Aside from acting as agents of diseases, members of the genus also participate in producing beneficial effects by antagonizing other phytopathogenic organisms, mainly fungi. This effect has been reported in the literature for *B. cepacia* in a number of instances (Kawamoto and Lorbeer, 1976; Fantino and Bazzi, 1982; Janisiewicz and Roitman, 1988; Homma et al., 1989; Jayaswal et al., 1990; Parke et al., 1991).

Pathogenicity for humans and animals The most serious animal and human pathogenic species of the genus *Burkholderia* are *B. mallei* and *B. pseudomallei*, the agents of glanders or farcy of equids, and of melioidosis in humans, respectively. Detailed descriptions of these organisms and the diseases that they cause are available (Redfearn et al., 1966; Redfearn and Palleroni,

1975). As a free-living species present in the warm regions of the planet, *B. pseudomallei* has not spread far from the equator, although in China it has reached a northern latitude of at least 25.5 degrees (Yang et al., 1995b).

A useful updated treatment of the bacteriology of glanders and melioidosis is available (Pitt, 1998). Many years ago, melioidosis was recognized as a glanders-like disease (Whitmore, 1913), and subsequently the organism was assigned to several different genera. In fact, this has also been true of *B. mallei*, which has spent much of its scientific career in search of a proper generic allocation.

Two different biotypes have been recognized among various strains of *B. pseudomallei* isolated from patients and from soil in Thailand. However, all of the strains were recognized by using a specific polyclonal antibody. One of the biotypes may have low virulence or it may represent a different species altogether, based on the distribution of these phenotypes and the respective incidence of melioidosis in different areas (Wuthiekanun et al., 1996).

Strains of *B. pseudomallei* isolated in Australia were examined for their genomic relationships using random amplification of polymorphic DNA and multilocus enzyme electrophoresis. The strains could be divided into two groups that correlated with the clinical presentation and not with the geographic origin; in other words, there was a correlation between the clinical manifestation of the disease and the molecular characteristics of the pathogen (Norton et al., 1998).

Some of the human pathogens are "opportunistic pathogens" that create major medical problems in patients with reduced levels of natural resistance. This situation emerges because of an increasing use of instrumentation or drugs (including antibiotics) that reduce or bypass the level of natural resistance and/or the specific immune mechanisms (Spaulding, 1974).

In reference to *B. cepacia*, it seems appropriate here to highlight the main points of the abstract of an excellent article published more than a decade ago (Goldmann and Klinger, 1986). From its original habitat as a plant pathogen, *B. cepacia* has invaded the hospital environment as an important pathogen of compromised human hosts. Many nosocomial infections have their source in contaminated medicaments and even disinfectants and antiseptics. Various conditions in hospital patients can be complicated by *B. cepacia* infections, but the properties that define the virulence of strains of this species are still poorly defined. The last addition to the long list of pathological conditions that are further deteriorated by infections of this pathogen is cystic fibrosis. As in other conditions, some patients may be simply colonized, while other patients' initial conditions can be very seriously complicated, to which the remarkable resistance of *B. cepacia* to a wide range of antibiotics contributes very effectively. This bleak panorama has become even worse in the intervening years, particularly with respect to pulmonary exacerbations in cystic fibrosis patients, in many cases ending in rapid and fatal deterioration of lung function.

Characteristics that occur more frequently among strains isolated from infections in cystic fibrosis patients include catalase, ornithine decarboxylase, valine amino-peptidase, lipase, alginase, trypsin, ability to reduce nitrate, hydrolysis of xanthine and urea, complete hemolysis of bovine red blood cells, cold-sensitive hemolysis of human red blood cells, and greening of horse and rabbit red blood cells. Although some of these properties are associated with pathogenicity in other bacteria, their relationships to cystic fibrosis-associated pulmonary disease are far from clear (Gessner and Mortensen, 1990). Acid phosphatase in *Burkholderia* species is a factor that may be related to pathogenicity. It is present in *B. cepacia* and *B. pseudomallei*, and in fact the activity in the latter species is remarkably high (Dejsirilert Butraporn et al., 1989).

In addition to these factors, as mentioned before in the section on antigenic structure, LPS preparations from clinical and environmental isolates of *B. cepacia* and from the closely related species *B. gladioli* exhibit a higher endotoxic activity and more pronounced cytokine response *in vitro* when compared to preparations of *P. aeruginosa* LPS. The latter species is also involved in infections in cystic fibrosis patients (Shaw et al., 1995).

B. gladioli, a species originally described as phytopathogenic, has been implicated in infections complicating cases of cystic fibrosis (Mortensen et al., 1988). In one study, the organism was isolated from respiratory tract specimens obtained from 11 cystic fibrosis patients and was identified by its biochemical properties, DNA hybridization, and fatty acid analysis. The authors recommend the inclusion of some of these criteria for the differentiation between *B. gladioli* and *B. cepacia*, two closely related species, and point out that most *B. gladioli* strains have $C_{10:0\ 3OH}$ fatty acid, which is absent from *B. cepacia* lipids (Christenson et al., 1989). Also based on the results of fatty acid analysis, a pseudomonad that was isolated from pleural fluid and pulmonary decortication tissue with granulomatous disease more closely resembled *B. gladioli* than *B. cepacia* (Trotter et al., 1990). Further information on the activity of *B. gladioli* as a human pathogen has been reported by Ross et al. (1995). A strain of this species was involved in empyema and bloodstream infection occurring after lung transplantation in a cystic fibrosis case (Khan et al., 1996c).

The pili of *B. cepacia* mediate adherence to mucous glycoproteins (Kuehn et al., 1992; Sajjan and Forstner, 1993) and epithelial cells in cystic fibrosis patients. Structural variant classes of pilus fibers have been identified in *B. cepacia* strains (Goldstein et al., 1995). One or more of five morphologically different types can be coexpressed. It has been noticed that, when present in the infective population, *Pseudomonas aeruginosa* cells enhance the adhesion of *B. cepacia* to epithelial cells (Saiman et al., 1990).

The major pilin subunit of *B. cepacia* corresponds to peritrichous fimbriae, which, based on their appearance as giant intertwined fibers, have been called "cable" (Cbl) pili. The *cblA* gene (the first pilin subunit gene to be identified in *B. cepacia*) has been detected in a DNA library (Sajjan et al., 1995).

One very infectious cystic fibrosis strain isolated as the agent of epidemics in England and Canada was found to have the cable pilin subunit gene. A conserved DNA marker in a 1.4-Kb fragment was present in epidemic strains, absent from the nonepidemic ones, and rare among the environmental strains. The presumed ORF was designated "epidemic marker regulator" (*esmR*) (Mahenthiralingam et al., 1997). Strains were recovered in cystic fibrosis centers in France. There was cross-colonization in 7 of 13 centers. The most chronically colonized patients harbored a single *B. cepacia* strain, which suggests a geographically clustered distribution of *B. cepacia*, with the exception of one genotype. This genotype was detected in four regions and proved to be different from the British-Canadian highly transmissible strain and was able to spread among cystic fibrosis units (Segonds et al., 1997).

Biochemical and genomic properties have been used for the typing of *B. cepacia* strains of nosocomial origin. In a first step, six enzymes and pigment production subdivided a collection of

strains of this species into 12 groups, and the strains from one-third of the collection were further characterized by DNA fingerprinting, ribotyping, and plasmid analysis. By testing the typing scheme on strains isolated years later, the results showed the usefulness and consistency of the genomic typing, and the marked diversity of phenotypes among the strains of the species (Ouchi et al., 1995).

The amplified products of the internal transcribed spacers (ITS) separating the 16S and 23S rRNA genes in the DNA have been effective as tools for identification of reference strains of *Pseudomonas aeruginosa* and *B. pseudomallei*, but the primer pairs tested for *B. cepacia* have not provided much help in strain identification (Tyler et al., 1995). In contrast, PCR-ribotyping targeted on the 16S-23S intergenic spacer to determine the length heterogeneity of this region is a rapid and accurate method for *B. cepacia* strain typing (Dasen et al., 1994).

The internal diversity of *B. cepacia* strains is also manifested in differences in whole-cell protein profiles (Li and Hayward, 1994) and in the fatty acid composition of populations from various cystic fibrosis centers (Mukwaya and Welch, 1989).

A novel marker has been found to be associated with epidemic *B. cepacia* strains causing infections in cystic fibrosis patients. A highly infectious strain had both the cable pilin subunit gene (*cblA*) and a unique combination of insertion sequences. Although no specific marker was identified in common with other epidemic strains, a conserved DNA fragment among epidemic strains was detected. This fragment (called the "*B. cepacia* epidemic strain marker") was absent from other strains infecting individual cystic fibrosis patients and rarely found in environmental strains (Mahenthiralingam et al., 1997).

In a related study on 97 clinical and 2 environmental strains of *B. cepacia*, a search for possible correlations was made with respect to parameters such as certain insertion sequence (IS) elements, the *cblA* gene for a pilin subunit, the electrophoretic type (ET), and the ribotype (RT) (Tyler et al., 1996). No linkage was found between the presence of each of five different IS elements and ET or RT. All strains of a given ET also possessed *cblA*. One IS element different from the five initially identified was present in 72% of all isolates, and in half of them the new IS element was inserted in one of the original five. This hybrid IS element only was found in epidemic strains from Ontario, Canada, and the UK.

Methods were developed to detect the presence of *B. cepacia*, *Pseudomonas aeruginosa*, and *Stenotrophomonas maltophilia* in sputum, using primers based on 16S rRNA sequences. The results are in agreement with those of direct isolation of cultures from the samples (Campbell et al., 1995; Karpati and Jonasson, 1996).

Bongkreik acid (also named flavotoxin A), a product of fermentation by *B. cocovenenans*, is the cause of serious food poisoning outbreaks in China and other Far East countries (Hu et al., 1989). An isomer, isobongkreik acid, was later identified, and, like bongkreik acid, it acts as an uncompetitive inhibitor of ADP transport in mitochondria, although it is less active than bongkreik acid (Lauquin et al., 1976).

Ecology, habitats, and niches The habitats from which *Burkholderia* species have been isolated are quite diverse: soils and rhizospheres (*B. cepacia*, *B. vietnamiensis*, *B. pseudomallei*, *B. pyrrocinia*, *B. phenazinium*, *B. multivorans*, *B. thailandensis*, *B. glathei*), water (*B. norimbergensis*), plants (*B. cepacia*, *B. gladioli*, *B. caryophylli*, *B. glumae*, *B. plantarii*, *B. andropogonis*, *B. vandii*), foods (*B. cocovenenans*), animals (*B. mallei*, *B. pseudomallei*), and clinical specimens (*B. cepacia*, *B. vietnamiensis*, *B. gladioli*, *B. multivorans*). The occurrence of *B. pseudomallei* mainly in soils of tropical regions has been discussed elsewhere (Redfearn et al., 1966).

As mentioned in the section on metabolic properties, some species of the genus are metabolically very versatile, and there is little doubt that those normally found in soils and water must contribute substantially to the mineralization of carbon compounds in nature.

B. cepacia is commonly found in natural materials, particularly soil, and methods have been developed for its detection. One such method of detection in the environment was based on amplification of sequences in genomic DNA using primers specific for repetitive extragenic palindromic segments, followed by cloning of the amplified fragments. Probes were constructed based on the strain-specific sequences (Matheson et al., 1997). A striking example of the power of molecular approaches was the report of the detection of a single *B. cepacia* cell in a soil sample containing a population of 10^{10} procaryotic cells (Steffan and Atlas, 1988). Estimates of the relative abundance of *B. cepacia* in stream bacterioplankton can be performed after collecting the cells by various procedures, of which the use of filters made of inorganic materials was found to give the highest recoveries (Lemke et al., 1997).

Strains of *B. cepacia* can be isolated from rhizosphere environments (Tabacchioni et al., 1995). This is also the habitat from which *B. graminis* was originally obtained (Viallard et al., 1998). Rhizosphere strains of *B. cepacia* differed in phenotypic characteristics from those isolated from clinical materials. Among the differences were nitrogen fixation, indole-acetic acid production, a wide temperature range, antibiosis vs. phytopathogenic fungi, and growth promotion of *Cucumis sativus*—all positive for rhizosphere strains. These properties were absent from clinical strains, which instead possessed characteristics such as adhesion to human cells, protease production, and synthesis of siderophores different from those found in the nonclinical strains (Bevivino et al., 1994). The character of N_2 fixation is not clear-cut, since DNA preparations from clinical strains hybridized with the *nifA* gene probe from *Klebsiella pneumoniae*, and the DNA of one of the rhizosphere strains hybridized with the *nifHDK* from *Azospirillum brasilense* (Tabacchioni et al., 1995).

As far as animal pathogenicity is concerned, observations made in other laboratories seem to support somewhat different conclusions. Thus, strains isolated from plant or clinical materials did not differ in their lethality to mice, i.e., they have similar LD_{50} values (González and Vidaver, 1979). Indeed, strains of species known to be causal agents of human infections may be isolated from rhizosphere environments (Tabacchioni et al., 1995).

Although *B. cepacia* helps in the degradation of toxic compounds and has an inhibitory action on soil-borne plant pathogens, it can also behave as a serious opportunistic human pathogen. The key question of interest for its use in biotechnological projects is whether the two types of populations can interact to the point of transmission of the characteristics required for the pathogenic condition. Yohalem and Lorbeer (1994) state that "although there are (*B. cepacia*) strains with significant potential for the remediation of environmental toxins . . . and others with potential as biological controls of plant disease . . . environmental release of any strain may be prohibited because some strains of the nomenspecies have been implicated in nosocomial infections." The same considerations apply to other versatile species of the genus that manifest pathogenic propensities.

Enrichment and Isolation Procedures

For the specific isolation of *B. cepacia* from environmental water samples or various aqueous solutions, a medium containing 9-chloro-9-(4-diethylaminophenyl)-10-phenylacridan (C-390) and polymyxin B sulfate (PBS) has been proposed.[3] The two drugs inhibited all the organisms tested, with the exception of *B. cepacia* and *Serratia marcescens* (Wu and Thompson, 1984).

A medium proposed for the isolation of *B. cepacia* contains tryptamine and azelaic acid as sole sources of nitrogen and carbon, respectively, in addition to the antifungal compound chlorothalonil (Diamond Shamrock Corp., Cleveland, Ohio) (Burbage and Sasser, 1982). Later on it was found that the effectiveness of this medium was rather low, and a different one, medium (TB-T)[4], based on the combined action of trypan blue (TB) and tetracycline (T) at a relatively low pH (5.5), was proposed. Using this medium, the efficiency of recovery was very variable among strains, and for some of them reached 76–86% (Hagedorn et al., 1987).

A medium for *B. cepacia* has been described in a patent (Lumsden and Sasser, 1986).

Three selective enrichment liquid media and four solid media were evaluated at two temperatures (35°C and room temperature) for their capacity of supporting growth of *B. pseudomallei* strains. Enrichment with trypticase soy broth with addition of 5 mg of crystal violet and 20 mg of colistin per liter and subculture in Ashdown medium[5] gave the highest recovery rates and the greatest suppression of other members of the soil microflora. The results were comparable at the two temperatures (room temperatures ranged between 20°C and 32°C).

Differentiation of the genus *Burkholderia* from other genera

Similarities between *Burkholderia* and other Gram-negative bacteria A sharp differentiation of members of *Burkholderia* and *Pseudomonas* is difficult because of many similarities between these organisms. In the course of biochemical studies carried out at Berkeley before the rRNA–DNA hybridization experiments showed that *"P. multivorans"* (*B. cepacia*) was not closely related to the fluorescent group, it was noticed that key steps of the metabolism of aromatic compounds were remarkably similar between the two groups. In the section on the metabolism of aromatic compounds, some comments have been made on the similarity of components of some of the enzymes involved in the degradation by distantly related organisms. In fact, many details of the metabolic constitution of the fluorescent pseudomonads are far closer to those found in some species of RNA similarity group II—in particular, *B. cepacia*—than to those characteristic of RNA group V (*Stenotrophomonas* and *Xanthomonas*), which is closer to RNA group I. Such is the case of the enzymes codified by genes *bphB* and *bphC* in *P. putida* and *B. cepacia*, and the same is true for the gamma-carboxymuconolactone decarboxylases of these species. Fluorescent organisms and *B. cepacia* are able to synthesize salicylic acid, which acts both as a siderophore and also as the precursor of another siderophore found in both groups of organisms, pyochelin. Members of the fluorescent group and *B. pyrrocinia*, a species related to *B. cepacia*, produce the antifungal antibiotic pyrrolnitrin, and similarities also have been observed in the pilin antigenic structures of *P. aeruginosa* and *B. cepacia* (Saiman et al., 1989).

Similarities have also been observed between *B. cepacia* and bacteria of groups other than the aerobic pseudomonads. With respect to the production of chaperonins (so named for their relationship with eucaryotic chaperones), an evolutionary homolog of the protein involved in plants in the assembly of ribulose-bisphosphate carboxylase-oxygenase (the key enzyme in CO_2 fixation) was identified in *E. coli*. This protein, GroEL, is one of the chaperonins, a group widely present in procaryotes and organelles of procaryotic origin (chloroplasts and mitochondria) (Hemmingsen et al., 1988). Aside from *E. coli* and pseudomonads, chaperonins have been identified in species of *Legionella*, *Bacillus*, *Borrelia*, *Treponema*, *Mycobacterium*, and *Coxiella* (Kaijser, 1975; Houston et al., 1990). In work performed on the cloning and nucleotide sequencing of the *groE* operons of *P. aeruginosa* and *B. cepacia*, a high degree of similarity was found, which extended to the *E. coli groEL*. The level of similarity with the human protein was lower, but still considerable. Comparable results were obtained in the study of a second chaperonin, GroES (Jensen et al., 1995).

The above-cited findings on chaperonins indicate that the similarities between groups I and II (*Pseudomonas* and *Burkholderia*) in some cases go beyond the dispensable catabolic systems or the biosynthesis of secondary products.

Differentiation of *Burkholderia* from related genera The examples of similarities mentioned in the previous section show that a sharp differentiation of members of *Burkholderia* and *Pseudomonas* is difficult. Studies on DNA–DNA hybridization (Ballard et al., 1970) and on rRNA–DNA hybridization (Palleroni et al., 1973) demonstrated that species of the genus were members of RNA similarity group II. They were eventually allocated to a newly proposed genus under the name *Burkholderia* (Yabuuchi et al., 1992), but two of the species (*B. pickettii* and *B. solanacearum*) were later transferred to the new genus *Ralstonia*, and the criteria for the differentiation of this genus from *Burkholderia* were defined (Yabuuchi et al., 1995). Unfortunately, as in the case of the proposal of the genus *Burkholderia*, the published differential characteristics were limited to those of a single strain of each species, which makes it impossible to estimate the intraspecies diversity.

In a polyphasic study of *Burkholderia* species, Gillis et al. (1995) redefined this genus. Among the characteristics of differential value, these authors mention the presence of $C_{16:0\ 3OH}$ in the cellular fatty acid composition. Most of the properties given in the definition of the genus *Burkholderia* apply equally well to other genera of aerobic pseudomonads, and, as in the case of the genus *Pseudomonas*, the fatty acid composition and the 16S rRNA characteristics remain among the few useful differential criteria.

3. Plate Count Agar (PCA, Difco Laboratories) is rehydrated according to the manufacturer's instructions. Aqueous stock solutions containing 0.1% C-390 or 7.5% PBS are prepared. One milliliter of each of these solutions is added to each liter of rehydrated PCA to reach a final concentration of 1 μg/ml of C-390 and 75 μg/ml PBS. The medium is autoclaved at 121°C for 15 min.

4. TB-T agar medium (g/l): glucose, 2.0; L-asparagine, 1; $NaHCO_3$, 1.0; KH_2PO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 0.1; trypan blue, 0.05; and agar, 20.0. The pH is adjusted to 5.5 with phosphoric acid solution (4 ml/l of a 10% solution). After autoclaving, tetracycline (20 mg/l) is added from a filter-sterilized stock solution. When fungi are abundant in the sample, crystal violet (5 mg/l) and filter-sterilized nystatin (50 mg/l) are added.

5. Ashdown medium (Ashdown, 1979a, b) is trypticase soy agar (BBL) with the following additions (per liter): glycerol, 40 g; crystal violet, 5 mg; neutral red, 50 mg; and gentamicin, 4 mg.

Taxonomic Comments

In the 1960s, a project that focused on the construction of a rational system of classification of *Pseudomonas* species was organized at the Department of Bacteriology of the University of California at Berkeley. This project had its main justification in the highly unsatisfactory situation of the taxonomy of this genus to which were assigned several hundreds of species names, many of which could not be identified based on published descriptions, and their type strains had been lost.

A thorough phenotypic characterization of a large collection of strains resulted in a subdivision of the genus into species and species groups (Stanier et al., 1966). With time, species not included in the original project were subjected to the same analysis and located in the classification scheme. Eventually, the phenotypic characterization received confirmation from the results of DNA–DNA hybridization experiments. More significantly, the results of these experiments revealed a very wide range of DNA similarity values among the species assigned to the genus, suggesting a considerable degree of genomic heterogeneity among the members of the genus. This hypothesis was corroborated by rRNA–DNA hybridization experiments. They clearly showed that *Pseudomonas*, as classically described, could be subdivided into five RNA similarity groups representing at least five different genera (Palleroni et al., 1973).

This demonstration that the genus *Pseudomonas* was in fact a complex entity of suprageneric hierarchy was taken as the basis for proposals from various other laboratories to give different generic names to designate members of the five rRNA similarity groups. Of the five groups, rRNA group I retained the name *Pseudomonas* and the type species *P. aeruginosa* was originally proposed for the genus. For rRNA group II, the new genus name *Burkholderia* was introduced (Yabuuchi et al., 1992), comprising seven new combinations: *B. cepacia* (Palleroni and Holmes, 1981), *B. mallei* (Zopf, 1885), *B. pseudomallei* (Whitmore, 1913), *B. caryophylli* (Burkholder, 1942), *B. gladioli* (Severini, 1913), *B. pickettii* (Ralston et al., 1973), and *B. solanacearum* (Smith, 1896). Since the heterogeneity of the genus even extended to the rRNA similarity group level, some of the groups could still be further subdivided to include more than one bacterial genus. Thus, the last two of the above-mentioned species, were assigned to a newly created genus, *Ralstonia* (Yabuuchi et al., 1995). The overall similarity of *Ralstonia solanacearum* and *R. pickettii* already had been noticed in studies on their phenotypic characteristics and on DNA homologies (Ralston et al., 1973).

The present treatment refers to those species of rRNA group II assigned to the genus *Burkholderia*.

In their studies on the aerobic pseudomonads, Stanier et al. (1966) described a group of metabolically versatile organisms under the new species name *"Pseudomonas multivorans"*. In the plant pathology department of the University of California, David Sands applied the same methodology to the study of phytopathogenic pseudomonads. Soon his studies resulted in the unexpected finding that the properties of the above strains were virtually identical to those of a species that had been known to phytopathologists for almost two decades under the name of *P. cepacia*. The remarkable versatility of strains of this species had been totally overlooked by the early workers.

DNA–DNA hybridization experiments confirmed the synonymy soon thereafter (Ballard et al., 1970). The collection of strains of *B. cepacia* examined at the time could be differentiated from other species on the basis of the capacity to grow at the expense of D-arabinose, D-fucose, cellobiose, saccharate, mucate, 2,3-butylene glycol, sebacate, *meso*-tartrate, citraconate, *o*-hydroxybenzoate, *m*-hydroxybenzoate, L-threonine, DL-ornithine, and tryptamine. This set of characteristics sharply separated *B. cepacia* from all other members of the various phenotypic groups, as can be seen in Table 52 of the original reference (Stanier et al., 1966).

The early observations that helped to uncover the remarkable metabolic versatility of *B. cepacia* and other species of the genus *Burkholderia* also contributed substantial lists of phenotypic characteristics for use in the identification of newly isolated strains. Some of the results are summarized in the tables included in this chapter. Substantial collections of strains of the species are now available, and studies on intraspecific diversity have been published. The interesting metabolic properties of members of this group of procaryotes stimulated the isolation of many strains, which has contributed to the recent proliferation of names for new species and for groups (biovars, genomovars) at the intraspecific level. On the one hand, the nutritional versatility of *Burkholderia* species—which includes the ability to degrade toxic environmental contaminants—suggests an important function in the carbon cycle in nature. However, research directed to the use of these characteristics in bioremediation projects has to take into account the fact that some of the species are serious pathogenic agents for plants and animals, and proper precautions should be taken to counteract these activities.

Early studies on *B. cepacia* and its synonym *"Pseudomonas multivorans"* (Stanier et al., 1966; Ballard et al., 1970) clearly indicated considerable intraspecific heterogeneity in phenotypic characteristics such as pigmentation and nutritional properties, and in the DNA similarity results of DNA–DNA hybridization experiments. One hundred strains of *B. cepacia* were examined, and a proposal for a subdivision of the species into biovars was suggested (Richard et al., 1981). In recent times, other comparative studies showed marked differences between *B. cepacia* strains isolated from the clinical environment and those found in plant rhizospheres (Bevivino et al., 1994; Tabacchioni et al., 1995). Excellent reviews are available on the intraspecific diversity of this species (Yohalem and Lorbeer, 1994) and on its genomic complexity and versatility (Lessie et al., 1996). All these reports have had a taxonomic impact, resulting in the proposal of converting some of the intraspecific groups into independent taxa at the species level, as discussed below.

The newly proposed species names include *B. vietnamiensis* and *B. multivorans*, related to *B. cepacia*, *B. thailandensis*, a relative of *B. pseudomallei*, and *B. graminis*, which is close to the group *B. caryophylli–B. glathei–B. phenazinium*. Some of the descriptions fail to create a precise circumscription of the proposed taxa, but it is to be expected that the interest in these organisms will eventually contribute to generate characterizations that are more comprehensive.

A genotypic analysis of 128 strains of *Burkholderia*, *Ralstonia*, and *Pseudomonas* was taken as the basis for a definition of the taxonomic structure of *B. cepacia* (Vandamme et al., 1997b). The strains isolated from cases of cystic fibrosis could be grouped into five so-called genomic species, very similar from the phenotypic standpoint. One of the genomic species of this "*B. cepacia* complex" corresponded to the previously described *B. vietnamiensis*, and a second one received the formal name *B. multivorans*, a revival of a synonym of *B. cepacia* used many years before (Stanier et al., 1966). The rest of the genomovars (I, III, and IV) have remained unnamed.

A description of *B. multivorans* is given in this chapter (see

List of Species of the genus *Burkholderia*), and a more complete report of its properties can be found in the original description (Vandamme et al., 1997b). Four of the strains of genomovar II—now *B. multivorans*—exhibited a high level of relatedness by DNA–DNA hybridization. The organisms are phenotypically similar to other biovars of *B. cepacia* and cannot be readily differentiated from them.

The name *B. thailandensis* was recently proposed for a group of strains closely related to *B. pseudomallei* based on a high 16S rRNA sequence similarity (Brett et al., 1998). The organisms differ phenotypically from *B. pseudomallei* by relatively few characteristics, including an ability to use L-arabinose, 5-ketogluconate, adonitol, erythritol, and dulcitol. Differences in biochemical profile and virulence also occur. DNA–DNA hybridization studies of the two species have not been reported.

The position occupied by *B. graminis* in the phylogenetic tree of Fig. BXII.β.2 indicates that this species is located in a cluster that includes *B. glathei* and *B. phenazinium*. This is further supported by a set of phenotypic properties of differential value and clear-cut differences in the DNA reassociation values, as can be seen in Tables 2 and 3 of the original publication (Viallard et al., 1998).

Finally, a new species with rather unique properties, *B. norimbergensis* (*Pandoraea norimbergensis*), has been described for a strain isolated from an oxic water layer above a sulfide-containing sediment (Wittke et al., 1997). This organism oxidizes several inorganic sulfur compounds including sulfur and produces sulfate. The reported characteristics of the new species do not fit the organization of the tables in this chapter. The description is given in the list of species for the genus *Pandoraea*, together with some comments on its phylogenetic relationships. The 16S rRNA sequence of a new species of *Burkholderia* that has been named *B. caribensis* has been deposited in GenBank under the accession numbers Y17009, Y17010, and Y17011. The sequence places this species near *B. graminis* (V. Viallard and J. Balandreau, personal communication).

Following the recommendation formulated by Vandamme et al. (1997b), buttressed by the evidence reported by Viallard et al. (1998), three species previously assigned to *Pseudomonas* are now being included in the list of *Burkholderia* species as *B. glathei*, *B. pyrrocinia*, and *B. phenazinium*.

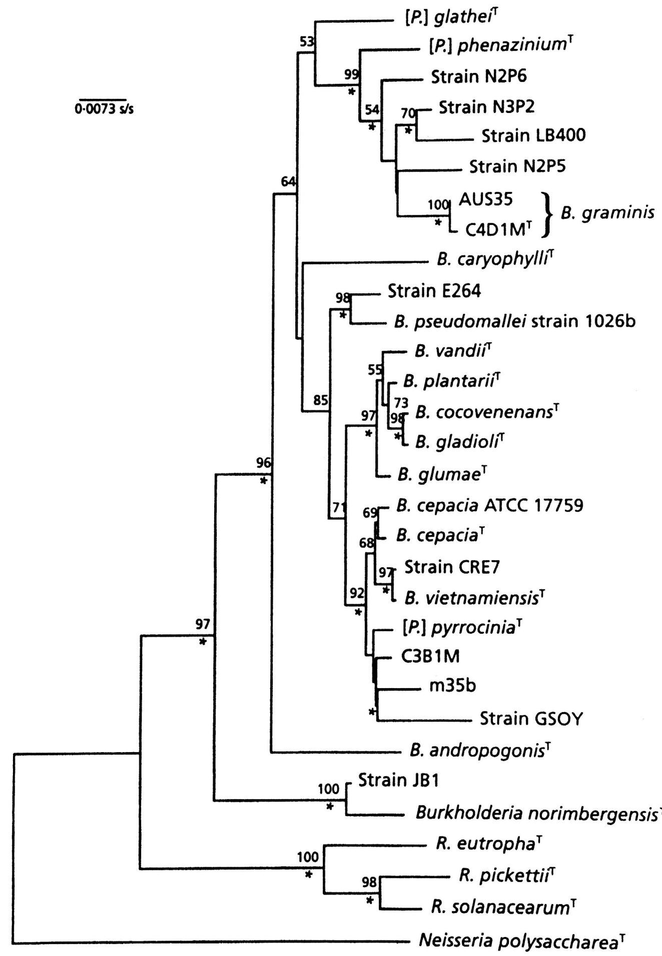

FIGURE BXII.β.2. Neighbor-joining tree obtained with the 16S rDNA sequences of *Burkholderia*, [*Pseudomonas*], and *Ralstonia* species. Bootstrap values (1000 resamplings) greater than 50% are indicated at the nodes, and asterisks indicate values higher than 50% found in the parsimony analysis. Bar = 0.0073 fixed mutations per nucleotide position. Three additional strains of *B. vietnamiensis* had the same sequence as the type strain represented in the tree. The tree shows the position of several unnamed strains whose source is indicated in the original paper (Viallard et al., 1998). Of these, strain E264 has been named recently *B. thailandensis* (Brett et al., 1997). *[P.] glathei*, *[P.] phenazinium*, and *[P.] pyrrocinia* are described in this chapter as *Burkholderia* species. List of species of the genus Burkholderia

1. **Burkholderia cepacia** (Palleroni and Holmes 1981) Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398^{VP} (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1271) (*Pseudomonas cepacia* Palleroni and Holmes 1981, 479.)

ce.pa' ci.a. L. fem. n. *caepa* or *cepa* onion; M.L. fem. adj. *cepacia* of or like an onion.

Properties useful for differentiation from other species of the genus are given in Table BXII.β.2. Characteristics of the species are presented in Table BXII.β.3. As suggested in the description of *"Pseudomonas multivorans"* (Stanier et

al., 1966), strains of *B. cepacia* can be differentiated from other species on the basis of their ability to grow at the expense of D-arabinose, D-fucose, cellobiose, saccharate, mucate, 2,3-butylene glycol, sebacate, *m*-tartrate, citraconate, *o*-hydroxybenzoate, *m*-hydroxybenzoate, L-threonine, DL-ornithine, and tryptamine. These characteristics, although not present in all strains, are useful for the identification of newly isolated strains. For further descriptive information see Ballard et al. (1970) and Palleroni and Holmes (1981). Optimal growth temperature, ~30–35°C.

Many strains have been isolated from rotten onions, soils, various natural materials, and clinical specimens. The species is considered a serious opportunistic human pathogen, and it has been found associated with infections of nosocomial origin. A study by Vandamme et al. (1997b) on strains isolated from cystic fibrosis cases has resulted in the identification of multiple genomovars of *B. cepacia*, among which some (genomovar II) are being described under the new species name *Burkholderia multivorans* (see comments in the description of this species below).

The mol% G + C of the DNA is: 67.4 (Bd).

Type strain: ATCC 25416, Ballard 717, DSM 7288, ICPB 25, NCTC 10743.

GenBank accession number (16S rRNA): M22518, U96927.

2. **Burkholderia andropogonis** (Smith 1911) Gillis, Van, Bardin, Goor, Hebbar, Willems, Segers, Kersters, Heulin and Fernandez 1995, 287[VP] (*Pseudomonas andropogonis* (Smith 1911) Stapp 1928, 27; *Pseudomonas andropogoni* (sic) Smith 1911, 63.)

an.dro.po' go.nis. M.L. n. *Andropogon* genus of widely distributed grasses; M.L. gen. n. *andropogonis* of the genus *Andropogon.*

The following description is slightly modified from the one given by Palleroni (1984) in the first edition of this *Manual.*

Slender rods with rounded ends, 0.5–0.7 × 1–2 μm, with one or rarely two polar flagella. Colonies change from butyrous to viscid with age. No fluorescent pigment is produced. Most strains are oxidase negative. Gelatin liquefaction, nitrate reduction, lipolysis, and arginine dihydrolase reactions negative. Production of sheathed flagella (flagella surrounded by a membrane that is a continuation of the cell wall) was reported by Fuerst and Hayward (1969a).

Although the species had been tentatively assigned to the rRNA similarity group III based on its enzymatic properties, it is now considered a member of the genus *Burkholderia* (Gillis et al., 1995). Further details of its phenotypic properties are given by Palleroni (1984) and in Tables BXII.β.2 and BXII.β.3. A comprehensive description is given in the Ph.D. thesis of Xiang Li (1993).

Recommendations to consider *P. stizolobii* and *P. woodsii* as synonyms of *B. andropogonis* were formulated by several workers (Goto and Starr, 1971; Hayward, 1972; Nishiyama et al., 1979; Shanks and Hale, 1984), and this opinion was reinforced by the demonstration of similar protein profiles (Vidaver and Carlson, 1978) and polyamine composition (Auling et al., 1991).

Pathogenic for sorghum, corn, clover, and velvet bean (*Stizolobium deeringianum*). To the host list should be added highbush blueberry, in which the pathogen causes leaf spot lesions in hardwood cuttings (Kobayashi et al., 1995). Perhaps the host specialization may justify creating two pathovars—pathovar *andropogonis* for the causal agent of the bacterial stripe of sorghum, and pathovar *stizolobii* for that of the bacterial leaf spot of velvet bean (Palleroni, 1984). As mentioned in a previous section, strains of *B. andropogonis* are able to synthesize rhizobitoxine, a phytotoxin capable of causing foliar chlorosis.

The mol% G + C of the DNA is: 59–61.3 (T_m).

Type strain: ATCC 23061, DSM 9511, LMG 2129.

GenBank accession number (16S rRNA): X67037.

3. **Burkholderia caribensis** Achouak, Christen, Barakat, Martel and Heulin 1999, 792[VP]

ca.ri.ben' sis. M.L. adj. *caribensis* pertaining to the Caribbean Islands, where the strains were isolated.

The description is taken from the original paper.

Short rods, 1–2 × 0.5 μm. Motile and pleomorphic in actively growing cultures in LB medium. In sugar-rich media (with 2% glucose, xylose, fructose, sorbitol, arabinose, mannitol, or sorbitol) it produces abundant exopolysaccharide.

Oxidase, catalase, urease, arginine dihydrolase, and β-galactosidase are produced. A list of organic compounds that have been tested as substrates of oxidative activities is given in the paper. Isolated from a vertisol fraction in the island of Martinique.

The mol% G + C of the DNA is: 63.1 (T_m).

Type strain: LMG 18531, MWAP 64.

GenBank accession number (16S rRNA): Y17009.

4. **Burkholderia caryophylli** (Burkholder 1942) Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398[VP] (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1273) (*Pseudomonas caryophylli* (Burkholder 1942) Starr and Burkholder 1942, 601; *Phytomonas caryophylli* Burkholder 1942, 143.)

ca.ry.o' phyl.li. M.L. masc. n. *caryophyllus* specific epithet of *Dianthus caryophyllus*, carnation; M.L. gen. n. *caryophylli* of the carnation.

The general characteristics of the species are presented in Tables BXII.β.2, BXII.β.3, and BXII.β.6. The main properties for differentiation from several other *Burkholderia* species and other denitrifying pseudomonads, are summarized in Table BXII.β.4. Optimal growth temperature ~30–33°C. For further descriptive information, see Ballard et al. (1970). Isolated from diseased carnations.

The mol% G + C of the DNA is: 65.3 (Bd).

Type strain: ATCC 25418, DSM 50341, ICPB PC113, NCPPB 2151, PDDCC 512.

GenBank accession number (16S rRNA): X67039.

5. **Burkholderia cocovenenans** (van Damme, Johannes, Cox and Berends 1960) Zhao, Qu, Wang and Chen 1995, 601[VP] (*Pseudomonas cocovenenans* van Damme, Johannes, Cox and Berends 1960, 255.)

co.co.ve' ne.nans. M.L. n. *Cocos* genus of coconut; L. v. *veneno* to poison; M.L. part. adj. *cocovenenans* coconut poisoning.

The following description is taken from the paper by Zhao et al. (1995). Rods 0.3–0.5 × 1.6–2.0 μm, occurring singly or in pairs. Motile by means of one to five polar flagella. No lipid soluble or fluorescent pigment is produced; however, a greenish-yellow diffusible pigment (tox-

[a]For symbols see standard definitions.

[b]Data for the type strains, taken from Yabuuchi et al. (1992).

oflavin) is formed after 1–2 d of incubation on potato dextrose agar or other media.

Growth temperature range goes from 6–41°C. Metabolism is respiratory and denitrification is negative, but nitrate is reduced to nitrite. Oxidase reaction is negative. Gelatinase, Tween 80 hydrolysis, and lecithinase reactions are all positive. Many organic compounds can be used as sole carbon and energy sources. Detailed information can be found in the original report (Zhao et al., 1995), in Gillis et al. (1995), and in Tables BXII.β.2 and BXII.β.3.

Strains have been isolated from fermented coconut food (bongkrek) in Indonesia, fermented cornmeal in China, deteriorated white fungus (*Tremella fuciformis*), and soil. DNA– DNA hybridization experiments have shown that this species is close to *B. cepacia* and *B. gladioli* (Zhao et al., 1995). The organism is not infectious to humans, but it is responsible for serious cases of food poisoning due to the production of a yellow poisonous compound, toxoflavin.

Recent studies by Coenye et al. (1999b) based on whole protein electrophoretic profiles, DNA–DNA hybridization, and comparison of many biochemical properties indicate that *B. cocovenenans* should be considered a junior synonym of *B. gladioli*.

The mol% G + C of the DNA is: 69 ± 0.5 (T_m).

Type strain: ATCC 33664, DSM 11318, LMG 11626, NCIB 9450.

GenBank accession number (16S rRNA): U96934.

6. **Burkholderia gladioli** (Severini 1913) Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398[VP] (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1273) (*Pseudomonas gladioli* Severini 1913, 420.)

gla.di.o′ li. L. n. *gladiolus* a small sword lily; M.L. masc. n. *gladioli* of gladiolus.

The characteristics of the species are summarized in Tables BXII.β.2, BXII.β.3, and BXII.β.6. Optimal growth temperature, ~30–35°C. Further descriptive information may be found in Ballard et al. (1970), where the species appears under the name *"Pseudomonas marginata"* (see also Hildebrand et al., 1973).

Isolated from decayed onions, *Gladiolus* spp, and *Iris* spp., for which the species is believed to be pathogenic. Two pathovar names have been proposed for the phytopathogenic strains, pathovar *gladioli* and pathovar *aliicola* (Young et al., 1978). To these, the new pathovar name pathovar *agaricicola* has been created to distinguish the *B. gladioli* strains producing rapid soft rot of cultivated mushrooms (*Agaricus bitorquis*) (Lincoln et al., 1991). *B. gladioli* was identified as the agent of leaf spot and blight of the bird's nest fern *Asplenium nidus* (Chase et al., 1984). As indicated in the section on pathogenicity for humans, strains of the species have been found to be serious opportunistic pathogens.

As a phytopathogen, *B. gladioli* pathovar *alliicola* behaves in a manner similar to that of *B. cepacia*, causing soft rot of onions (61-gl; 21-gl) (Tesoriero et al., 1982; Wright et al., 1993). It has also been identified as a probable agent of early blight in cherries (26-gl) (Li and Scholberg, 1992), and to cause rapid soft rot disease of the edible mushroom *Agaricus bitorquis* (38-gl; 29-gl) (Lincoln et al., 1991; Atkey et al., 1992). *B. gladioli* also contributes to postharvest dis-

TABLE BXII.β.7. Nutritional properties of *Burkholderia mallei* and *Burkholderia pseudomallei* [a]

Characteristics[b]	*B. mallei*	*B. pseudomallei*
Utilization of:		
Acetate, *N*-acetylglucosamine[c], adipate, D-alanine, L-alanine, β-alanine, γ-aminobutyrate, D-arabinose, L-arginine, L-aspartate, benzoate, betaine, cellobiose, D-fucose, fumarate, galactose, glucose, L-glutamate, glycerate, glycerol, hippurate, L-histamine, β-hydroxybutyrate, *p*-hydroxybenzoate, *m*-inositol, α-ketoglutarate, lactate, L-malate, mannitol, mannose, phenylacetate, poly-β-hydroxybutyrate, propionate, pyruvate, quinate, sorbitol, succinate, sucrose, L-threonine, trehalose, tryptamine, L-tyrosine	+	+

[a]For symbols see standard definitions.

[b]The following compounds are not used by either species: acetamide, aesculin[c], *m*-aminobenzoate, *p*-aminobenzoate, α-aminovalerate, amygdalin[c], arbutin[c], benzylamine, *n*-butanol, 2,3-butylene glycol, citraconate, L-citrulline, creatine, dodecane, ethylene glycol, gentiobiose[c], geraniol, glycolate, histamine, *m*-hydroxybenzoate, *o*-hydroxybenzoate, hydroxymethylglutarate, inulin, isobutanol, isophthalate, isopropanol, 5-ketogluconate, lactose, L-leucine, lyxose[c], maleate, D-mandelate, melibiose[c], mesaconate, methanol, methylamine[c], mucate, nicotinate, norleucine, L-ornithine, oxalate[c], pantothenate, phenol, phenylethanediol, phthalate, *n*-propanol, propylene glycol, raffinose[c], L-rhamnose, saccharate, salicin[c], tagatose[c], D(−)-tartrate, L(+)-tartrate, *meso*-tartrate, terephthalate, testosterone, tryptamine, D-tryptophan, xylitol[c].

[c]Data for the type strains, taken from Yabuuchi et al. (1992).

eases of fruits and vegetables, an activity in which the species has been identified by analyses of fatty acid composition (24-gl) (Wells et al., 1993).

The mol% G + C of the DNA is: 68.5 (Bd).

Type strain: ATCC 10248, DSM 4285, NCPPB 1891, PDDCC 3950.

GenBank accession number (16S rRNA): X67038.

Additional Remarks: This is also the reference strain for *B. gladioli* pathovar *gladioli*. The reference strain for *B. gladioli* pathovar *alliicola* is ATCC 19302 (PDDCC 2804; NCPPB 947). The reference strain for *B. gladioli* pathovar *agaricicola* is NCPPB 3580.

7. **Burkholderia glathei** (Zolg and Ottow 1975) Vandamme, Holmes, Vancanneyt, Coenye, Hoste, Coopman, Revets, Lauwers, Gillis, Kersters and Govan 1997b, 1199[VP] (*Pseudomonas glathei* Zolg and Ottow 1975, 296.)
gla' the.i. M.L. gen. *glathei* of Glathe, named after H. Glathe of Giessen, Germany.

The description is taken from Zolg and Ottow (1975). Rods to oval cocci, 0.5–0.7 × 1.5 μm, motile by a polar flagellum. Optimal growth temperature 30–37°C. Oxidase reaction positive. Negative for hydrolysis of starch, gelatin, lecithin (egg yolk reaction), esculin, and polypectate. Tributyrin, urea, and hippurate are hydrolyzed. Nitrate is reduced to nitrite. Denitrification and H_2S production are negative. No growth factor requirement has been found. The organism is capable of growth in nitrogen-deficient media, but acetylene reduction by cells grown under those conditions is negative. Acid tolerant (pH 4.5).

From the extensive phenotypic characterization of *B. glathei* following the methodology described by Stanier et al. (1966), it has been found that at least 68 organic compounds can be utilized as sole carbon and energy sources for growth. These include aldoses, ketoses, deoxysugars, sugar-alcohols, and sugar-acids. Except for lactose, melibiose, and melezitose, no di-, tri-, and polysaccharides are utilized. The only amino acids that are not utilized are glycine, L-serine, L-isoleucine, L-methionine, and β-alanine. Of 28 aliphatic organic acids, 23 are utilized. The list of utilizable acids includes oxalate. Some properties are summarized in Table BXII.β.3.

A 1,2-oxygenase responsible for the *ortho* cleavage of aromatic compounds is produced constitutively. This species differs in several important characteristics from other species of the genus. The main differences include the capacity for growing in nitrogen-deficient media, the acid tolerance, and the utilization of oxalate for growth. A study by Vandamme et al. (1997b), which includes fatty acid analysis, indicates that this species should be allocated to the genus *Burkholderia*, an opinion that has found confirmation by rRNA sequencing studies (Viallard et al., 1998).

The mol% G + C of the DNA is: 64.8 (T_m).

Type strain: N15, ATCC 29195, DSM 50014, LMG 14190.

GenBank accession number (16S rRNA): U96935, Y17052.

8. **Burkholderia glumae** (Kurita and Tabei 1967) Urakami, Ito-Yoshida, Araki, Kijima, Suzuki and Komagata 1994, 242[VP] (*Pseudomonas glumae* Kurita and Tabei 1967, 111.)
glu' mae. L. n. *gluma* hull; L. gen. n. *glumae* of a husk.

The following description is taken from the original paper by Kurita and Tabei (1967). Rods, 0.5–0.7 × 1.5–2.5 μm, motile by means of two to four flagella. A fluorescent pigment is produced in potato agar. Nitrate reduction, starch hydrolysis, and H_2S production are negative. Gelatin liquefaction was not reported in the original paper, but Ura-

kami et al. (1994) found that the test was positive. Temperature limits for growth: 11–40°C; optimum: 30–35°C. Acid is produced from arabinose, glucose, fructose, galactose, mannose, xylose, glycerol, mannitol, and inositol. No acid is produced from rhamnose, sucrose, maltose, lactose, raffinose, dextrin, starch, inulin, or salicin. Milk is coagulated and peptonized. Pathogenic for the rice plant (*Oryza sativa*, fam. Gramineae).

To the above description, Urakami et al. (1994) have added a substantial amount of information on the nutritional spectrum of the type strain, and part of it has been summarized in Tables BXII.β.2 and BXII.β.3. A peculiar property of this species is the production of fluorescent pigment, but no further details are available on its relationship to the pigment characteristic of the fluorescent species of the genus *Pseudomonas*. This is a point of interest for further investigation. As mentioned before, two subgroups of *B. glumae* strains can be distinguished based on their fatty acid composition (Stead, 1992).

The mol% G + C of the DNA is: 68.2 (reversed HPLC) (Urakami et al., 1994).

Type strain: ATCC 33617, DSM 7169, LMG 2196, NCPPB 2981, NIAES 1169.

GenBank accession number (16S rRNA): U96931.

9. **Burkholderia graminis** Viallard, Poirier, Cournoyer, Haurat, Wiebkin, Ophel-Keller and Balandreau 1998, 560[VP]
gra' mi.nis. M.L. adj. *graminis* referring to its isolation from the rhizosphere of grasses.

The description is taken from the original paper (Viallard et al., 1998). Rods, 0.3–0.8 × 1.0–1.5 µm; motile. The number of flagella per cell is not reported. Colonies on LB agar are thin, brownish-yellow, and translucent. On agar prepared with the special medium PCAT (Burbage and Sasser, 1982) after 3 d at 28°C, the colonies are white, somewhat opaque and creamy, with entire margin. Oxidase, catalase, urease, and arginine deiminase reactions are positive. Nitrates are reduced, but there is no denitrification. Characteristics in common with other *Burkholderia* species are the assimilation of glycerol, D- and L-arabinose, ribose, galactose, glucose, fructose, mannose, inositol, mannitol, sorbitol, D-arabitol, gluconate, and 2-ketogluconate, and the inability to use L-sorbose, methyl-α-D-xyloside, methyl-α-D-mannoside, methyl-α-D-glucoside, inulin, melezitose, starch, glycogen, or D-turanose. Properties not found in some of the other species include the incapacity of acid formation from glucose, to hydrolyze esculin or to produce gelatinase. In addition, the strains grow on L-xylose, lactose, rhamnose, trehalose, D-lyxose, L-arabitol, xylitol, and raffinose, but not on dulcitol or D-tagatose. Isolated from the rhizosphere of wheat, corn, and pasture grasses.

The mol% G + C of the DNA is: 62.5–63.0 (HPLC).

Type strain: C4D1M, ATCC 700544.

GenBank accession number (16S rRNA): U96939.

10. **Burkholderia kururiensis** Zhang, Hanada, Shigematsu, Shibuya, Kamagata, Kanagawa and Kurane 2000a, 747[VP]
ku.ru.ri.en' sis. M.L. adj. *kururiensis* referring to Kururi, Chiba Prefecture, Japan, where the strain was isolated.

The following description is taken from the original paper. The cells are Gram negative and ovoid or rod shaped. (1 × 1.2–1.5 µm), occurring singly or in pairs. Growth occurs between 15–42°C, with an optimum at 37°C. The optimal growth pH is 7.2. Under optimal conditions, the doubling time is about 1 h. Oxidase and catalase positive. Starch and gelatin are not hydrolyzed, but glycogen and Tween 80 are. The following organic compounds are degraded aerobically: arabinose, fructose, fucose, galactose, glucose, lactulose, maltose, mannose, psicose, rhamnose, adonitol, arabitol, glycerol, inositol, mannitol, sorbitol, xylitol, *N*-acetylgalactosamine, acetate, citrate, formate, galacturonate, gluconate, lactate, propionate, alanine, asparagine, aspartate, glutamate, glycine, histidine, leucine, phenylalanine, proline, serine, threonine, inosine, 2,3-butanediol, benzene, *p*-cresol, fluorobenzene, and phenol. The following compounds are not oxidized: cellobiose, lactose, melibiose, raffinose, sucrose, trehalose, dextrin, malonate, uridine, thymidine, glucose-1-phosphate, and glucose-6-phosphate. UQ-8 is the dominant respiratory quinone. Main cellular fatty acids are $C_{16:0}$, cyclopropanic acids $C_{17:0}$, cyclopropanic acid $C_{19:0}$, $C_{16:1}$, and $C_{18:1}$. $C_{13:1}$ and $C_{17:1}$ are also present. The organism was isolated from an aquifer polluted with trichloroethylene (TCE) in Kururi, Chiba Prefecture, Japan, and shows degradation activity for this contaminant when the cells are grown in the presence of phenol.

The mol% G + C of the DNA is: 64.8 (HPLC).

Type strain: KP23, ATCC 700977, CIP 106643, DSM 13646, LMG 19447.

GenBank accession number (16S rRNA): AB024310.

This species has some properties that are not common in the genus *Burkholderia*. The cells are nonmotile, a characteristic shared only with *B. mallei*. The strain uses maltose, which is rarely used by strains of other species, and fails to use disaccharides used by the latter. No DNA–DNA hybridization data have been reported.

11. **Burkholderia mallei** (Zopf 1885) Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398[VP] (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1271) (*Pseudomonas mallei* (Zopf 1885) Redfearn, Palleroni and Stanier 1966, 305; *Bacillus mallei* Zopf 1885, 89.)
mal' le.i. L. n. *malleus* the disease of glanders; L. gen. n. *mallei* of glanders.

Characteristics of the species are listed in Tables BXII.β.2, BXII.β.3, and BXII.β.7, and those that are useful for the differentiation of the species from various other denitrifying pseudomonads are summarized in Table BXII.β.4. Optimal growth temperature ~37°C. For further descriptive information, see Redfearn et al. (1966) and Redfearn and Palleroni (1975). Parasitic on horses and donkeys, in which it causes glanders and farcy. The infection is transmissible to humans and to other animal species.

The mol% G + C of the DNA is: 69 (Bd).

Type strain: NBL 7, ATCC 23344.

GenBank accession number (16S rRNA): S55000.

12. **Burkholderia multivorans** Vandamme, Holmes, Vancanneyt, Coenye, Hoste, Coopman, Revets, Lauwers, Gillis, Kersters and Govan 1997b, 1198[VP]
mul.ti' vo.rans. L. adj. *multus* much; L. part. adj. *vorans* devouring, digesting; M.L. part. adj. *multivorans* digesting many compounds.

Rods, 0.6–0.9 × 1.0–2.0 μm. Motile at room temperature and at 37°C. Number of flagella per cell not reported. Able to grow at 42°C but not at 5°C. According to the original description, some strains grow at room temperature. No pigments are produced. Growth in some media used for enteric bacteria is reported. No information is given on utilization of carbon compounds for growth, but, instead, production of acids from some compounds is reported. Tolerance to cyanide is strain dependent. No fluorescence occurs in King's B medium. Tween 20 and 80 are hydrolyzed. Urease, catalase, oxidase, and lecithinase activities are all positive. Nitrate is reduced, but not nitrite. Gelatin liquefaction is negative. No hydrolysis of casein, starch, or esculin occurs. Arginine deiminase is negative. PHB is accumulated and, according to the description, is utilized. The report does not specifically state whether this refers to extracellular PHB.

The strains assigned to this species belonged to one of the genomovars (genomovar II) into which was subdivided a collection of *B. cepacia* isolated from cases of cystic fibrosis. Four strains of this genomovar shared high DNA sequence similarity as determined by hybridization methods, and the melting temperatures of rRNA–DNA hybrid molecules using *B. cepacia* as reference were lower than the homologous *B. cepacia* reassociated molecules. The phenotypic differences between *B. multivorans* and *B. cepacia* are limited to casein digestion, growth at 42°C, and acid production from sucrose and raffinose. In fact, these last two properties may be redundant, since the two saccharides may be hydrolyzed by the same enzyme, for instance, invertase. Acid may be produced from the resulting monosaccharides (glucose and fructose). Since the physiological properties used for the description of this species differ from those used for other species of the genus, it is not possible to use them in a more extensive comparison, and therefore the species has been excluded from the comparative Table BXII.β.3.

The mol% G + C of the DNA is: 68–69 (method unknown).

Type strain: LMG 13010, ATCC BAA-247, CCUG 34080, CIP 105495, DSM 13243, NCTC 13007.

GenBank accession number (16S rRNA): AF14855.

13. **Burkholderia phenazinium** (Bell and Turner 1973) Viallard, Poirier, Cournoyer, Haurat, Wiebkin, Ophel-Keller and Balandreau 1998, 5618^VP^ (*Pseudomonas phenazinium* Bell and Turner 1973, 753.)
phe.na.zi' ni.um. Orthography and etymology uncertain; possibly refers to iodinin, which is a phenazine pigment.

The original bacteriological information on this species is fragmentary. It is included in a paper describing the production of iodinin under various conditions (Bell and Turner, 1973). The strain was isolated from soil after an enrichment using L-threonine as the sole carbon source. This property is mentioned by Viallard et al. (1998) in their short description. It has no value whatsoever as a diagnostic character, since many aerobic pseudomonads use this amino acid and the property is usually shared by all the strains of a given species.

An unusual feature mentioned in the original description of the species is its acidophilic character. The strain was acidophilic, the optimal pH for growth being 5.0. It failed to grow at pH 7.0. This feature apparently has not been mentioned by later researchers who have worked with this strain. Colonies on agar media produced iodine crystals, and the presence of L-threonine or glycine in the medium seemed to enhance pigment synthesis. In experiments designed to test iodinin production, growth was observed with threonine, glycine, fumarate, glycerol, sucrose, malate, succinate, DL-lactate, citrate, glucose, glutamate, pyruvate, and serine. Growth was poor with aminopropanol, and no growth was observed with propionate. Additional information, taken from Viallard et al. (1998), is summarized in Table BXII.β.2. The description does not mention specifically use of extracellular PHB as a growth substrate. Acid production from various sugars is given in the original paper.

The mol% G + C of the DNA is: (HPLC).

Type strain: ATCC 33666, DSM 10684, LMG 2247, NCIB 11027.

GenBank accession number (16S rRNA): U96936.

As a general comment, the phenotypic properties of the description for *B. phenazinium* do not clearly differentiate this species from *B. cepacia*, and no data on DNA similarity expressed by percent DNA hybridization are reported. Only the $T_{m(e)}$ values of the DNA–rRNA hybrids obtained with 23S rRNA seem to differentiate this species from *B. cepacia*. For the moment, it is advisable to consider this taxon as a genomovar of *B. cepacia* until more evidence is available to decide on its independent species rank.

14. **Burkholderia plantarii** (Azegami, Nishiyama, Watanabe, Kadota, Ochuchi and Fukazawa 1987) Urakami, Ito-Yoshida, Araki, Kijima, Suzuki and Komagata 1994, 242^VP^ (*Pseudomonas plantarii* Azegami, Nishiyama, Watanabe, Kadota, Ochuchi and Fukazawa 1987, 151.)
plan' tar.i.i. L. n. *plantarium* seedbed; L. gen. n. *plantarii* of seedbed.

The following description is summarized from that in the original paper by Azegami et al. (1987). Nonencapsulated straight rods (0.7–1.0 × 1.4–1.9 μm), motile with one to three polar flagella. They occur singly, in pairs, or in short chains. Colonies have a slightly yellow tint, and they produce a water-soluble reddish brown pigment depending on the conditions and the medium. Oxidase positive. Do not produce fluorescent pigment. Gelatinase, lecithinase, hydrolysis of Tween 80, and denitrification are all positive. Arginine dihydrolase negative. Acid production on a number of carbon compounds and nutritional properties are described in the original paper. Further details are summarized in Tables BXII.β.2, BXII.β.3, and BXII.β.4. The species causes rice seedling blight, and strains have been isolated from rice seedlings and from bed soil in nursery boxes in Japan.

The mol% G + C of the DNA is: 64.8 (Bd).

Type strain: ATCC 43733, AZ 6201, DSM 9509, JCM 5492, LMG 9035, NIAES 1723.

GenBank accession number (16S rRNA): U96933.

15. **Burkholderia pseudomallei** (Whitmore 1913) Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398^VP^ (Effective publication: Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1992, 1273) (*Pseudomonas pseudomallei* (Whitmore 1913) Haynes and Burkholder 1957, 100; *Bacillus pseudomallei* Whitmore 1913, 9.)
pseu.do.mal' le.i. Gr. adj. *pseudes* false; L. n. *malleus* the disease glanders; M.L. gen. n. *pseudomallei* of false glanders.

The general characteristics of the species and properties useful for differentiation from the related species *B. mallei* are given in Tables BXII.β.2, BXII.β.3, and BXII.β.7. Colonies can range in structure from extremely rough to mucoid, and in color from cream to bright orange. Optimal growth temperature, ~37°C. For further descriptive information see Redfearn et al. (1966) and Redfearn and Palleroni (1975). Isolated from human and animal cases of melioidosis and from soil and water in tropical regions, particularly Southeast Asia. Probably a soil organism and accidental pathogen, causing melioidosis.

The mol% G + C of the DNA is: 69.5 (Bd).

Type strain: ATCC 23343, NCTC 12939, WRAIR 286.

16. **Burkholderia pyrrocinia** (Imanaka, Kousaka, Tamura and Arima 1965) Vandamme, Holmes, Vancanneyt, Coenye, Hoste, Coopman, Revets, Lauwers, Gillis, Kersters and Govan 1997b, 1199[VP] (*Pseudomonas pyrrocinia* Imanaka, Kousaka, Tamura and Arima 1965, 205.)
pyr.ro.ci' ni.a. Etymology uncertain, possibly M.L. adj. *"pyrrocin"* referring to the antibiotic properties of pyrrolnitrin, which is produced by strains of this species.

The following description is taken from the original paper. Rods, 0.5–0.8 × 1.2–2.0 µm, occurring singly. Motile by means of polar flagella. No pigment is produced. Oxidase reaction, nitrate reduction, denitrification, and starch hydrolysis are all negative. H_2S is produced. Optimal temperature for growth, 26–30°C. Growth is scanty at 37°C and negative at 42°C. Acid produced from glucose, galactose, lactose, sucrose, and glycerol, but not from maltose, trehalose, mannose, raffinose, starch, or inulin. 2-Ketogluconate is produced from gluconate.

Growth on glucose, gluconate, 2-ketogluconate, and *p*-hydroxybenzoate as sole carbon sources. 5-Ketogluconate, citrate, ethanol, phenol, succinate, benzoate, salicylate, *m*-hydroxybenzoate, protocatechuate, gentisate, anthranilate, and *p*-aminobenzoate are not utilized for growth. Some of the properties are summarized in Table BXII.β.2. The strains produce the antibiotic pyrrolnitrin. This compound is also produced by some strains of *Pseudomonas chlororaphis*, *P. aureofaciens*, and *Burkholderia cepacia* (*"Pseudomonas multivorans"*) (Elander et al., 1968), indicating that the synthesis occurs in organisms of different branches of the *Proteobacteria*.

The first suggestion of allocation of *B. pyrrocinia* to the RNA similarity group II was made by Byng et al. (1980). In their proposal for the transfer of *Pseudomonas pyrrocinia* to the genus *Burkholderia*, Vandamme et al. (1997b) add to the above description, the characteristic fatty acid composition. Allocation to the genus *Burkholderia* also has been recommended by Viallard et al. (1998) based on nucleic acid sequencing studies.

The mol% G + C of the DNA is: 65.

Type strain: ATCC 15958, DSM 10685, LMG 14191.

GenBank accession number (16S rRNA): U96930.

17. **Burkholderia thailandensis** Brett, Deshazer and Woods 1998, 318[VP]
thai.lan.den' sis. M.L. adj. *thailandensis* pertaining to Thailand, where the organism was originally isolated.

Rods, motile due to the presence of two to four polar flagella. Colonies are smooth and glossy with a pink pigmentation on modified Ashdown's selective medium (see Enrichment and Isolation Procedures), while *B. pseudomallei* colonies are rough and wrinkled, with a dark purple pigmentation. The API 20NE and API 50CH biochemical profiles are similar to those of *B. pseudomallei*. Exceptions are the capacity to use L-arabinose, 5-ketogluconate, and adonitol, and the inability to utilize erythritol and dulcitol. Strains of the species are avirulent for Syrian golden hamsters. Growth occurs at temperatures between 25°C and 42°C. Production of siderophore, lipase, lecithinase, and protease are positive. The strains are resistant to aminoglycosides but sensitive to tetracycline, ceftazidime, and trimethoprim. Type strain was isolated from a rice field soil sample in central Thailand.

The mol% G + C of the DNA is: unknown.

Type strain: E264, ATCC 700388.

GenBank accession number (16S rRNA): U91838.

A comparison of sequences of 16S rRNA genes indicates a close relationship of *B. thailandensis* to *B. pseudomallei*. No DNA–DNA hybridization experiments between strains of the two species have been reported. In view of the low resolving power of 16S rRNA sequence similarity at the species level and the limited number of phenotypic differences, it is hoped that future studies may provide evidence supporting the taxonomic position of this group of organisms as an independent species of *Burkholderia*.

18. **Burkholderia vandii** Urakami, Ito-Yoshida, Araki, Kijima, Suzuki and Komagata 1994, 242[VP]
van' di.i. M.L. gen. n. *vandii* of *Vanda*, a genus of orchids.

Description taken from Urakami et al. (1994). The cells are 0.5–1.0 × 1.5–3.0 µm and have rounded ends. They occur singly, rarely in pairs, and are motile by one or several polar flagella. Abundant growth occurs in nutrient broth and peptone water. The colonies are white to light yellow. No diffusible fluorescent pigment is produced.

The methyl red and the Voges–Proskauer reactions are negative. Indole and hydrogen sulfide are not produced. Starch is not hydrolyzed. Denitrification and hydrolysis of gelatin are positive. Acids are weakly produced from inositol and glycerol oxidatively, but not from L-arabinose, D-xylose, D-glucose, D-mannose, D-fructose, D-galactose, maltose, sucrose, lactose, trehalose, D-sorbitol, D-mannitol, or soluble starch. No fermentation of sugars occurs. Nitrate is not used as a nitrogen source. Results of nutritional studies at the expense of many organic compounds, as well as extensive physiological information, are given in the original paper (Urakami et al., 1994) and in Gillis et al. (1995). The single known strain was isolated from orchids of the genus *Vanda* as an antibiotic-producing bacterium active against the plant pathogenic organisms *Clavibacter michiganensis* and *Fusarium oxysporium.*

According to Coenye et al. (1999b), *B. vandii* is a junior synonym of *B. plantarii.*

The mol% G + C of the DNA is: 68.5 (HPLC).

Type strain: ATCC 51545, DSM 9510, JCM 7957, LMG 16020, VA-1316.

GenBank accession number (16S rRNA): U96932.

Studies by Coenye et al. (1999b) based on SDS-PAGE of whole cell proteins, DNA–DNA hybridization, and extensive

biochemical characterization indicate that *B. vandii* should be considered a junior synonym of *B. plantarii.*

19. **Burkholderia vietnamiensis** Gillis, Van, Bardin, Goor, Hebbar, Willems, Segers, Kersters, Heulin and Fernandez 1995, 287[VP]

vi.et' na.mi.en.sis. M.L. adj. *vietnamiensis* referring to Vietnam, where the rice strains were isolated.

Motile cells are 0.8–2 × 0.3–0.8 μm. No details on the number of flagella per cell are given. Colonies on nutrient agar are not pigmented and do not produce fluorescent pigment on King B medium, a property that is uniformly negative for species of *Burkholderia.* Growth occurs on nutrient agar between 20°C and 41°C. Strains are oxidase, catalase, β-galactosidase, and gelatinase positive. All strains fix N_2 and produce ornibactin siderophores, but not pyochelin or cepabactin. Nutritional properties and characteristics useful for differentiation from other *Burkholderia* species have been summarized in Tables BXII.β.2 and BXII.β.3.

Further details are to be found in Gillis et al. (1995). In one of the tables in that article, denitrification is recorded as positive, although the property is not specifically mentioned in the text, where *B. vietnamiensis* is described as capable of reducing nitrate to nitrite. Further reduction to gases (N_2O or N_2) and the ability to grow under anaerobic conditions in the presence of nitrate are not mentioned. It may be inferred that strains of this species, as those of *B. cepacia*, are unable to denitrify. Differences between *B. vietnamiensis* and *B. cepacia* are in the utilization of L-arabitol, adonitol, butylamine, tryptamine, citraconate, and 5-ketogluconate by *B. cepacia*, and the ability of *B. vietnamiensis* to grow on itaconate. Strains of the latter do not synthesize the siderophores cepabactin and pyochelin (Gillis et al., 1995). *B. vietnamiensis* is capable of N_2 fixation, a property recorded earlier for rhizosphere strains of *B. cepacia* (Bevivino et al., 1994). However, extracts from clinical strains also gave a single hybridization signal with a *nifA* probe from *Klebsiella pneumoniae*, although they did not fix nitrogen (Tabacchioni et al., 1995). Interestingly, the clinical strains produced pyochelin and its precursor, salicylic acid, a property absent from the rhizosphere strains (Bevivino et al., 1994). Therefore, it is very likely that the latter may have corresponded to the taxon to be described later as *B. vietnamiensis* (Gillis et al., 1995).

There is little doubt, however, that *B. cepacia* and *B. vietnamiensis* are closely related, as suggested by their relative position in the tree of Fig. BXII.β.2. Aside from many phenotypic characteristics, their similarity extends to the production of the siderophore ornibactin (Meyer et al., 1995), and to the structure of the putative O-specific polymer isolated from the LPS of *B. vietnamiensis*, which resembles the O-antigen of *B. cepacia* serogroup J (Gaur and Wilkinson, 1996). The strains of *B. vietnamiensis* have been isolated from rice field soils and from clinical specimens. They are not pathogenic for onions.

The mol% G + C of the DNA is: 67.9 (T_m).

Type strain: DSM 11319, LMG 10929, TVV75.

GenBank accession number (16S rRNA): U96928, U96929.

Genus II. **Cupriavidus** *Makkar and Casida 1987a, 325*[VP]

DAVID L. BALKWILL

Cup.ri.a.vi' dus. L. n. *cuprum* copper; L. adj. *avidus* eager for, loving; M.L. neut. n. *Cupriavidus* lover of copper.

Coccoid rods, 0.7–0.9 × 0.9–1.3 μm. Gram negative. **Motile by two to ten peritrichous flagella. Chemoheterotrophic.** An organic nitrogen source is not required. Glucose not utilized. **Strictly respiratory metabolism** with oxygen as the terminal electron acceptor. Oxidase positive. Catalase positive. Nitrate reduced. Gelatin, starch, and urea not hydrolyzed. Indole and H_2S not produced. **Can use any of several amino acids—but not L-lysine or L-methionine—as the sole source of carbon and nitrogen.** Optimal temperature, 27°C. Optimal pH, 7.0–8.0. NaCl at 3% inhibits growth. **Resistant to copper** at concentrations up to at least 800 μM. Growth initiation is stimulated by copper. Colonies on nutrient agar after 2 d at 27°C are off-white, glistening, mucoid, smooth, and convex, with an entire edge; 2–4 mm in diameter. Isolated from soil. **Nonobligate predator causing lysis of various Gram-positive and Gram-negative bacteria in soil.** Can lyse certain other nonobligate bacterial predators. Growth does not require presence of prey species.

The mol% G + C of the DNA is: 57 ± 1 (T_m).

Type species: **Cupriavidus necator** Makkar and Casida 1987a, 325.

FURTHER DESCRIPTIVE INFORMATION

C. necator cells are Gram-negative short rods measuring 0.7–0.9 × 0.9–1.3 μm, based on electron micrographs of negatively stained cells. The cells decrease somewhat in size and become more rounded as cultures age, or when the organism is placed in contact with soil during soil column studies (Byrd et al., 1985). In soil, the rounded forms of *C. necator* appear to be dormant (Byrd et al., 1985). *C. necator* reproduces by binary fission and is motile by 2–10 peritrichous flagella.

Colonies of *C. necator* on nutrient agar after 2 d of incubation at 27°C are 2–4 mm in diameter, off-white, glistening, mucoid, smooth, and convex, with an entire edge. Nonmucoid variants of *C. necator* that form slightly smaller colonies appear after many transfers on laboratory media. The colonies of these variants are flat and do not glisten. A phage that lyses the mucoid form of the organism does not lyse the nonmucoid form, but the two variants are similar in all other respects.

C. necator grows aerobically on nutrient agar or synthetic medium with L-glutamic acid, but only scant growth occurs on these media under anaerobic conditions. In thioglycolate broth, the organism grows only in the oxidized zone. Good growth occurs in acetate or fructose broth media with NH_4Cl as the sole source of nitrogen. Excellent growth is obtained in N-1 synthetic medium (Makkar and Casida, 1987a) broth with L-glutamic acid as the nitrogen and carbon source. The optimal growth temperature for *C. necator* is 27°C, but it can grow well at 37°C. Growth occurs after a delay at 15°C, but there is no growth at 55°C. *C.*

necator grows over a pH range of 5.5–9.2, and its optimal growth pH is 7.0–8.0. It grows well in media that contain 1% NaCl, but growth is poor at 2% NaCl and inhibited fully at 3% NaCl.

C. necator does not grow in a modified Burk's N-free medium (see Makkar and Casida, 1987a) with glucose or sucrose as the sole source of carbon. Limited growth takes place with fructose but is not sustained during repeated transfers in N-free medium. *C. necator* can grow in a synthetic medium (Makkar and Casida, 1987a) without added magnesium. It is quite resistant to copper and grows well in the presence of 1200 μM $CaCl_2 \cdot 2H_2O$ (Casida, 1987). Copper also stimulates growth initiation of *C. necator* but has no significant effect on its subsequent growth rate at concentrations up to at least 800 μM (Casida, 1987; Makkar and Casida, 1987a).

The metabolism of *C. necator* is oxidative, as determined by the Hugh-Leifson test (Hugh and Leifson, 1953) performed in a synthetic medium with fructose as the carbon source. It grows and produces acid without gas in the top portion of aerobic tubes, but does not grow or produce acid in anaerobic tubes (Makkar and Casida, 1987a). *C. necator* is catalase positive and oxidase positive. It does not show hemolysis on blood agar. Hippurate, tributyrin, Tween 20, and Tween 80 are hydrolyzed, but esculin, gelatin, starch, and urea are not hydrolyzed. DNase activity is negative. *C. necator* degrades tyrosine. It does not produce indole or H_2S. In litmus milk, the reaction is basic with reduction of the litmus. Acetate, L-aspartate, citrate, fructose, fumarate, gluconate, L-glutamate, glutarate, β-hydroxybutyrate, lactate, L-leucine, oxalacetate, and succinate are utilized as sources of carbon for growth. Use of sucrose as a carbon source is equivocal. Utilization of acetate, fructose, L-glutamate, and L-leucine occurs after a brief delay (13–15 h). Somewhat longer delays are seen with L-alanine, and L-valine (61 and 92 h, respectively; Makkar and Casida, 1987a). *C. necator* does not utilize arabinose, adonitol, benzoate, glucose, glycerol, lactose, L-lysine, mannitol, mannose, melibiose, L-methionine, rhamnose, or xylose as carbon sources for growth.

The mol% G + C content of *C. necator* chromosomal DNA is 57 ± 1, as determined by the thermal melting point technique (Makkar and Casida, 1987a). The 16S rRNA gene sequence for the type strain of *C. necator* (ATCC 43291) has been determined (Balkwill, unpublished data; GenBank accession no. AF191737). Phylogenetic analyses of this sequence with distance matrix (see Fig. BXII.β.3), parsimony, and maximum likelihood methods indicated that *C. necator* should be assigned to the *Burkholderiaceae*. Moreover, all of the analytical methods placed *C. necator* within a cluster of strains representing the genus *Ralstonia* (Yabuuchi et al., 1995). *C. necator* was most closely related to two strains (including the type strain) of *Ralstonia eutropha* that were included in the analysis. Its 16S sequence was virtually identical to those of the two *Ralstonia* strains, differing from them by only a single base over 1338 bases compared (sequence similarity 99.9%). Technically, this high sequence similarity alone does not demonstrate that *C. necator* and *R. eutropha* are the same species. Stackebrandt and Goebel (1994) have suggested that DNA–DNA reassociation values should be used to determine whether strains of bacteria are members of the same species when their 16S rDNA sequence similarities are greater than 97.5%. Nevertheless, the phylogenetic analyses do provide strong evidence that *C. necator* is a member of the genus *Ralstonia*.

The habitat for *Cupriavidus* is soil. *C. necator* is a nonobligate predator that can cause lysis of various types of Gram-positive and Gram-negative bacteria in soils, including several other nonobligate predator species. However, growth of *C. necator* in soil or laboratory media does not require the presence of prey species. *C. necator* produces the heat-labile, magnesium-related growth initiation factor (GIF) that was first described by Casida (1984) and that is produced by various types of bacteria in soils. This GIF can initiate the growth of *Agromyces ramosus* and other species in soil (Casida, 1984; Byrd et al., 1985), thereby increasing the supply of suitable prey cells for nonobligate bacterial predators like *C. necator*. The actual mechanism by which *C. necator* kills its prey cells is not yet known, although Casida (1987) has suggested that a copper-related peptide used to scavenge copper from the environment (see below) might also be used to deliver excess (and toxic) amounts of copper to prey cells.

Zeph and Casida (1986) used an indirect phage analysis method involving soil percolator columns and plaque assays (see Byrd et al., 1985) to assess the ability of *C. necator* and several other nonobligate bacterial predators to attack various types of potential prey species in soil. Of the 11 predators examined, *C. necator* strain N-1 (the type strain) and an uncharacterized predator strain (designated L-2) were capable of attacking the widest variety of prey species. Nonpredatory bacteria attacked by *C. necator* included *Arthrobacter globiformis*, *Azotobacter vinelandii*, *Bacillus subtilis*, *Bacillus thuringiensis*, *Escherichia coli*, *Micrococcus luteus*, and *Staphylococcus aureus*. Other nonobligate bacterial predators attacked by *C. necator* included *Agromyces ramosus*, *Ensifer adhaerens*, strain C2 (an uncharacterized predator), and a streptomycete-like isolate (strain 3). *C. necator* did not attack *Agrobacterium tumefaciens*, *Nocardia salmonicolor*, *Salmonella typhi* (all of which are nonpredatory), or four uncharacterized predatory strains, including L-2. *C. necator* itself was attacked by *A. ramosus* and one uncharacterized predatory strain, but was not attacked by *E. adhaerens* or seven other uncharacterized predators. Comparison of prey ranges for different predators indicated that Gram-negative predators like *C. necator* are likely to be more important than Gram-positive predators, all of which had comparatively narrow prey ranges. It is also possible that nonobligatory predators such as *C. necator* control the populations of Gram-positive predators (like *A. ramosus*), and thus might be at the top of the hierarchy of bacterial predators in soils.

When *C. necator* interacts with *Agromyces ramosus* in a soil, a predator-on-predator attack and counterattack phenomenon occurs (Byrd et al., 1985). *A. ramosus* is a Gram-positive species that occurs in high numbers in soils and functions as a nonobligatory predator that destroys cells of several other bacterial species. It typically occurs in soils as coccoid rods but can produce a mycelium that eventually fragments. Within 2 d after *A. ramosus* and *C. necator* are added to a soil, *A. ramosus* forms a mycelium wherever the *C. necator* cells are situated, and roughly one-third of the *C. necator* cells become ghosted. *C. necator* apparently produces the magnesium-related GIF cited above, which stimulates the growth of *A. ramosus* and subsequent development of its mycelium. While this occurs, however, *A. ramosus* attacks and lyses some of the *C. necator* cells. The mycelium appears to deliberately seek out the cells of *C. necator*, possibly to make contact with them. Lysis of the *A. ramosus* mycelium in contact with cells of *C. necator* is seen within 4–5 d after adding the two bacteria to a soil. Proliferation of *C. necator* wherever the *A. ramosus* mycelium grew is also seen by this time, indicating that *C. necator* has counterattacked *A. ramosus*. *C. necator* only attacks the mycelial form of *A. ramosus*, so portions of the mycelium that fragment to the rod form before *C. necator* can attack them survive the attack-

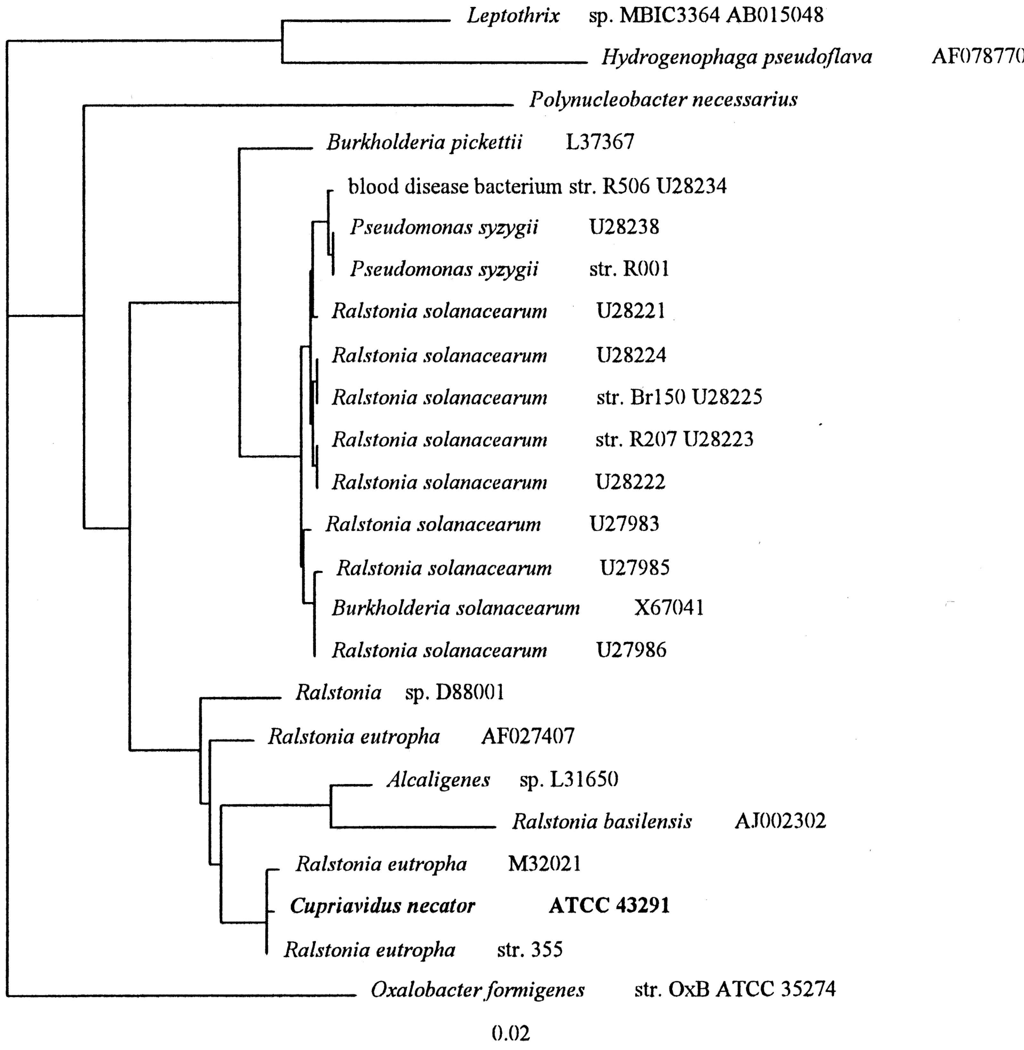

FIGURE BXII.β.3. Phylogenetic tree for *Cupriavidus necator* ATCC 43291 and selected strains of eubacteria, based on a distance matrix analysis. Bar = 2 substitutions per 100 bases. *Oxalobacter formigenes* was used as the outgroup. Parsimony and maximum likelihood analyses yielded virtually identical trees with respect to the positions of *C. necator* and *Ralstonia eutropha* and the branching patterns within the cluster containing strains of these two organisms. The numbers in parentheses are the GenBank/ EMBL accession numbers for the sequences used in the analysis. The accession number for the *C. necator* 16S rDNA sequence is AF191737.

counterattack interaction. This might explain why *A. ramosus* maintains high numbers in soils despite being a prey organism.

Casida (1989a) investigated the possibility that *Arthrobacter globiformis*, which is usually present in relatively high numbers in soils, might serve as a major reservoir of prey cells for *C. necator* and other copper-resistant Gram-negative bacterial predators. This study found that a large increase in the culturable numbers of an uncharacterized bacterium that hydrolyzes GELRITE occurs within 2.5 h. Because of the short time period involved, it was felt that exposure to *A. globiformis* caused the hydrolyzers to break dormancy (and thus become more readily culturable), rather than to multiply extensively. The numbers of *C. necator* and other Gram-negative predator cells increased in response to addition of *A. globiformis* cells as well. However, as the numbers of predator cells increased, the levels of hydrolyzers in the soil decreased extensively while the numbers of *A. globiformis* cells did not. It appeared, then, that the predators were responding directly to the hydrolyzers that were activated after *A. globiformis* was added to the soil, rather than to *A. globiformis* itself. If so, *A. globiformis* most likely does not serve as the major reservoir of prey cells for *C. necator* and other copper-resistant Gram-negative predators, but it may play a role in enabling them to access prey cells such as the hydrolyzers.

Casida (1989b) also investigated the possibility that protozoa might be major predators of *C. necator* and other bacterial predators in soil. Protozoa that can attack *C. necator* were detected in soil, but no evidence was found that would indicate these protozoa and *C. necator* actually interact with each other in soils.

As noted above, *C. necator* is resistant to copper, and copper stimulates initiation of its growth. Casida (1987) found that growth initiation is delayed 13–120 h when *C. necator* is transferred to a synthetic medium with various carbon sources, the actual time depending on which carbon source is supplied in the medium. During this delay period, *C. necator* produces a GIF that is different from the heat-labile magnesium-associated GIF that it uses to stimulate the growth of *A. ramosus* and other bac-

teria in soil (Byrd et al., 1985). The newly discovered GIF was shown to specifically stimulate growth initiation of *C. necator* and to be a copper-related, heat-stable peptide with a molecular weight greater than 10,000 and a relatively low cysteine content. It is thought that *C. necator* uses this heat-stabile peptide GIF to marshal copper from the surrounding environment, as elevated levels of copper are apparently needed to initiate growth. After growth has been initiated, however, copper has no significant effect on the growth rate and production of the copper-associated peptide GIF stops. Casida (1987) also found that the copper-associated GIF strongly inhibits the growth of *A. ramosus*, perhaps by delivering lethal levels of copper to its cells. If so, *C. necator* may use a twofold strategy when it interacts with *A. ramosus* in soil. First, it could produce the heat-labile magnesium-associated GIF to stimulate growth of *A. ramosus* and development of the mycelium. Then, it could use the heat-stable copper-associated GIF to kill the mycelial cells.

Enrichment and Isolation Procedures

C. necator can be enriched and isolated from soils with a baiting technique developed by Sillman and Casida (1986). This method appears to utilize chemotaxis, although that has not been confirmed. Air-dried soil is passed through a fine sieve and placed to a depth of 3–4 mm in a sterile Petri plate. This soil is tamped lightly to produce a uniformly flat surface, and about 2 ml of sterile distilled water is added along the walls of the plate. The soil should be moist but not flooded. A 0.65-μm pore size membrane filter is next placed on a circle (8.5 mm diameter) of sterile Whatman no. 2 filter paper in a separate sterile Petri plate. A concentrated washed suspension of early stationary-phase host cells (of *Micrococcus luteus*) is spread over a 28 mm diameter area at the center of the membrane filter, and excess moisture is absorbed by the underlying filter paper. The membrane filter is then placed on the surface of the soil with the side containing the host cells facing upward. After gently pressing the edges of the filter against the soil, the Petri plate is sealed with tape and incubated (right side up) at 27°C. Several filters are prepared in this way, so that one can check for the appearance of predators daily as incubation continues.

The following procedure is used to check for the appearance of predators during incubation. The host cells are removed from a filter by gentle scraping with an alcohol-flamed spatula and suspended in 5 ml of sterile tap water. This suspension is then mixed and diluted through a 1:2 dilution series. Aliquots (0.1 ml) of each dilution and the undiluted suspension are placed on the surfaces of agar plates, along with 0.1 ml of a fresh, concentrated host-cell suspension, and aseptically spread over the surfaces of the plates. Either 1.5% Noble agar (in distilled water) or a very dilute nutrient medium (such as 0.01 strength heart infusion broth) can be used in the plates for this part of the isolation procedure. The plates are then incubated for at least 3 d and checked for the development of plaques, colonies, or colonies within plaques. These are picked with a needle and spread through freshly prepared lawns of host cells on new plates of the same medium. After a sufficient period of incubation at 27°C, isolates growing on the plates are restreaked for purification on 0.01 strength heart infusion agar without added host cells. This approach establishes that the isolates are not obligatory predators.

C. necator typically appears on the initial isolation filters within 3 d of incubation at 27°C. Isolates can be tested for their ability to attach to host cells as follows. Microscope slides are positioned vertically along the inside walls of 250-ml wide-mouth Erlenmeyer flasks. The slides are then held in place by adding sterile glass beads to a depth of 4 cm. Sufficient sterile tap water is added to nearly submerge the glass beads, and host cells of *M. luteus* are added to produce a turbid suspension. One loopful of potential predator cells is also added, and the flasks are incubated on a rotary shaker at 27°C. After incubation, the slides are removed from the flask, stained with crystal violet, and examined for predator attachment to host. This should be done both at the splash line and on the part of the slide that was submerged.

The above procedure has been used to isolate a number of Gram-negative, nonobligate bacterial predators from soil, including several copper-resistant strains. If one in interested in isolating *C. necator* specifically, then it will be necessary to screen isolates for the key descriptive characteristics of this species.

Maintenance Procedures

C. necator can be maintained on 0.1-strength heart infusion agar. It can be lyophilized by common procedures used for aerobes. It can also be preserved by freezing in cryoprotectant and subsequent storage at −80°C or under liquid nitrogen.

Differentiation of the genus *Cupriavidus* from other genera

When the genus *Cupriavidus* was proposed by Makkar and Casida in 1987a, it was most similar to *Alcaligenes*. As a result it was compared directly to that genus, especially to *Alcaligenes faecalis*. Among the characteristics that both organisms had in common were cell morphology, the mol% G + C content of their DNA, and lack of the ability to utilize glucose as a sole carbon source. However, *C. necator* could be differentiated from *A. faecalis* on the basis of five traits: lack of a requirement for added magnesium in synthetic media, its predatory activity, ability to utilize fructose as a carbon source, copper resistance, and stimulation of growth initiation by elevated levels of copper. In all likelihood, the combination of copper resistance and predatory behavior also differentiates *Cupriavidus* from other Gram-negative aerobic rods.

Analyses of 16S rRNA gene sequences indicate that *C. necator* is a member of the *Burkholderiaceae* and is phylogenetically situated within the genus *Ralstonia* (Yabuuchi et al., 1995). Among comparable phenotypic traits published to date, *C. necator* differs from all currently recognized species of *Ralstonia* only in that it cannot utilize glycerol as a carbon source (see Makkar and Casida, 1987a; Yabuuchi et al., 1992, 1995; Urakami et al., 1994; Gillis et al., 1995; Coenye et al., 1999a; Vandamme et al., 1999). However, *C. necator* differs from the phylogenetically most closely related species of *Ralstonia* (*R. eutropha*) in two other ways: it does not utilize benzoate as a carbon source and it does not cause hemolysis on blood agar. *C. necator* also differs from all recognized *Ralstonia* species in that it has a considerably lower mol% G + C content (57 ± 1 versus 64–68.3).

Taxonomic Comments

Phylogenetic analysis data and the apparent paucity of phenotypic differences between *C. necator* and *Ralstonia* spp. raise serious doubts that *Cupriavidus* and *Ralstonia* are distinct genera. The predatory behavior of *Cupriavidus* might distinguish it from *Ralstonia*, but no *Ralstonia* species have been tested for this characteristic. The reported mol% G + C content for *C. necator* (57 ± 1) is outside the range of values reported for *Ralstonia* spp. (64–68.3), and all determinations were done by the same

method. A thorough direct comparison of *C. necator* with all recognized *Ralstonia* spp. might detect additional differences. Based on information available at this time, however, it appears that *C. necator* should be transferred to the genus *Ralstonia*.

Phylogenetic analyses indicated that *C. necator* and *Ralstonia eutropha* have virtually identical 16S rRNA gene sequences. At noted earlier, this very high sequence similarity does not prove that *C. necator* and *R. eutropha* are the same species; DNA–DNA reassociation values must be determined to resolve that question (see Stackebrandt and Goebel, 1994). This has not been done for *C. necator* and *R. eutropha*, but their differing mol% G + C contents (see above) imply that the reassociation values resulting from such an experiment might be quite low. Moreover, several phenotypic differences between these two strains have been reported in the literature (see above). Copper resistance and predatory behavior could be additional differences, but *R. eutropha* has not been examined for these traits. In addition, the copper resistance in *Cupriavidus* could be plasmid-coded (as metal resistance often is) and, if so, it should not be considered a characteristic that defines the species. At this point, there is insufficient information to know whether *C. necator* and *R. eutropha* are distinct species. DNA–DNA hybridization studies would be most helpful in clarifying the situation.

Acknowledgments

For the most part, this chapter is a minor revision of the original description of *Cupriavidus* published by Makkar and Casida (1987a). The principal changes include the addition of information from analysis of 16S rDNA sequences and the addition of data from several more recent publications. The author thanks L.E. Casida, Jr. for providing reprints and other information related to his research on *Cupriavidus necator*. The strain of *C. necator* for which the 16S rDNA sequence was determined was obtained from the American Type Culture Collection.

List of species of the genus Cupriavidus

1. **Cupriavidus necator** Makkar and Casida 1987a, 325^{VP}
ne.ca' tor. L. n. *necator* slayer.

The characteristics are as described for the genus. During growth under laboratory conditions, *C. necator* may produce small numbers of a nonmucoid variant. The variant resembles the mucoid form except that its colonies are smaller and display a drier, flatter appearance. However, a bacteriophage isolated from soil that lyses the mucoid form does not lyse the nonmucoid variant.

The habitat is soil.

The mol% G + C of the DNA is: 57 ± 1 (T_m).

Type strain: ATCC 43291.

GenBank accession number (16S rRNA): AF191737.

Genus III. **Lautropia** *Gerner-Smidt, Keiser-Nielsen, Dorsch, Stackebrandt, Ursing, Blom, Christensen, Christensen, Frederiksen, Hoffmann, Holten-Andersen and Ying 1995, 418^{VP} (Effective publication: Gerner-Smidt, Keiser-Nielsen, Dorsch, Stackebrandt, Ursing, Blom, Christensen, Christensen, Frederiksen, Hoffmann, Holten-Andersen and Ying 1994, 1795)*

Peter Gerner-Smidt

Lau.tro' pi.a. M.L. fem. n. *Lautropia* of Lautrop, named after Hans Lautrop.

Cocci may occur in at least **three forms: (1) encapsulated**, nonmotile 1–2 µm in diameter, forming aggregates of 10 to >100 cells; **(2) unencapsulated**, nonaggregated 1–2 µm in diameter, **motile** by a tuft of three to nine flagella; and **(3)** large (>5 µm in diameter), **spherical nonaggregated, nonmotile**. Do not form endospores. **Gram negative.** Nonpigmented. **Grow only on enriched media. Facultative**, but grow best under aerobic conditions. CO_2 is not required. Growth occurs between 30 and 44°C. **Oxidase, catalase, and urease positive.** A polysaccharide is produced on sucrose agar. Various carbohydrates are fermented. Belongs phylogenetically to a separate branch of the class *Betaproteobacteria*. Habitat: the oral cavity and upper respiratory tract of humans.

The mol% G + C of the DNA is: 65.

Type species: **Lautropia mirabilis** Gerner-Smidt, Keiser-Nielsen, Dorsch, Stackebrandt, Ursing, Blom, Christensen, Christensen, Frederiksen, Hoffmann, Holten-Andersen and Ying 1995, 418^{VP} (Effective publication: Gerner-Smidt, Keiser-Nielsen, Dorsch, Stackebrandt, Ursing, Blom, Christensen, Christensen, Frederiksen, Hoffmann, Holten-Andersen and Ying 1994, 1795.)

Further descriptive information

Rough to smooth colonies grow on many plating media and are composed of extremely pleomorphic cocci with round cells with diameters from 1 to >10 µm. The smallest cells are often motile with circular movements. Glucose, fructose, sucrose, and mannitol are fermented.

An aggregate-forming coccus identified as *L. mirabilis* was the predominant microorganism in sputa from a cystic fibrosis patient on consecutive days (Ben Dekhil et al., 1997c). *L. mirabilis* has also been isolated from the oral cavities of 32 of 60 children infected with human immunodeficiency virus (HIV) and 3 of 25 HIV-uninfected controls (Rossmann et al., 1998); however, the bacterium was not associated with clinical disease in these children.

Enrichment and Isolation Procedures

The organism may be isolated on most nonselective enriched media after aerobic incubation for 1–2 d at 35°C. Microscopy of wet mounts of different colony types is essential to identify the organism in mixed cultures. No selective enrichment procedures have been described for this organism.

Maintenance Procedures

Lautropia cells can either be stored in 10% glycerol broth at −80°C or lyophilized.

Differentiation of the genus *Lautropia* from other genera

Organisms of the genus *Lautropia* are differentiated from other organisms by their requirement for enriched media, their characteristic colony morphology, their microscopic appearance, and their positive oxidase, urease, and nitrate reduction reactions.

Taxonomic Comments

In 1994, Gerner-Smidt et al. (1994), isolated six strains of an organism that seemed to be identical to an organism that had been described by Ørskov (1930). 16S rRNA sequencing revealed that the organisms belonged to class *Betaproteobacteria* of the phylum *Proteobacteria*, separate from all other described genera, but most closely related to *Burkholderia* (Gerner-Smidt et al., 1994). The organisms were assigned to a new genus, *Lautropia*, as the species *L. mirabilis*.

List of species of the genus Lautropia

1. **Lautropia mirabilis** Gerner-Smidt, Keiser-Nielsen, Dorsch, Stackebrandt, Ursing, Blom, Christensen, Christensen, Frederiksen, Hoffmann, Holten-Andersen and Ying 1995, 418^{VP} (Effective publication: Gerner-Smidt, Keiser-Nielsen, Dorsch, Stackebrandt, Ursing, Blom, Christensen, Christensen, Frederiksen, Hoffmann, Holten-Andersen and Ying, 1994, 1795.)
mi.ra' bi.lis. L. n. *mirabilis* wonderful.

The characteristics are as described for the genus and as follows. Grows on most enriched media, especially on chocolate, Levinthal, tryptose glucose yeast (TGY) extract, and Tween 80 agar. At least three colony morphologies are seen: (1) flat, dry, and circular; (2) larger, wrinkled, crisp, and crateriform; and (3) smooth, glistering, raised, round, and mucoid. Colonies adhere to the substrate; diameter of the colonies between pinpoint size and >5 mm. Growth in broth granular with a coarse sediment and granules adherent to the side of the tube. Acid is produced from D-glucose, D-fructose, maltose, sucrose, and mannitol; acid is not produced from lactose, trehalose, raffinose, inulin, salicin, adonitol, dulcitol, sorbitol, inositol, D-xylose, L-rhamnose, and L-arabinose. Negative for lysine decarboxylase, ornithine decarboxylase, arginine decarboxylase/dihydrolase, phenylalanine deaminase, Voges–Proskauer test, gelatinase, starch hydrolysis, and H_2S. Hippurate and Tween 80 not hydrolyzed. Most strains hydrolyze esculin. Some strains produce β-xylosidase. β-Galactosidase and β-glucuronidase are not produced.

Rossmann et al. (1998) found variable reactions for arginine dihydrolase, lysine decarboxylase, Voges–Proskauer test, gelatinase at 35°C, and sorbitol fermentation using a commercial identification system (API20E).

Unlike the strains isolated by Gerner-Smidt et al. (1994), the strain isolated by Ben Dekhil et al. (1997c) was hemolytic on blood agar. Rossmann et al. (1998) reported that, with their strains, the catalase test was weakly positive with 10% hydrogen peroxide, and catalase was undetectable with 3% H_2O_2.

Sensitive to penicillin G, ampicillin, piperacillin, cefuroxime, gentamicin, and erythromycin.

The mol% G + C of the DNA is: 64.6–65.4 (T_m).

Type strain: AB2188, ATCC 51599, CCUG 34794, NCTC 12852.

GenBank accession number (16S rRNA): X73223.

Additional Remarks: The type strain was isolated from human dental plaque.

Genus IV. **Pandoraea** *Coenye, Falsen, Hoste, Ohlen, Goris, Govan, Gillis and Vandamme 2000, 895^{VP}*

The Editorial Board

Pan.do.rae' a. N.L. fem. n. *Pandoraea* referring to Pandora's box in Greek mythology, the origin of diseases of mankind.

Gram-negative, **motile**, **nonsporeforming rods** (0.5–0.7 × 1.5–4.0 μm). **One polar flagellum.** Positive reactions: catalase, alkaline phosphatase, leucine arylamidase; assimilation of D-gluconate, L-malate, and phenylacetate; **growth on Drigalsky agar** and in 0.5 and 1.5% NaCl. Major fatty acids include $C_{12:0}$, $C_{12:0\ 2OH}$, $C_{16:0}$, $C_{16:0\ 2OH}$, $C_{16:0\ 3OH}$, $C_{17:0\ cyclo}$, $C_{18:1\ 2OH}$, and $C_{19:0\ cyclo\ \omega8c}$.

The mol% G + C of the DNA is: 61.2–64.3.

Type species: **Pandoraea apista** Coenye, Falsen, Hoste, Ohlen, Goris, Govan, Gillis and Vandamme 2000, 896.

Further descriptive information

Negative reactions include nitrite reduction and denitrification; liquefaction of gelatin; hydrolysis of esculin, poly-β-hydroxybutyrate, and Tween 80; production of acid or sulfide in TSI agar; production of indole; production of *N*-acetyl-β-glucosaminidase, C_{14}-lipase, chymotrypsin, DNase, α-fucosidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucuronidase, lysine decarboxylase, α-mannosidase, ornithine decarboxylase, trypsin, tryptophanase, and valine arylamidase; growth in 10% lactose and 6% NaCl; and growth in O/F medium containing adonitol, fructose, or xylose.

All strains grow on *Burkholderia cepacia* selective medium. Most strains of *Pandoraea* spp. have been isolated from clinical samples, primarily from respiratory tracts of patients suffering from cystic fibrosis but also from blood and from nonclinical sources such as water, sludge, soil, and dried milk (Coenye et al., 2000; Moore et al., 2001).

Coenye et al. (2000) and Daneshvar et al. (2001) provide tables of phenotypic traits that distinguish the five species and four described genomospecies of the genus *Pandoraea*. Coenye et al. (2001b) have described PCR primers that can be used to distinguish among the species of the genus *Pandoraea*. Coenye and LiPuma (2002) have described a PCR-RFLP scheme based on the *gyrB* locus that distinguishes four of the five *Pandoraea* species from each other and from members of three of the four genomospecies described by Daneshvar et al. (2001).

Differentiation of the genus *Pandoraea* from other genera

Because of their phenotypic similarity to *Burkholderia cepacia* and the importance of accurate identification for the treatment of cystic fibrosis patients, considerable effort has been devoted to the development of methods to distinguish *Pandoraea* spp. from *B. cepacia* and other organisms found in the respiratory tracts of

cystic fibrosis patients. Phenotypic tests that distinguish *Pandoraea* species from *B. cepacia* genomovars I, III, and IV; *B. multivorans*; *B. vietnamiensis*; *Ralstonia paucula*; and *R. pickettii* are given by Coenye et al. (2000). Phenotypic tests that distinguish *Pandoraea* species from *B. cepacia* genomovars I–VII, *B. gladioli*, and *R. pickettii* are given by Henry et al. (2001). Coenye et al. (2001b) have described PCR primers that can be used to separate isolates belonging to the genus *Pandoraea* from selected members of the genera *Alcaligenes*, *Burkholderia*, *Pseudomonas*, *Ralstonia*, and *Stenotrophomonas* as well as distinguishing among the species of the genus *Pandoraea*.

List of species of the genus Pandoraea

1. **Pandoraea apista** Coenye, Falsen, Hoste, Ohlen, Goris, Govan, Gillis and Vandamme 2000, 896^{VP}
a.pis′ta. Gr. adj. *apistos* disloyal, unfaithful, treacherous.

As described for the genus with the following additional characteristics. Does not reduce nitrate. Grows on cetrimide agar; grows at 42°C; does not grow in O/F medium with glucose. Does not grow on acetamide. Assimilates caprate, citrate, and DL-lactate; does not assimilate maltose or sucrose. Produces amylase, arginine dihydrolase, C8-ester lipase, phosphoamidase, and urease.

The mol% G + C of the DNA is: 61.8 (HPLC).

Type strain: ATCC BAA-61, CCUG 38412, CIP 106627, LMG 16407.

GenBank accession number (16S rRNA): AF139173.

2. **Pandoraea norimbergensis** (Wittke, Ludwig, Peiffer and Kleiner 1998) Coenye, Falsen, Hoste, Ohlen, Goris, Govan, Gillis and Vandamme 2000, 896^{VP} (*Burkholderia norimbergensis* Wittke, Ludwig, Peiffer and Kleiner 1998, 631)
no.rim.ber.gen′sis. M.L. *Norimberga* Nurnberg (Bavaria, Germany); M.L. fem. adj. coming from Nurnberg, referring to its place of isolation.

As described for the genus with the following additional characteristics. No reduction of nitrate. Grows on cetrimide agar. Does not grow on acetamide; does not grow at 42°C. Assimilates citrate; does not assimilate adipate, maltose, or sucrose. Produces oxidase and phosphoamidase. Does not produce cysteine arylamidase; some strains produce urease.

The mol% G + C of the DNA is: 63.2 (HPLC).

Type strain: ATCC BAA-65, CCUG 39188, CIP 105463, LGM 18379.

GenBank accession number (16S rRNA): Y09879.

3. **Pandoraea pnomenusa** Coenye, Falsen, Hoste, Ohlen, Goris, Govan, Gillis and Vandamme 2000, 896^{VP}
pno.me.nu′sa. Gr. n. *pnoe* breath, breathing; Gr. v. *meno* to reside, stay, live; (fem. part. pres. *menusa* N.L. part. adj. *pnomenusa* referring to the lung as the niche of these bacteria.

As for the genus with the following additional characteristics. Most strains reduce nitrate. Grows at 42°C; does not grow in O/F medium with glucose. Assimilates caprate, citrate, and DL-lactate; does not assimilate adipate, D-glucose, maltose, or sucrose. Produces C_8-ester lipase and urease; most strains produce C_4-ester lipase and phosphoamidase.

The mol% G + C of the DNA is: 64.3 (HPLC).

Type strain: ATCC BAA-63, CIP 106626, CCUG 38742, LMG 18087.

GenBank accession number (16S rRNA): AF139174.

4. **Pandoraea pulmonicola** Coenye, Falsen, Hoste, Ohlen, Goris, Govan, Gillis and Vandamme 2000, 896^{VP}
pul.mo.ni′co.la. L. n. *pulmo* lung; L. suff. *cola* dwelling, occurring in; N.L. n. *pulmonicola* occurring in lungs.

As for the genus with the following additional characteristics. No reduction of nitrate. Grows at 42°C; grows on cetrimide agar and in O/F medium with glucose. Does not grow on acetamide. Assimilates caprate, citrate, D-glucose, and DL-lactate; does not assimilate adipate, maltose, or sucrose. Produces oxidase and phosphoamidase; does not produce amylase, arginine dihydrolase, cysteine arylamidase, C_4-esterase, C_8-ester lipase, or urease.

The mol% G + C of the DNA is: 61.8 (HPLC).

Type strain: ATCC BAA-62, CIP 106625, CCUG 38759, LMG 18106.

GenBank accession number (16S rRNA): AF139175.

5. **Pandoraea sputorum** Coenye, Falsen, Hoste, Ohlen, Goris, Govan, Gillis and Vandamme 2000, 896^{VP}
spu.to′rum. L. n. *sputum* spit, sputum; L. gen. pl. n. *sputorum* of sputa.

As for the genus with the following additional characteristics. Does not grow on acetamide or in O/F medium with glucose. Does not assimilate sucrose. Produces C_8-ester lipase and phosphoamidase.

The mol% G + C of the DNA is: 61.9.

Type strain: CCUG 39682, LMG 18819.

GenBank accession number (16S rRNA): AF139176.

Other Organisms

Note: this description, like those of the other organisms in this section, is based on a single strain. 16S rDNA sequence analyses place all of these organisms in the genus *Pandoraea*; other data show that they are distinct from the five described species (Coenye et al., 2000; Daneshvar et al., 2001).

1. *Pandoraea* sp. (genomospecies 1). Described by Coenye et al. (2000); originally isolated by Parsons et al. (1988). This organism was studied because of its ability to degrade chlorinated aromatic compounds. Reduces nitrate. Does not grow at 42°C, in O/F medium with glucose, or on acetamide or cetrimide agar. Assimilates DL-lactate; does not assimilate adipate, caprate, or mannose. Produces C_4-ester lipase, C_8-ester lipase, oxidase, phosphoamidase, and urease.

The mol% G + C of the DNA is: unknown.

Deposited strain: JB1, R-5199, CCUG 39680.

GenBank accession number (16S rRNA): X92188.

2. *Pandoraea* genomospecies 2. Described by Daneshvar et al. (2001). Does not reduce nitrate. Grows at 42°C. Does not grow on cetrimide agar. Produces oxidase; produces urease after 7 d on Christensen's agar.

The mol% G + C of the DNA is: 65.2 (T_m).

Deposited strain: CDC G5084, ATCC BAA-108.
GenBank accession number (16S rRNA): AF247693.

3. *Pandoraea* genomospecies 3. Described by Daneshvar et al. (2001). Does not reduce nitrate. Grows at 42°C. Does not grow on cetrimide agar. Produces urease after 7 d on Christensen's agar; does not produce oxidase.
The mol% G + C of the DNA is: 67.1 (T_m).
Deposited strain: CDC G9805, ATCC BAA-109.
GenBank accession number (16S rRNA): AF247697.

4. *Pandoraea* genomospecies 4. Described by Daneshvar et al. (2001). Does not reduce nitrate. Grows at 42°C. Does not grow on cetrimide agar. Produces urease after 7 d on Christensen's agar; produces oxidase.
The mol% G + C of the DNA is: 68.6 (T_m).
Deposited strain: CDC H652, ATCC BAA-110.
GenBank accession number (16S rRNA): AF247698.

Genus V. **Paucimonas** *Jendrossek 2001, 906*[VP]

THE EDITORIAL BOARD

Pau.ci.mo' nas. L. adj. *paucus* little, few; Gr. fem. n. *monas* unit, cell; M.L. n. *Paucimonas* bacterium with restricted (few) metabolic capacities.

Gram-negative, strictly respiratory chemoorganotroph. Catalase positive; oxidase positive. **Preferred substrates are organic acids**; does not utilize alcohols or polyalcohols, amino acids or polypeptides, sugars or polysaccharides. **Accumulates poly-β-hydroxybutyrate.**

The mol% G + C of the DNA is: 59 ± 2.

Type species: **Paucimonas lemoignei** (Delafield, Doudoroff, Palleroni, Lusty and Contopoulos 1965) Jendrossek 2001, 906 (*Pseudomonas lemoignei* Delafield, Doudoroff, Palleroni, Lusty and Contopoulos 1965, 1460.)

FURTHER DESCRIPTIVE INFORMATION

Analysis of 16S rDNA sequences placed *Paucimonas lemoignei* in the *Betaproteobacteria* with *Herbaspirillum* spp. as its closest relatives (Jendrossek, 2001).

ENRICHMENT AND ISOLATION PROCEDURES

Organisms were isolated from soil. Soil samples were emended with poly-(3-hydroxyvalerate) and incubated; the soil was then diluted into a liquid enrichment medium containing poly-(3-hydroxyvalerate). Procedures and liquid and solid media are described by Mergaert et al. (1996).

List of species of the genus Paucimonas

1. **Paucimonas lemoignei** (Delafield, Doudoroff, Palleroni, Lusty and Contopoulos 1965) Jendrossek 2001, 906[VP] (*Pseudomonas lemoignei* Delafield, Doudoroff, Palleroni, Lusty and Contopoulos 1965, 1460.)
le.moig' ne.i. M.L. gen. n. *lemoignei* of Lemoigne; named after M.H. Lemoigne, a French bacteriologist.

Gram-negative motile rods (0.6–0.8 × 1.5–3.0 µm). Nonsporeforming; do not produce fluorescent pigments. Polyhydroxyalkanoate depolymerases produced. Grow on acetate, butyrate, 3-hydroxybutyrate, 3-hydroxyvalerate, pyruvate, valerate, and succinate. Major fatty acids are $C_{12:0}$, $C_{16:0}$, $C_{16:1\ \omega7c}$, $C_{10:0\ 3OH}$, $C_{12:0\ 3OH}$, $C_{14:0\ 2OH}$.
The mol% G + C of the DNA is: 59 ± 2 (T_m).
Type strain: ATCC 17989, CCUG 2114, CIP 103794, DSM 7445, LMG 2207.
GenBank accession number (16S rRNA): X92555.

Genus VI. **Polynucleobacter** *Heckmann and Schmidt 1987, 456*[VP]

HANS-DIETER GÖRTZ AND HELMUT J. SCHMIDT

Pol.y.nuc' le.o.bac.ter. Gr. adj. *polys* numerous; L. masc. n. *nucleus* nut, kernel; masc. *bacter* the equivalent of Gr. neut. n. *bactrum* a rod; *polynucleobacter* the bacterium with many nucleoids.

Bacterial endosymbiont formerly called omikron. Multiple nucleoids. Inhabits the cytoplasm of the following closely related *Euplotes* spp. (Ciliophora, Protozoa): *E. aediculatus*, *E. eurystomus*, *E. patella*, *E. plumipes*, *E. woodruffi*, *E. daidaleos*, and *E. octocarinatus*. Essential for their host species. Nonmotile.

The mol% G + C of the DNA is: 47.7 or 44.9.

Type species: **Polynucleobacter necessarius** Heckmann and Schmidt 1987, 456.

FURTHER DESCRIPTIVE INFORMATION

Only one species, *P. necessarius*, has been described. It has a number of features in common with other endosymbionts found in related *Euplotes* species (Heckmann et al., 1983). Approximately 900–1000 cells of *P. necessarius* inhabit the cytoplasm of *E. aediculatus* (Heckmann, 1975). If *P. necessarius* is stained with DNA-specific dyes, several intensely stained and regularly spaced dots become visible (Fig. BXII.β.4). They are considered to be nu-

FIGURE BXII.β.4. *Polynucleobacter necessarius* (omikron), endosymbiont of *Euplotes aediculatus.* Longitudinal section showing nucleoids. Bar = 0.5 μm. (Reproduced with permission from K. Heckmann, Journal of Protozoology *22:* 97–104, 1975, ©Society of Protozoologists.)

cleoids, and differ from those of most free-living bacteria by having an electron-dense central core. The symbionts reproduce by transverse binary fission. The fission products are often found to differ from each other in size. It is possible to isolate *P. necessarius* from *E. aediculatus* homogenates and to obtain pure preparations of the symbionts in quantities large enough for an extraction and characterization of their DNA (Schmidt, 1982). The data are given below under the formal description of the species.

It is possible to remove the symbionts from *E. aediculatus* by treating a rapidly growing culture with penicillin (Heckmann, 1975). Aposymbiotic hosts eventually die. Heckmann concluded that *P. necessarius* is essential for the life of its host. Fauré-Fremiet (1952) made the same observation for *E. patella* and *E. eurystomus* and reached the same conclusions.

Taxonomic Comments

Only the best-studied endosymbiont of *Euplotes*, *P. necessarius*, has been assigned a binomial name. This endosymbiont, previously known as omikron, lives obligately in *Euplotes aediculatus* and was named *Polynucleobacter necessarius* by Heckmann and Schmidt (1987). Similar, still unnamed endosymbionts inhabit related species of *Euplotes*, and are called omikron-like endosymbionts.

P. necessarius belongs to the *Betaproteobacteria* and is rather closely related to *Ralstonia eutrophus*, *R. solanacearum*, and *R. pickettii* (Fig. BXII.β.5). *In situ* hybridization with a specific oligonucleotide probe corroborated the assignment of the retrieved species to *P. necessarius* (Springer et al., 1996).

Omikron-like symbionts occur in several closely related species of freshwater *Euplotes* (*E. aediculatus*, *E. eurystomus*, *E. patella*, *E. plumipes*, *E. woodruffi*, *E. daidaleos*, and *E. octocarinatus*), but not in other unrelated freshwater species. In many stocks of these species, penicillin treatment has been found to remove the symbionts, which affected their hosts as described above, eventually resulting in their death (Heckmann et al., 1983; Heckmann, 1983). In this connection, it is of interest that Foissner (1977) described a species (*E. moebiusi f. quadricirratus* Kahl, 1930) in which he found omikron-like symbionts. This species is not closely related to the above *Euplotes* species. Foissner has not tested, however, whether or not the ciliate depends upon the symbionts. Fujishima and Heckmann (1984) tried to transfer symbionts between *Euplotes* species. They produced aposymbiotic cells by treating them with penicillin, and observed restoration of growth and the ability to divide when symbionts of *E. woodruffi*, of a stock collected in Japan, were introduced into a stock of *E. aediculatus*, which had been collected in France. The reverse combination, however, with *E. woodruffi* as the recipient and *E. aecliculatus* as the donor, did not work.

List of species of the genus Polynucleobacter

1. **Polynucleobacter necessarius** Heckmann and Schmidt 1987, 456[VP]

nec.es.sar' i.us. L. adj. *necessarius* indispensable, necessary.

Description as given for the genus. Three to twelve nucleoids. Cells are 0.3 × 2.5–7.5 μm. Divides by binary fission. DNA molecular weight 3.5×10^9 daltons (analytic complexity) or 0.57×10^9 daltons (kinetic complexity).

The mol% G + C of the DNA is: 47.7 (T_m) and 44.9 (Bd).

Type strain: ATCC 30859.

GenBank accession number (16S rRNA): X93019.

Additional Remarks: The type strain is isolated from stock 15 of *E. aediculatus* (ATCC 30859).

Other Organisms

Other bacterial endosymbionts found in *Euplotes* have not been given binomial names, nor have they been validly described. Several endosymbionts of *Euplotes* produce the killer phenotype, and strains of killers with associated bacteria in the cytoplasm have been described for *E. minuta* and *E. crassus.* They were named epsilon and eta, respectively, by Heckmann et al. (1967) and Rosati et al. (1976).

Certain stocks of *E. patella*, collected in Japan, were reported to be mate killers by Katashima (1965). Mate killers kill sensitive ciliates in the act of conjugation, when toxins produced by en-

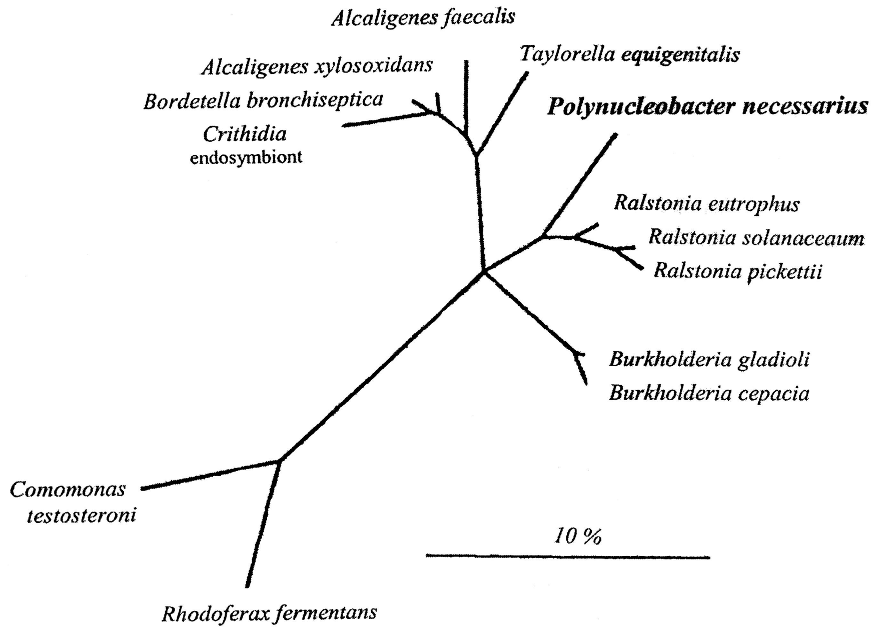

FIGURE BXII.β.5. Phylogenetic tree reflecting the relationship of *Polynucleobacter necessarius* and selected members of the *Betaproteobacteria*. The tree is based on a maximum likelihood analysis of a data set comprising a selection of 75 16S rRNA gene sequences containing no more than 140 ambiguities (for details see Springer et al., 1996) (Reproduced with permission from N. Springer et al., FEMS Microbiology Letters *135:* 333–336, 1996 ©Elsevier B.)

dosymbionts of mate killers are thought to be transferred to the sensitive mating partner not bearing endosymbionts. Mate killing was also observed for *E. minuta* by Heckmann et al. (1967) and for *E. crassus* by Rosati and Verni (1977). All these mate killers contained unnamed endosymbionts in their cytoplasm. *E. crassus* sometimes contains other endosymbionts with no known effects on their hosts. Rosati et al. (1976) observed them mostly in the cytoplasm. However, Rosati and Verni (1975) did find one endosymbiont in the macronucleus.

Genus VII. **Ralstonia** *Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1996, 625^VP^ (Effective publication: Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1995, 902)*

Eiko Yabuuchi, Yoshiaki Kawamura and Takayuki Ezaki

Ral.sto'n.ia. M.L. dim. *-ia* ending; M.L. fem. n. *Ralstonia* named after E. Ralston, the American bacteriologist who first described *Pseudomonas pickettii.*

Gram-negative asporogenous rods. Motile or nonmotile; motile species have either a single polar flagellum or peritrichous flagella. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Able to grow on ordinary peptone media. One species, *R. eutropha*, is a facultatively chemolithoautotrophic organism (a knallgas bacterium) and can oxidize H_2 as an electron donor. Furthermore, under anaerobic conditions, *R. eutropha* is able to utilize nitrate as the terminal electron acceptor. Colony color is beige in most species. Strains of *R. eutropha* are regarded as having outstanding biotechnological potential. **Oxidase and catalase positive.** Lysine and ornithine decarboxylase negative. Ubiquinone Q-8 is the major respiratory quinone. **None of the 26 carbohydrates tested are oxidized by the type strains of *R. campinensis* and *R. taiwanensis*.** Among 95 other organic compounds, 10—mainly salts of organic acids—were assimilated and 39 other compounds were not assimilated by all of the 11 type strains. **Cellular lipids of this genus contain two kinds of phosphatidylethanolamine, PE-1 and PE-2. The latter possesses 2-hydroxy fatty acid at *sn*-2 position of the glycerol moiety.** Major components of cellular fatty acids are $C_{16:0}$, a mixture of $C_{18:1\ \omega9t}$ and $C_{18:1\ \omega7c}$, and $C_{14:0\ 3OH}$. At present the genus is composed of 11 validated species. The sequence similarity of 11 type strains to that of *Ralstonia pickettii*—the type species—ranges from 95.0% to 98.1%. The genus contains **plant pathogens, human pathogens, knallgas bacteria, and metal-resistant bacteria**.

The mol% G + C of the DNA is: 64.0–68.0.

Type species: **Ralstonia pickettii** (Ralston, Palleroni and Doudoroff 1973) Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1996, 625 (Effective publication: Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1995, 903) (*Burkholderia pickettii* Yabuuchi, Kosako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398; *Pseudomonas pickettii* Ralston, Palleroni and Doudoroff 1973, 18.)

Further descriptive information

Morphology The cell dimensions are 0.5–0.8 × 1.2–3.0 μm, except for *R. oxalatica*, whose cells are as small as 0.3–0.4 × 0.9–1.5 μm.

Poly-β-hydroxybutyrate (PHB) granules have been reported in both Gram-negative and Gram-positive bacteria as intracellular reserve material (Doudoroff and Stanier, 1959). Morphological detection of PHB granules by optical or fluorescent microscopy has been reported (Stanier et al., 1966; Ostle and Holt, 1982). Rapid detection of polyhydroxyalkanoate-accumulating bacteria isolated from the environment by colony PCR has been reported by Sheu et al. (2000). *R. eutropha* synthesizes short chain length (SCL; 3–5 carbon atoms) poly-β-hydroxyalkanoates (PHAs), and the resulting polymers are accumulated as intracellular granules. The synthesis of the PHAs is catalyzed by PHA synthase (Song et al., 2000c; Zhang et al., 2000c). PHAs are now of commercial value as thermoplastics (Holmes, 1985). Accumulated PHB is degraded and used for growth and survival when an exogenous carbon source is not available (Handrick et al., 2000). Compared with PHB homopolymers, the PHA copolymer (poly-β-hydroxybutyrate-co-β-hydroxyvalerate) [P(HB)-co-HV)] has more useful thermomechanical properties. *R. eutropha* accumulates larger amount of [P(HB)-co-HV] copolymer when provided with glucose and pentanoic acid rather than propionic acid under nitrogen-limited conditions (Ramsay et al., 1990).

Cloning of the gene encoding PHB polymerase and its expression by recombinant *E. coli* has been reported (Schubert et al., 1988). The PHB production by the recombinant *E. coli* was analyzed metabolically and kinetically (van Wegen et al., 2001). An intracellular PHB depolymerase gene from *R. eutropha* H16 was cloned and gene product was characterized (Saegusa et al., 2001).

Colonial morphology and pigmentation Colonies on tryptic soy agar are less than 1 mm in diameter after 48 h incubation at 28–30°C. When the colonies are fully-grown, their diameter is >1 mm. In six species, the colonies are beige-colored, domed, smooth, and glistening with entire margin. The colonies of two species (*R. campinensis* and *R. metallidurans*) sometimes have scalloped margins (Goris et al., 2001). *R. solanacearum* EY 2181 produces a water-soluble slightly brown pigment, but the color appears different from that of alcaptone.

Cells of *R. solanacearum* strain 1609 convert to a viable-but-nonculturable (VBNC) form in water microcosms kept at 4°C, but not in those at 20°C (van Elsas et al., 2001). The viability of a fraction of these VBNC forms was evidenced by the direct viable count staining with the redox dye 5-cyano-2,3-ditolyl tetrazolium chloride (van Elsas et al., 2001). Recently, it was reported that cells of *R. solanacearum* enter into a VBNC state under certain conditions, as in response to cupric sulfate when in a saline solution, and when placed in autoclaved soil (Grey and Steck, 2001). It was also verified that *R. solanacearum* cells in the VBNC state were able to infect and multiply in the tissue. Thus the VBNC form of plant pathogens might explain the persistence of infection in nature. The occurrence of VBNC cells of *R. solanacearum* in natural water poses new problems for the detection (van Elsas et al., 2001) and persistence of infection (Grey and Steck, 2001) of *R. solanacearum*.

Growth conditions and nutrition Growth occurs aerobically on ordinary peptone media at 25–41°C. The type strains of *R. basilensis*, *R. metallidurans*, and *R. solanacearum* do not grow at 41°C, but the type strains of the other species can do so. The organisms do not require any growth factors, including sodium chloride. *Ralstonia eutropha* is a H_2-oxidizing (knallgas) chemolithoautotroph (Aragno and Schlegel, 1992); [NiFe] hydrogenases play a role as H_2 sensors (Kleihues et al., 2000; Buhrke et al., 2001). Cells of *R. eutropha* also grow well aerobically on nutrient-rich ordinary media.

Physiology and metabolism *Ralstonia eutropha* strain H16 mediates the reduction of nitric oxide (NO) to nitrous oxide (N_2O) by a single-component nitric oxide reductase (Cramm et al., 1999; Pohlmann et al., 2000). Resistance to nickel (Schmidt et al., 1991) and to both cobalt and nickel (Tibazarwa et al., 2000) has been reported in *R. eutropha*. Lead resistance was reported in *R. metallidurans* (Borremans et al., 2001). Genetically engineered *R. eutropha* strain MTB has an enhanced ability to immobilize external Cd^{2+} ions, and inoculation of this strain into Cd^{2+}-polluted soil reduces the toxic effects of heavy metal on the growth of tobacco plants (*Nicotiana bentamiana*) (Valls et al., 2000).

Recently, many reports concerning metabolic activities of *R. eutropha* have appeared in the literature (Lütke-Eversloh and Steinbuchel, 1999; Grzeszik et al., 2000; Happe et al., 2000; Padilla et al., 2000; Bernhard et al., 2001; Bramer and Steinbuchel, 2001; Drewlo et al., 2001; Schräder et al., 2001; Taguchi et al., 2001; York et al., 2001; Zarnt et al., 2001). The depolymerase gene for intracellular PHB of *R. eutropha* strain H16 was successfully cloned and its product was characterized (Saegusa et al., 2001). Under anaerobic conditions, *R. eutropha* undergoes nitrate respiration by utilizing nitrate as a terminal electron acceptor (Schwartz and Friedrich, 2001). Genetic determinants essential for these metabolic processes are linked to the megaplasmid pHG1.

Cellular lipids and fatty acids composition All of the two-dimensional TLCs (thin-layer chromatograms) of the type strains of eight *Ralstonia* species and of *Burkholderia cepacia* (Fig. BXII.β.6) reveal two spots of phosphatidylethanolamine (PE-1 and PE-2) and one spot of phosphatidylglycerol (PG). PE-2 possesses 2-hydroxy fatty acid, at the sn-2 position of the glycerol moiety. In addition, two spots of ornithine lipid (OL-1 and OL-2) have been visualized in *B. cepacia*. The major components of the nonpolar acids are $C_{16:0}$ followed by $C_{16:1\ \omega7c}$ and mixture of $C_{18:1\ \omega9t}$ and $C_{18:1\ \omega7c}$. The major polar acid is $C_{14:0\ 3OH}$. Percentage of minor components of fatty acids against the total amount of each of them cannot be a key of differentiation of species, because it could vary by differences in cultural condition and/or analyzing method.

Genetics and plasmids The complete genome sequence and its analysis of *R. solanacearum* strain GMI100 have been reported (Salanoubat et al., 2002). Part of their summary is as follows: "The 5.8-megabase (Mb) genome is organized into two replicons, one 3.7-Mb chromosome and another 2.1-Mb megaplasmid. Both replicons have a mosaic structure providing evidence for the acquisition of genes through horizontal gene transfer. Regions containing genetically mobile elements associated with the percentage of G + C bias may have an important function in genome evolution. The genome encodes many proteins potentially associated with a role in pathogenicity. In particular, many putative attachment factors were identified. The complete repertoire of type III secreted effector proteins can be studied. Over 40 candidates were identified. Comparison with other genomes

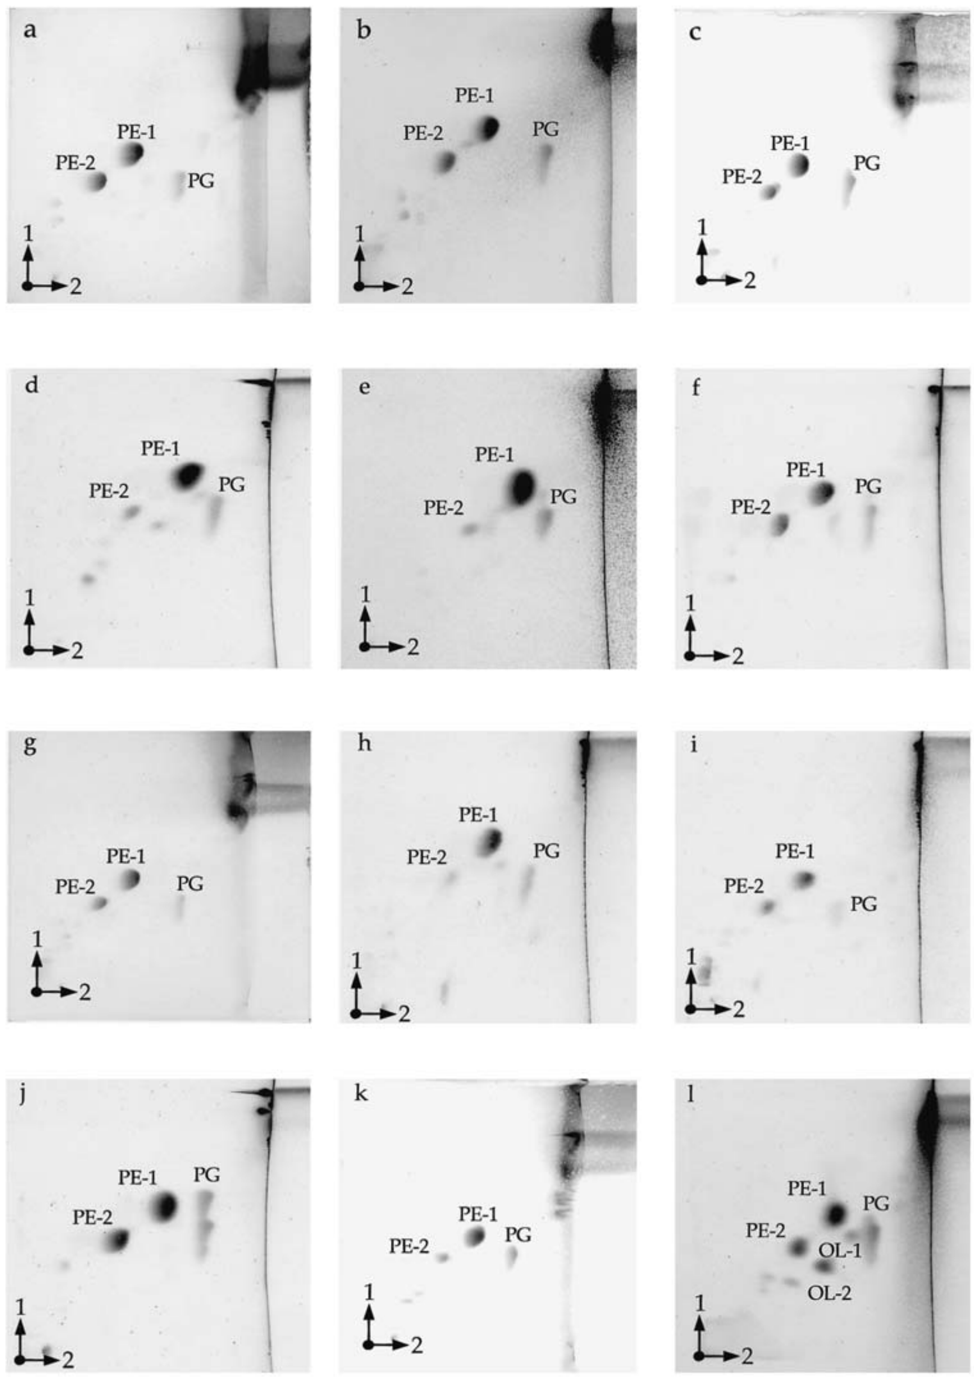

FIGURE BXII.β.6. Two-dimensional thin-layer chromatograms of cellular lipids of type strains of eight *Ralstonia* species and of *Burkholderia cepacia* (N. Fujiwara and T. Naka, unpublished data). The solvent system for the first direction was chloroform:methanol:water (65:25:4, v/v); for the second direction it was chloroform:methanol:acetic acid (65:25:10, v/v). (*a*) *R. pickettii* EY 4382; (*b*) *R. basilensis* EY4358; (*c*) *R. campinensis* EY 4379(*d*) *R. eutropha* EY 3798; (*e*) *R. gilardii* EY 4363; (*f*) *R. mannitolilytica* EY 4364; (*g*) *R. metallidurans* EY 4380; (*h*) *R. oxalatica* EY 4365; (*i*) *R. paucula* EY 4366; (*j*) *R. solanacearum* EY 2181; (*k*) *R. taiwanensis* EY 4381; (*l*) *B. cepacia* EY 645. Abbreviations: PE, phosphatidylethanolamine; PG, phosphatidylglycerol; OL, ornithine lipid.

suggests that bacterial plant pathogens and animal pathogens harbor distinct arrays of specialized type III-dependent effectors."

The genome sequence of *R. solanacearum* is a first step toward an exhaustive functional analysis of pathogenicity determinants in this plant pathogen. Prior to this report, much genetic research on the virulence factors of *R. solanacearum* was reported (Rosenberg et al., 1982; Boucher et al., 1986; Allen et al., 1997; Huang and Allen, 1997; Lasserre et al., 1997; Huang et al., 1998; Aldon et al., 2000; Bertolla et al., 2000; Garg et al., 2000; Vasse et al., 2000; Wang et al., 2000; Belbahri et al., 2001; Schwartz and Friedrich, 2001; Staskawicz et al., 2001; van Overbeek et al., 2002).

The genome of *R. eutropha* strain H16 is composed of two circular chromosomes measuring 4.1 and 2.9 Mb. A physical map of the megaplasmid pHG1 has been given by Schwartz and Fiedrich (2001).

A bacteriophage P4284 encoding a *R. solanacearum* bacteriolytic protein has been described (Ozawa et al., 2001).

Pathogenicity The plant pathogens produce a pilus structure. Morphologically similar structures are associated with type III protein secretion systems found in animal pathogens, and are essential for the delivery of virulence proteins directly into host cells.

Ralstonia solanacearum causes a lethal vascular wilt disease in more than 200 plant species in 50 botanical families in the tropics, subtropics, and warm temperate regions of the world. Its agronomically important hosts include tomato, potato, tobacco, peanut, and banana. This pathogenic organism was named and described as early as 1896 by Smith (1896). The instability of virulence and correlation with colony morphology of this organism led to elucidation of the existence of a regulatory network modulating transcription of multiple virulence genes (Brumbley et al., 1993). A type IV pilus system is responsible for a twitching type of motility and seems to contribute significantly to the plant pathogeneses (Liu et al., 2001; Tans-Kersten et al., 2001). After *R. solanacearum* cells penetrate the xylem vessels of tomato plants, they rapidly travel to the upper part of the plant and become readily detectable throughout the stem. Viable counts of the organism can reach $>10^{10}$ cells per cm of stem by day 8. Infected plants rapidly collapse and die, and virulent organisms released from the host plant roots or collapsed stems in contact with the ground results in a return of the bacteria to a saprophytic life in the soil, where they await a new host (Schell, 2000). The primary virulence factor of wild type *R. solanacearum* is an exopolysaccharide I (EPS I)—a large, nitrogen-rich, acidic exopolysaccharide that occludes vascular tissues and inhibits water flow (Schell, 2000). A type II secretion system exports all the cell wall-degrading exoenzymes such as pectinolytic enzymes and cellulolytic enzymes (Saile et al., 1997). A type III secretion system seems to deliver toxic proteins directly into the plant cell cytoplasm. Production of several virulence determinants is governed by growth in the presence of a volatile extracellular factor (VEF) produced by the wild-type strain of the organism (Clough et al., 1994). The VEF is active at $\leq$1 nM for stimulating biosynthesis of extracellular polysaccharide (*eps*) (Flavier et al., 1997a). The virulence of *R. solanacearum* is regulated by a complex network, the core of which is the Phc (phenotype conversion) system (Schell, 2000). The PhcA system is composed of PhcA (Brumbley and Denny, 1990; Brumbley et al., 1993) and the products of the *phcBSRQ* operon (Clough et al., 1994, 1997). Transcriptional activity of PhcA is controlled by 3-OH PAME (Clough et al., 1997; Flavier et al. 1997b).

Three *Ralstonia* species infect predisposed humans: *R. pickettii*, *R. mannitolilytica*, and *R. gilardii*. *R. pickettii* has been associated with acute meningitis (Fass and Barnishan, 1976), osteomyelitis and intervertebral discitis (Wertheim and Markovitz, 1992), nosocomial infection (Phillips et al.; 1972; Kahan et al., 1983; Raveh et al., 1993; Maroye et al., 2000), bacteremia (Fujita et al., 1981; Roberts et al., 1990), pseudobacteremia (Verschraegen et al., 1985), and colonization (McNeil et al., 1985; Centers for Disease Control and Prevention, 1998; Labarca et al., 1999; Yoneyama et al., 2000). One case each of recurrent meningitis and hemoperitoneum infection due to *R. mannitolilytica* (Vaneechoutte et al., 2001) has been reported. In addition, a case of catheter sepsis associated with *R. gilardii* (Wauters et al., 2001) has been reported.

It is remarkable that a certain strain of *Pseudomonas aeruginosa* is not only pathogenic to predisposed humans but also capable of causing disease in plants. Such "interkingdom" pathogens are able to colonize the surface of both plant and animal cells and to escape from diverse host defense mechanisms. Such features that allow them to be pathogenic on both procaryotic and eucaryotic hosts should be elucidated in the future (Staskawicz et al., 2001).

Ecology Organisms belonging to genus *Ralstonia* appear to be free-living in nature. However, because of their metabolic or pathogenic specialties, the type strains of certain species have been isolated from human clinical specimens (*R. pickettii*, *R. mannitolilytica*, and *R. paucula*), from a fixed-bed reactor with 2,6-dichlorophenol as the sole carbon and energy source (*R. basilensis*), from a zinc-decertified area in Lommel, Belgium (*R. campinensis*), from water (*R. eutropha* and *R. metallidurans*), from plants (*R. solanacearum* and *R. taiwanensis*), and from earthworms (*R. oxalatica*). Thus, *Ralstonia* organisms might be living in a variety of ecological niches. Furthermore, the long survival of *R. solanacearum* organisms in soil and rhizospheres might be possible by an asymptomatic infection of the roots of nonhost plants, such as bean, peas, soybean, corn, and rice (Granada and Sequeira, 1983).

Differentiation of the genus *Ralstonia* from other genera

Differential characteristics of the type species of five genera in the order *Burkholderiales* (class *Betaproteobacteria*) with one genus each in the order *Sphingomonadales* and *Caulobacterales* (class *Alphaproteobacteria*) and the type genus of the order *Pseudomonadales* (class *Gammaproteobacteria*) are summarized in Table BXII.β.8.

Taxonomic Comments

The genus *Ralstonia* was named after Ericka Ralston, the American bacteriologist who first named and described *Pseudomonas pickettii* and suggested a taxonomic relationship to *Pseudomonas solanacearum* (Ralston et al., 1973). Based on polyphasic taxonomic research, *Burkholderia pickettii*, *Burkholderia solanacearum*, and *Alcaligenes eutrophus* were transferred to a new genus, *Ralstonia*, by Yabuuchi et al. (1995, 1996). *R. pickettii* was designated as the type species for the genus, because neither plant nor animal quarantine law restricts its exchange. This is important for taxonomic research to proceed smoothly. The genus *Ralstonia*, when proposed, contained *R. pickettii*, a species pathogenic to predisposed humans and pathogenic to plants in the botanical

[e]Data from Palleroni (1984).

family Soranaceae. The genus also contained *R. solanacearum* and the hydrogen-oxidizing knallgas bacterium, *R. eutropha*. Eight new species were also added.

A phylogenetic dendrogram of the 16S rDNA similarities of the type strains of 11 *Ralstonia* species and of *Burkholderia cepacia* is shown in Fig. BXII.β.7. The percent similarity values among the type strains of 10 *Ralstonia* species and *B. cepacia* versus the type strain of *R. pickettii* are summarized in Table BXII.β.9. The values range from 95.0% to 98.1% among the *Ralstonia* species and 91.3% between *R. pickettii* and *B. cepacia*. In view of the latter value, inclusion of the genus *Ralstonia* in the family *Burkholderiaceae* is supported.

Differentiation of the species of the genus *Ralstonia*

Tables BXII.β.10 and BXII.β.11 list the differential characteristics of the species of *Ralstonia* and of *Burkholderia cepacia*. Additional features are listed in Tables BXII.β.12, BXII.β.13, and BXII.β.14.

List of species of the genus Ralstonia

1. **Ralstonia pickettii** (Ralston, Palleroni and Doudoroff 1973) Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1996, 625[VP] (Effective publication: Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1995, 903) (*Burkholderia pickettii* Yabuuchi, Ko-

sako, Oyaizu, Yano, Hotta, Hashimoto, Ezaki and Arakawa 1993, 398; *Pseudomonas pickettii* Ralston, Palleroni and Doudoroff 1973, 18.)

pick.et′ ti.i. M.L. gen. n. *pickettii* Pickett patronymic, of Pickett; named after M.J. Pickett.

The characteristics are as described for the genus and in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. The cell size is 0.5–0.6 × 1.5–3.0 μm. Accumulate poly-β-hydroxy-butyrate granules as a reserve carbon source (Ralston et al., 1973). Growth occurs at 41°C but not at 5°C. Nitrate respiration is positive. Cellular lipids of the type strain contain two kinds of ornithine lipids (Fig. BXII.β.6). The former CDC group Va-2 as well as Va-1 corresponds to *R. pickettii*, because the DNA–DNA hybridization value between type strain of *R. pickettii* and Va-2 strain was 84% (Pickett and Greenwood, 1980). The type strain was isolated from a patient who had undergone tracheostomy.

The mol% G + C of the DNA is: 64.0 (Bd).

Type strain: Ralston K-288, ATCC 27511, CCUG 3318, DSM 6297, EY 4382, GTC 1882, JCM 5969, LMG 5942.

GenBank accession number (16S rRNA): S55004, X67042.

2. **Ralstonia basilensis** Steinle, Stucki, Stettler and Hanselmann 1999, 1325[VP] (Effective publication: Steinle, Stucki, Stettler and Hanselmann 1998, 2569) emend. Goris, De Vos, Coenye, Host, Janssens, Brim, Diels, Mergeay, Kersters and Vandamme 2001, 1781.

ba.si.len′ sis. M.L. adj. *basilea, basilensis* pertaining to Basel, Switzerland, where the strain was isolated.

The characteristics are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. The cell size is 0.8 × 1.2–2.2 μm (Goris et al., 2001). Able to grow utilizing 2,6-dichlorophenol as the sole source of carbon and energy. The type strain was isolated from a fixed-bed reactor with 2,6-dichlorophenol as the sole carbon and energy source.

The mol% G + C of the DNA is: 65.0 (HPLC).

Type strain: Steinle RK1, DSM 11853, EY 4368, GTC 1873.

GenBank accession number (16S rRNA): AF312022, AJ002302.

3. **Ralstonia campinensis** Goris, De Vos, Coenye, Host, Janssens, Brim, Diels, Mergeay, Kersters and Vandamme 2001, 1780[VP]

cam.pin.en′ sis. L. adj. *campinensis* pertaining to the ikempen or Campine, the geographical region of northeast Belgium, where the strains were isolated.

The characteristics are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. The cell size is 0.8 × 1.2–1.8 μm. Colonies are round (sometimes with a slightly scalloped margin), smooth, convex, and transparent. The colony diameter is less than 0.5 mm in diameter on TSA agar plate after 24 h incubation at 30°C. Able to grow at 41°C, but not at 4°C. For enzyme activities determined with API Zyme, see Goris et al. (2001). The type strain was isolated from a zinc-decertified area in Lommel, Belgium.

The mol% G + C of the DNA is: 66.6–66.8 (HPLC).

Type strain: WS2, CCUG 44526, EY 4379, GTC 1881, LMG 19282.

GenBank accession number (16S rRNA): AF312020.

4. **Ralstonia eutropha** (Davis, Doudoroff, Stanier and Mandel 1969) Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1996, 625[VP] (Effective publication: Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1995, 903) (*Alcaligenes eutrophus* Davis *in* Davis, Doudoroff, Stanier and Mansel 1969, 386.)

eu.troph′ a. Gr. prep. *eu* good, beneficial; Gr. n. *trophus* one who feeds; M.L. n. *eutropha* good nutrition, well nourished.

The characteristics are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. Cells are 0.7 × 1.8–2.6 μm and have peritrichous flagella. Able to grow at 41°C. Resistant to nickel (Schmidt et al., 1991) and to a combination of cobalt and nickel (Tibazarwa et al., 2000). A genetically engineered strain has an enhanced ability to immobilize external Cd^{2+} ions and reduced the toxic effects of heavy metals on the growth of tobacco plants (Valls et al., 2000). Synthesizes short chain length (SCL) (3–5 carbon atoms) PHAs by means of PHA synthase (Song et al., 2000c; Zhang et al., 2000c) and accumulates them as intracellular granules. PHAs are now of commercial value as thermoplastics (Holmes, 1985), and have been extensively studied (Lütke-Eversloh and Steinbuchel, 1999; Grzeszik et al., 2000; Happe et al., 2000; Padilla et al., 2000; Bernhard et al., 2001; Bramer and Steinbuchel, 2001; Drewlo et al., 2001; Schräder et al., 2001; Taguchi et al., 2001; Zarnt et al., 2001). Accumulated PHB is degraded and used for growth and survival when an exogenous carbon source is not available (Handrick et al., 2000). Genetic determinants essential for synthesis of these polymers are linked to the megaplasmid pHG1. Genome of *R. eutropha* strain H16 is composed of two circular chromosomes measuring 4.1 and 2.9 Mb. A physical map of the megaplasmid pHG1 has been given (Schwartz and Fiedrich, 2001). The type strain was isolated from soil with hydrogen gas.

The mol% G + C of the DNA is: 65.5 (HPLC).

Type strain: ATCC 17697, DSM 531, EY 3798, GTC 1874, JCM 11282, LMG 1199.

GenBank accession number (16S rRNA): M32021.

5. **Ralstonia gilardii** Coenye, Falsen, Vancanneyt, Hoste, Govan, Kersters and Vandamme 1999a, 412[VP]
gi.lar′ di.i. M.L. gen. n. *gilardii* named after G.L. Gilardi, an American microbiologist who contributed much to our knowledge of *Alcaligenes* species.

The characteristics are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. The cell size is 0.7 × 1.8–2.6 μm. Motile by means of a single polar flagellum. Able to grow at 41°C. Growth occurs in the presence of 5.0% NaCl.

The mol% G + C of the DNA is: 68–69 (T_m).

Type strain: ATCC 700815, EY 4363, GTC 1875, JCM 11283, LMG 5886.

GenBank accession number (16S rRNA): AF076645.

6. **Ralstonia mannitolilytica** De Baere, Steyaert, Wauters, De Vos, Goris, Coenye, Suyama, Verschraegen and Vaneechoutte 2001, 556[VP]
man.ni.to.li.ly′ ti.ca. N.L. adj. *mannitolilytica* cleaving mannitol.

The species accommodates strains previously known as the *Ralstonia pickettii* biovar 3/*'thomasii'* strains and at least some of the strains known as *"Pseudomonas thomasii"* Phillips et al. 1972. The characteristics are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. Motile by means of single polar flagellum, with the only exception being the type strain. Able to grow at 41°C. For enzymatic activity, see the results by means of API ZYM (De Baere et al., 2001). The type strain was isolated from blood of patient at St. Thomas' Hospital, London, UK, in 1971 (Phillips et al., 1972).

The mol% G + C of the DNA is: 66.2 (HPLC).

Type strain: LMG 6866, EY 4364, GTC 1876, JCM 11284, NCIB 10805.

GenBank accession number (16S rRNA): AJ270258.

7. **Ralstonia metallidurans** Goris, De Vos, Coenye, Host, Janssens, Brim, Diels, Mergeay, Kersters and Vandamme 2001, 1780[VP]
me.tal.li.du′ rans. L. n. *metallum* metal; L. pres. part. *durans* enduring; N.L. part. adj. *metallidurans* enduring metal, to indicate that these strains are able to survive high heavy-metal concentrations.

The characteristics of the type strain are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. Cells are short motile rods 0.8 × 1.2–2.2 μm. Colonies are round (sometimes with a slightly scalloped margin), smooth, slightly convex, and beige colored when fully grown. Unable to grow either at 4° or 41°C. For enzyme activities, see Goris et al. (2001). The type strain was isolated from wastewater from a zinc factory at Liege, Belgium.

The mol% G + C of the DNA is: 63.7 (HPLC).

Type strain: DSM 2389, EY 4380, GTC 1882, LMG 1195.

GenBank accession number (16S rRNA): Y10824.

8. **Ralstonia oxalatica** (ex Khambata and Bhat 1953) Sahin, Isik, Tamer and Goodfellow 2000b, 1953[VP] (Effective publication: Sahin, Isik, Tamer and Goodfellow 2000a, 207.)
o.xa.la′ ti.ca. M.L. fem. adj. *oxalatica* pertaining to oxalate.

The characteristics of the type strain are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. Motile by means of one polar or subpolar flagellum. Cell size is 0.3–0.4 × 0.9–1.5 μm. Able to grow on ordinary peptone media without supplementing with oxalate. Unable to grow autotrophically with hydrogen. The type strain was isolated from the alimentary tract of an Indian earthworm.

The mol% G + C of the DNA is: 68 (T_m) or 67 (Bd).

Type strain: ATCC 11883, DSM 1105, EY 4365, JCM 11285, NCIB 8642, LMG 2235.

GenBank accession number (16S rRNA): AF155567.

9. **Ralstonia paucula** Vandamme, Goris, Coenye, Hoste, Janssens, Kersters, De Vos and Falsen 1999, 668[VP]
pau′ cu.la. L. adj. *pauculus* rare, very few, to indicate that these strains only sporadically cause human infections.

The characteristics of the type strain are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. Cell size is 0.8 × 1.2–2.0 μm. Motile by means of peritrichous flagella. Does not denitrify. These organisms were previously placed in CDC group Ivc-2. Isolated from a variety of human clinical sources (Vandamme et al., 1999) as well as environmental sources such as pool water, groundwater, and bottled mineral water. Differentiated from other species by peritrichous flagellation, ability to form acid oxidatively from L-arabinose, and absence of cystine arylamidase, phosphoamidase, and lipase C_{14} activity. The type strain was isolated from a human respiratory tract in USA.

The mol% G + C of the DNA is: 65–67 (T_m).

Type strain: CCUG 12507, CDC E6793, EY 4366, GTC 1878, JCM 11286, LMG 3244.

GenBank accession number (16S rRNA): AF085226.

10. **Ralstonia solanacearum** (Smith 1896) Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1996, 625^VP (Effective publication: Yabuuchi, Kosako, Yano, Hotta and Nishiuchi 1995, 903.) (*Pseudomonas solanacearum* (Smith 1896) Smith 1914, 178; *Bacillus solanacearum* Smith 1896, 10.)
so.la.na.ce.a'rum. M.L. fem. pl. n. *Solanaceae* the nightshade family; M.L. fem. pl. gen. n. *solanacearum* of the *Solanaceae*.

The characteristics of the type strain are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. Nonmotile. Pathogenic for tomato, potato, tobacco, banana, and peanut by the production of a copious amount of extracellular polysaccharide, which occludes vessels in the stem, inhibits water flow, and causes death of plant by wilt disease. Recently the nucleotide full sequence of the chromosome and megaplasmid were determined in order to elucidate and manipulate genes related to the virulence of the organism. The type strain was isolated from tomato.

The mol% G + C of the DNA is: 66.6 (HPLC).

Type strain: ATCC 11696, DSM 9544, EY2181, GTC 1879, JCM 10489, LMG 2299, NCPPB 325.

GenBank accession number (16S rRNA): X67036.

11. **Ralstonia taiwanensis** Chen, Laevens, Lee, Coenye, De Vos, Mergeay and Vandamme 2001, 1734^VP
tai.wan.en' sis. N.L. fem. adj. *taiwanensis* pertaining to Taiwan, where the root nodule strains were isolated.

The characteristics of the type strain are as described for the genus and listed in Tables BXII.β.10, BXII.β.11, BXII.β.12, BXII.β.13, and BXII.β.14. Motile; type of flagellation unknown. Cell size, 0.5–0.7 × 0.8–2.0 μm. Growth is observed at 28°, 30°, and 37°C. Nitrate is reduced. Esculin is hydrolyzed.; gelatin and Tween 80 are not. Susceptible to tetracyclines and quinolines; resistant to β-lactams and aminoglycosides. Urease, β-galactosidase, and DNase are negative. Indole is not produced. Autotrophic growth does not occur. The type strain was isolated from root nodules of *Mimosa pudica*.

The mol% G + C of the DNA is: 67.3 (HPLC).

Type strain: R1, CCUG 44338, EY4381, GTC 1883, LMG 19424.

GenBank accession number (16S rRNA): AF300324.

Genus VIII. Thermothrix *Caldwell, Caldwell and Laycock 1981, 217^VP (Effective publication: Caldwell, Caldwell and Laycock 1976, 1515)*

Anna-Louise Reysenbach, Paula Aguiar and Douglas E. Caldwell

Ther' mo.thrix. Gr. adj. *thermos* hot; Gr. n. *thrix* hair; N.L. fem. n. *Thermothrix* hot hair.

Rod-shaped cells, usually 0.5–1.0 × 3–5 μm. **Filamentous cells are produced** under unfavorable growth conditions such as when grown at temperatures near the maximum temperature, at extreme pH values, or when oxygen limits growth. **Motile by means of a single polar flagellum**. Gram negative. No spores are produced. **Growth occurs between 63–86°C and pH 6–8.5**. **Facultatively or obligately chemolithoautotrophic aerobic**. Oxygen or nitrate may be used as the electron acceptor. Electron donors can be organic compounds or inorganic sulfur compounds such as thiosulfate, sulfur, hydrogen sulfide, and tetrathionate.

The mol% G + C of the DNA is: 39.7.

Type species: **Thermothrix thiopara** Caldwell, Caldwell and Laycock 1981, 217 (Effective publication: Caldwell, Caldwell and Laycock 1976, 1515.)

Further descriptive information

Elemental sulfur is often deposited extracellularly as spherical granules (Figs. BXII.β.8 and BXII.β.9), although *T. azorensis* accumulates sulfur intracellularly when the oxidation of thiosulfate is incomplete and the pH does not drop below pH 7.0. Respired substrates may include glucose, sulfide, and thiosulfate. When thiosulfate is oxidized to sulfate, elemental sulfur, sulfite, and polythionate accumulate as intermediates in batch culture (Brannan and Caldwell, 1980, 1983).

This genus was found within the sulfide-oxygen interfaces of neutral pH geothermal springs, including Mammoth Hot Springs (Yellowstone National Park, Wyoming, USA), Jemez Hot Springs (Jemez Springs, New Mexico, USA), and Furnas (Sao Miguel Island, Azores).

The isolates of *Thermothrix* were obtained from thermal springs characterized by "sulfur turf" mats. These mats generally consist of a mixture of filamentous and rod-shaped cells, intertwined to form "streamers" up to 10 cm in length. Although many *in situ* studies have been conducted on these mats, recent molecular phylogenetic assessments of the Mammoth Hot Springs, the Jemez Spring, and the Furnas "streamers" revealed the dominance of *Aquificales*-like 16S rRNA sequences and no beta-proteobacterial sequences (A.L. Reysenbach, P. Aguiar, and T. Kieft, unpublished data). Additionally, fluorescent *in situ* 16S rRNA probes, specific for the order *Aquificales*—in the class *Aquificae*, phylum *Aquificae*—confirmed that this group of organisms forms the primary matrix of these mats (Fig. BXII.β.10). Based on this new molecular evidence, it is therefore unclear how significant the role of *Thermothrix*—in the class *Betaproteobacteria*, phylum *Proteobacteria*—is in the formation of the mats.

Enrichment and Isolation Procedures

Representatives of the genus are found within the sulfide-oxygen interface of terrestrial hot springs (40–80°C). Under these con-

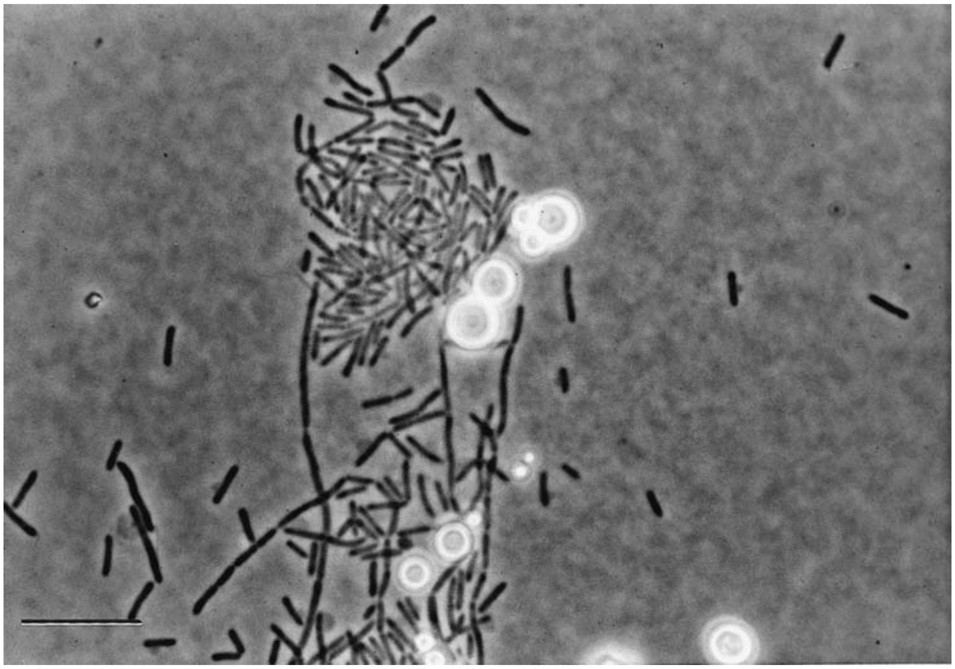

FIGURE BXII.β.8. *T. thiopara* during oxidation of thiosulfate, with extracellular deposition of elemental sulfur (spherical granules) shown. The culture was highly aerated, thus producing rod-shaped cells and cell chains but no cell filaments. Bar = 10 μm.

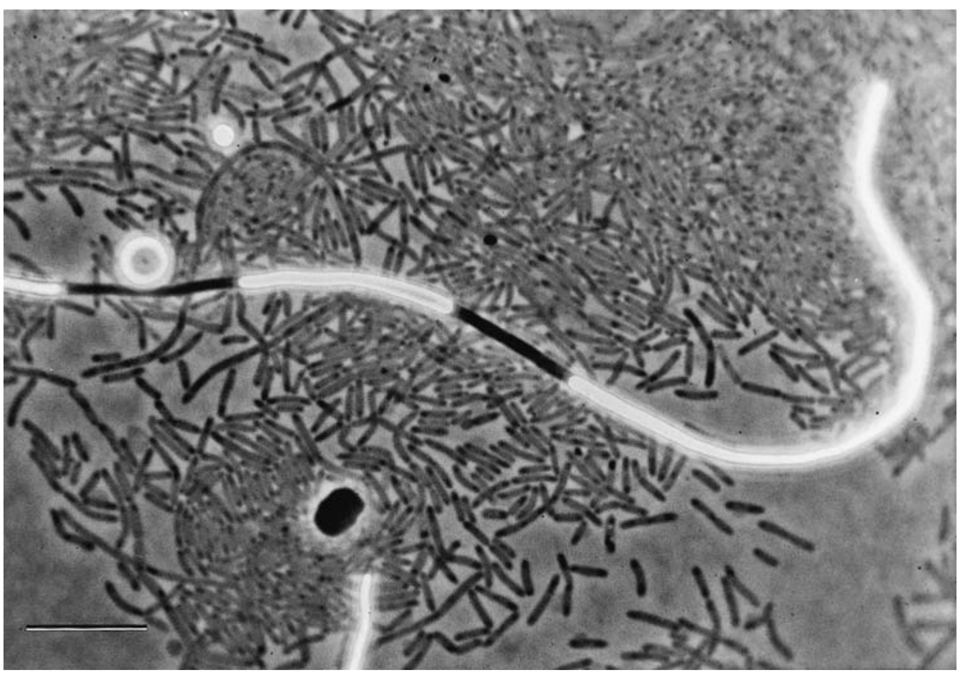

FIGURE BXII.β.9. Deposition of elemental sulfur in a smooth refractile layer partially surrounding a filament of *T. thiopara* (*center*) during the transition from nitrate broth to a synthetic medium with thiosulfate as sole energy source. Phase-contrast micrograph. Bar = 10 μm.

ditions, sulfide serves as the electron donor and oxygen as the electron acceptor. Consequently, a synthetic medium with either sulfide or thiosulfate as the sole energy source can be used for initial cultivation. The following medium has been used (g/l): $Na_2S_2O_3 \cdot 5H_2O$, 3.0; $NaHCO_3$, 2.0; NH_4Cl, 1.0; KNO_3, 2.0; $MgSO_4 \cdot 7H_2O$, 0.5; KH_2PO_4, 2.0; and $FeSO_4 \cdot 7H_2O$-EDTA, 0.02; plus trace elements (pH 6.8) (Brannan and Caldwell, 1980). Care should be taken to avoid the loss of bicarbonate as carbon dioxide if the medium is autoclaved and when the medium is stored and incubated. The enrichments are incubated at 73°C and should be transferred during logarithmic phase (reached after about 24 h), or stored in log phase of growth at 4°C, as cell death may

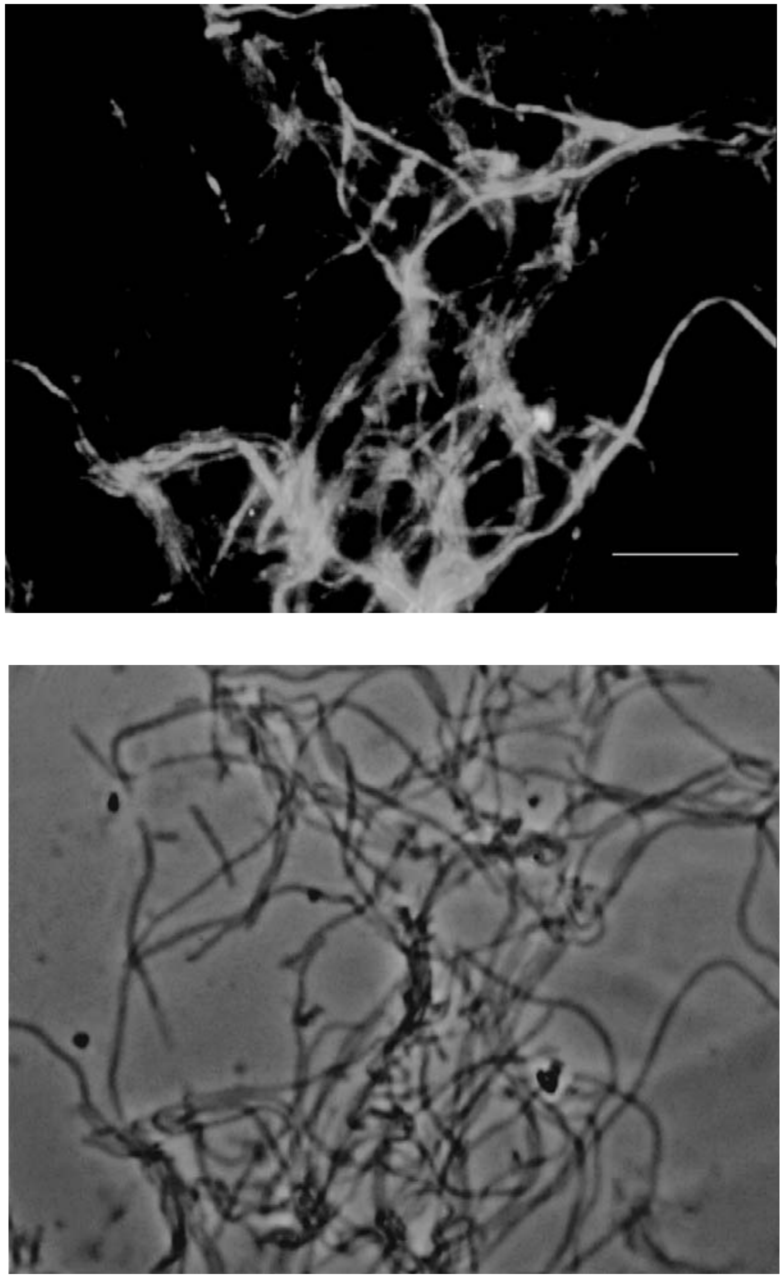

FIGURE BXII.β.10. *Upper panel*, streamers collected from Jemez Springs, New Mexico, probed with a fluorescein-labeled oligonucleotide 16S rDNA probe specific for the 16S rRNA from the *Aquificales* (Harmsen et al., 1997). *Bottom panel*, phase contrast micrograph of same frame. Bar = 10 μm.

occur within 4 h of reaching the stationary growth phase. Because of the low solubility of the oxygen at 73°C (approximately 3 mg/l), the organisms should be cultivated in shake flasks with a large headspace to provide sufficient aeration. Isolated colonies may be obtained on agar or Gelrite; however, recovery is poor. After initial isolation, some species of *Thermothrix* may be adapted, with difficulty, to grow on an organic medium such as a nutrient (aerobic) or nitrate (anaerobic) broth.

Maintenance Procedures

Cells may be frozen in a 15% glycerol (v/v) and stored at −80°C. Cultures of *T. thiopara* adapted to grow on nitrate broth (Difco) were more easily maintained than were autotrophically grown cells.

Differentiation of the genus *Thermothrix* from other genera

The primary basis for discrimination of *Thermothrix* species from thermophilic *Thiobacillus* species is the production of filaments when the concentration of the electron acceptor limits the rate of growth. Cells obtained during the initial isolation are usually motile and rod shaped. Induction of the filamentous growth form requires continuous cultivation under oxygen-limited con-

ditions. The oxygen tension should be maintained at 1 mg/l or less.

FURTHER READING

Brannan, D.K. and D.E. Caldwell. 1980. *Thermothrix thiopara*: growth and metabolism of a newly isolated thermophile capable of oxidizing sulfur and sulfur compounds. Appl. Environ. Microbiol. *40*: 211–216.

Odintsova, E.V., H.W. Jannasch, J.A. Mamone and T.A. Langworthy. 1996. *Thermothrix azorensis* sp. nov., an obligately chemolithoautotrophic, sulfur-oxidizing, thermophilic bacterium. Int. J. Syst. Bacteriol. *46*: 422–428.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *THERMOTHRIX*

Only two species are described: *Thermothrix thiopara* and *Thermothrix azorensis*. These have been distinguished by their 16S rRNA structure, temperature growth optima, and whether they are obligately or facultatively chemolithoautotrophs and obligately or facultatively aerobic.

List of species of the genus Thermothrix

1. **Thermothrix thiopara** Caldwell, Caldwell and Laycock 1981, 217[VP] (Effective publication: Caldwell, Caldwell and Laycock 1976, 1515.)
thi.o'par.a. Gr. n. *thios* sulfur; L. v. *paro* produce; M.L. adj. *thiopara* sulfur-depositing.

See the description of the genus for most features of the species. The cardinal temperatures are 60°, 73°, and 80°C (minimum, optimum, and maximum) for cells grown by using either inorganic or organic media (Caldwell et al., 1976; Brannan and Caldwell, 1982). The generation time at 73°C is approximately 2 h on either medium. When reduced sulfur compounds are used as the electron donor, elemental sulfur is frequently deposited as extracellular granules but is not deposited intracellularly (Fig. BXII.β.8). In batch culture, elemental sulfur, sulfite, and polythionates accumulate as transient intermediates but are subsequently oxidized to sulfuric acid. In continuous culture, elemental sulfur is not deposited during steady-state growth but is deposited during the transition from low to high dilution rates. During transfer from nitrate broth to autotrophic media containing thiosulfate, cell filaments often form and become encased in a coating of elemental sulfur (Fig. BXII.β.9).

Denitrification occurs only heterotrophically (Brannan and Caldwell, 1982). During denitrification, N_2 is the primary end product. Nitrite accumulates as a transient intermediate.

The mol% G + C of the DNA is: 39.7 (T_m).
Type strain: ATCC 29244.
GenBank accession number (16S rRNA): U61284.
Additional Remarks: The original strain is no longer available from the ATCC.

2. **Thermothrix azorensis** Odintsova, Jannasch, Mamone and Langworthy 1996, 426[VP]
a.zo' ren.sis. L. fem. adj. *azorensis* from the Azores.

Long, thin rods (2–5 × 0.3–0.5 μm) often in pairs. Filaments up to 70 μm long are produced under unfavorable growth conditions. Gram-negative nonsporulating cells, some contain sulfur inclusions. Strictly aerobic and obligately chemolithoautotrophic, using reduced sulfur compounds (hydrogen sulfide, tetrathionate, elemental sulfur, and thiosulfate) as electron donors and carbon dioxide as the carbon source. During the lag phase of growth, elemental sulfur oxidation is preceded by sulfide production. Grows best between 76° and 78°C, pH 7.0–7.5. Temperature and pH ranges for growth are 60–87°C and pH 6.0–8.5, respectively. Lipids include C_{14} to C_{22} fatty acids (95% C_{16} and C_{18}). No ribulose-1,5-bisphosphate carboxylase/oxygenase activity is present.

Isolated from a hot spring located at Furnas, Sao Miguel, the Azores, Portugal.
The mol% G + C of the DNA is: 39.7 (T_m).
Type strain: TM, ATCC 51754.
GenBank accession number (16S rRNA): U59127.

Family II. **Oxalobacteraceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Ox.al.o.bac.ter.a' ce.ae. M.L. masc. n. *Oxalobacter* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Oxalobacteraceae* the *Oxalobacter* family.

The family *Oxalobacteraceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Oxalobacter* (type genus), *Duganella*, *Herbaspirillum*, *Janthinobacterium*, *Massilia*, *Oxalicibacterium*, and *Telluria*. *Oxalicibacterium* was proposed after the cut-off date for inclusion in this volume (June 30, 2001) and is not described here (see Tamer et al. (2002)).

Family is metabolically diverse and includes strict anaerobes, strict aerobes, and nitrogen-fixing organisms.

Type genus: **Oxalobacter** Allison, Dawson, Mayberry and Foss 1985b, 375[VP] (Effective publication: Allison, Dawson, Mayberry and Foss 1985a, 6.)

Genus I. **Oxalobacter** *Allison, Dawson, Mayberry and Foss 1985b, 375[VP] (Effective publication: Allison, Dawson, Mayberry and Foss 1985a, 6)*

MILTON J. ALLISON, BARBARA J. MACGREGOR, RICHARD SHARP AND DAVID A. STAHL

Ox.al.o.bac'ter. Gr. n. *oxal* pertaining to oxalate; M.L. n. *bacter* the masculine form of the Gr. neut. n. *bactrum* a rod; M.L. masc. n. *Oxalobacter* an oxalate rod.

Straight or curved to vibrioid, Gram-negative, nonsporeforming rods 0.4–0.6 × 1.0–2.5 μm in length. Flagella may be present or absent. **Strictly anaerobic.** Chemoorganotroph. **Oxalate is used as the major carbon and energy source. Oxamate may also be used, but neither carbohydrates nor any of a wide variety of other compounds will replace oxalate as the growth substrate.** Acetate is assimilated for cell synthesis and is required by some, and perhaps by all, strains. Oxalate utilization is accompanied by alkalization of the medium, and formate is produced in approximately equimolar proportions to the amount of oxalate metabolized. Strains have been isolated from the rumens of cattle and sheep, from cecal and fecal samples from humans, guinea pigs, swine, domestic and wild rats, and from freshwater lake and marine sediments. It is probable that these bacteria colonize many other anaerobic habitats. *Oxalobacter* is currently classified in the class *Betaproteobacteria*, the order *Burkholderiales*, and the family *Oxalobacteraceae*.

The mol% G + C of the DNA is: 48–52.

Type species: **Oxalobacter formigenes** Allison, Dawson, Mayberry and Foss 1985b, 375 (Effective publication: Allison, Dawson, Mayberry and Foss 1985a, 6.)

FURTHER DESCRIPTIVE INFORMATION

Cultural and growth characteristics In anaerobic roll-tube cultures, colonies on the agar surface are colorless, transparent, and droplet-like, while subsurface colonies are colorless or white and are lens-shaped or globular. Colonies of anaerobic oxalate-degraders can be detected based on production of clear zones around colonies in media containing appropriate amounts of calcium oxalate.

Growth occurs under anaerobic conditions, under a gas phase of CO_2, in a defined carbonate–bicarbonate buffered medium that contains minerals, oxalate, and acetate, but growth is better with yeast extract in the medium. Specific growth rates (μ) may be as high as 0.3 h^{-1}. Isolations have been obtained on media containing 20–50 mM oxalate. Some freshly isolated strains are inhibited by 30 mM oxalate; laboratory adapted strains, however, grow well in media containing oxalate at concentrations of 100 mM or more. Acetate is required for growth of some, and perhaps all, intestinal strains, as well as by strains isolated from sediments. The temperature range for growth is 14–45°C, with gastrointestinal strains exhibiting a higher optimal temperature (about 37°C) than lake sediment strains.

Metabolism and metabolic pathways Oxalate serves as both the energy yielding substrate and the major source of carbon for growth. The products from oxalate metabolism are CO_2 and formate, with approximately 1 mol of each produced per mole of oxalate degraded. Approximately 1–1.7 g (dry wt.) of cells are produced per mole of oxalate degraded. Energy generation is centered around the development of a proton motive force through the electrogenic exchange of oxalate (in) and formate (out) across the cell membrane and the consumption of a proton inside the cell when the CoA-ester of oxalate is decarboxylated by oxalyl CoA-decarboxylase (Anantharam et al., 1989; Kuhner et al., 1996). An antiporter protein (OxlT) facilitates the oxalate–formate exchange (Ruan et al., 1992). Oxalate serves as a major source of cell carbon, but acetate and carbon dioxide are also used for biosynthesis (Cornick and Allison, 1996b). In tests with benzyl viologen as the electron acceptor, formate dehydrogenase activity is detected in both *O. formigenes* and *O. vibrioformis* (Dehning and Schink, 1989b; Cornick and Allison, 1996a). However, since neither NAD nor NADP are reduced in such tests and since formate accumulation is roughly equivalent to the amount of oxalate degraded, no role for formate dehydrogenase in the energy metabolism of *Oxalobacter* is expected. Neither nitrate nor sulfate are reduced, indole is not formed, and cytochromes are not present.

Pathogenicity There is no evidence that these bacteria, which are normal inhabitants of the gastrointestinal tract, are pathogenic. Large quantities of cells (10^{10}), representing strains isolated from sheep rumen, pig cecum, human feces, guinea pig cecum, and wild rats, have been fed to laboratory rats without ill effects (Daniel et al., 1987a).

Ecology Oxalate, a product of both plant and animal metabolism, is widely distributed in many ecosystems. Metabolism of oxalate by *O. formigenes* in freshwater sediments and gut habitats occurs under anaerobic conditions and at near neutral pH. Metabolism is accompanied by alkalization, since 1 mol of protons is consumed per mole of oxalate metabolized. Formate produced from oxalate has been used for methanogenesis in enrichment cultures of rumen microbes (Dawson et al., 1980a). Normal diets of humans and animals usually contain enough oxalate to maintain intestinal populations of *O. formigenes*. Increased concentrations of these bacteria in the intestine are selected for when diets with elevated concentrations of oxalate are fed to animals. This selection leads to increased rates of degradation of otherwise potentially toxic amounts of oxalate, a phenomenon that has survival value for the host animal (Shirley and Schmidt-Nielson, 1967; Allison and Cook, 1981). The absence of *O. formigenes* in the intestinal tracts of some humans appears to be correlated with increased absorption of dietary oxalate, leading to increased risk for kidney stones and other oxalate-related disease (Sidhu et al., 1998).

Antibiotic sensitivity Strains HC1 and OxK are both sensitive to chloramphenicol, colistin, doxycycline, erythromycin, polymyxin B, rifampin, and tetracycline. Strain OxK is also sensitive to cefuroxime. Both strains are resistant to 22 other antibiotics that have been tested. Similar patterns have been observed with *O. formigenes* strains from rats (Daniel et al., 1987b) and with the type strain, OxB (Dawson, 1979).

ENRICHMENT AND ISOLATION PROCEDURES

Anaerobic media with oxalate as the main, or only, energy source are used for enrichment cultures from either rumen samples (Dawson et al., 1980a, b) or freshwater lake sediments (Smith et al., 1985; Dehning and Schink, 1989b). Carbonate-buffered media, heated to remove dissolved oxygen and reduced with cysteine and/or sulfide, are used for enrichment cultures. Media for enrichment from sediments also contain acetate and either yeast

extract or a mixture of vitamins, while media for enrichment from the rumen contain rumen fluid.

Colonies of oxalate-degrading bacteria are identified based on the formation of clear zones around the colonies in media that are somewhat opaque due to the presence of calcium oxalate. Daniel et al. (1989) have compared variations in levels of calcium, yeast extract, and rumen fluid on culture counts of oxalate-degrading rumen bacteria, as detected by clear zones around colonies in roll-tube cultures. This method has been used for isolations of *O. formigenes* strains without prior enrichment steps and for enumeration of these bacteria from gastrointestinal samples from man and animals (Allison et al., 1985a).

Maintenance Procedures

Viable cultures may be recovered from cells stored at −80°C for several years or from freeze-dried cells stored at 0–4°C.

Procedures for Testing Special Characters

Successful detection of *O. formigenes* in fecal samples can be accomplished using PCR amplification of selected sequences of the *oxc* gene (Sidhu et al., 1997a, 1999). Tests can be successfully conducted with fecal samples that have not been cultured or with enrichment cultures in a medium containing 10–30 mM oxalate. The loss of oxalate from such media is usually nearly complete, and a simple test for this loss can be made based on precipitate formation when a calcium chloride solution is added (Sidhu et al., 1997b).

Differentiation of the genus *Oxalobacter* from other genera

Organisms of the genus *Oxalobacter* are the only known Gram-negative, anaerobic, oxalate degraders that are extreme specialists, to the extent that oxalate and/or the closely related compound oxamate are obligate requirements for growth. Oxalate serves as the major carbon and energy source, but a small amount of acetate may also be required.

Selected regions of the *oxc* gene (encoding oxalyl-CoA decarboxylase) and the *frc* gene (encoding formyl-CoA transferase) have been used to construct oligonucleotide probes able to distinguish *O. formigenes* DNA from DNA of any of a known group of strains of gastrointestinal bacteria. Further evidence for the specificity of these probes was obtained when it was found that they fail to hybridize or to amplify PCR products from whole fecal DNA isolated from fresh stool samples from an individual known not to be colonized with oxalate-degrading bacteria (Sidhu et al., 1997a).

Taxonomic Comments

Similarity values based on 16S rRNA sequences (1440 nucleotides) that allow *Oxalobacter* (represented by strain OxCR of *O. formigenes*) to be compared with other selected species are given in Table BXII.β.15. The corresponding phylogenetic tree (Fig. BXII.β.11) illustrates that strains of *Oxalobacter* within the class *Betaproteobacteria* share a specific relationship with the other genera currently in the *Oxalobacteraceae* family, *Telluria*, *Janthinobacterium*, and *Duganella*.

List of species of the genus Oxalobacter

1. **Oxalobacter formigenes** Allison, Dawson, Mayberry and Foss 1985b, 375[VP] (Effective publication: Allison, Dawson, Mayberry and Foss 1985a, 6.)

form.i.ge′ nes. M.L. n. *acidum formicum* formic acid; Gr. v. *gennaio* produce; M.L. adj. *formigenes* formic acid producing.

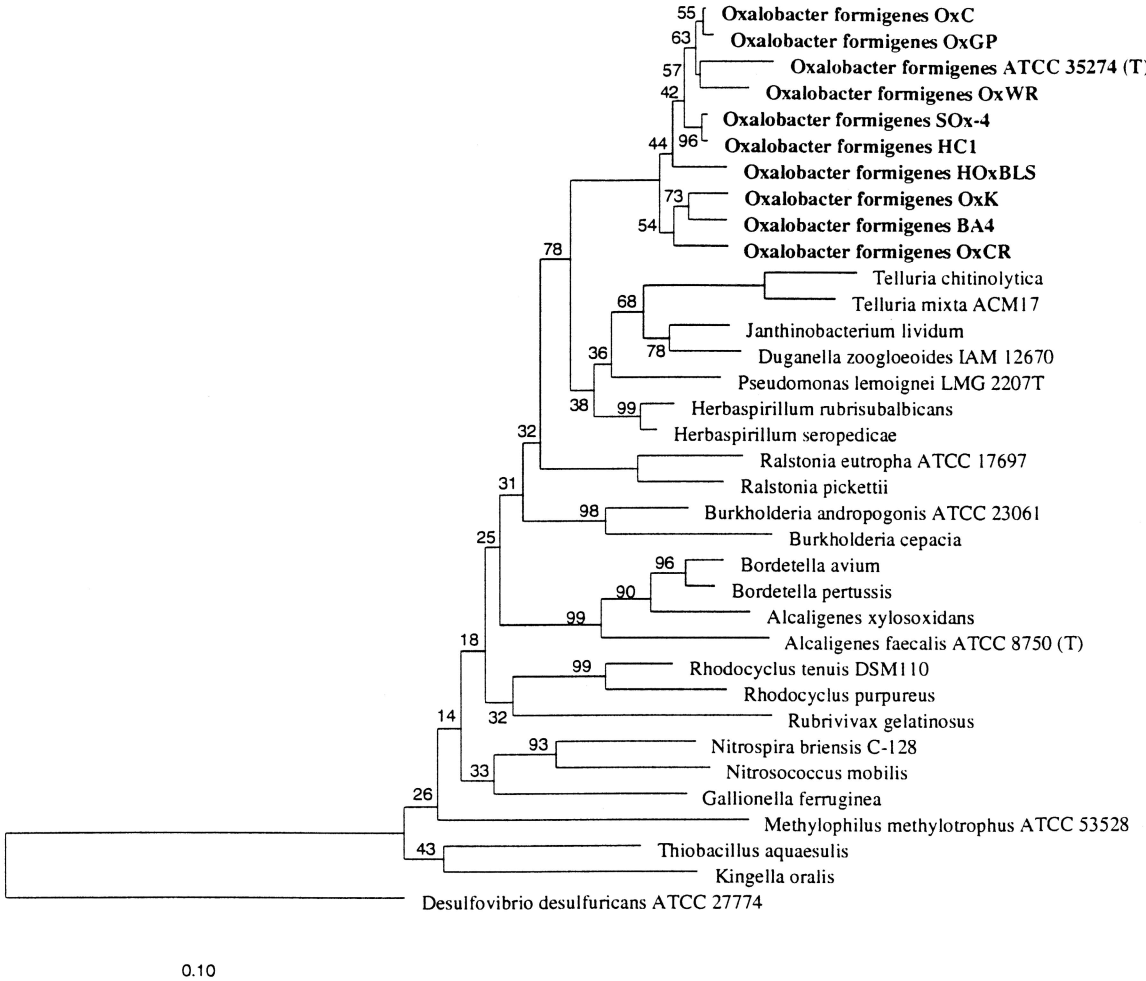

FIGURE BXII.β.11. Phylogenetic tree of *Oxalobacter formigenes* and other representatives of the *Betaproteobacteria* based on 16S rRNA sequence comparisons. The tree was constructed using the neighbor-joining method of Saitou and Nei (1987). Confidence limits were calculated by the bootstrap method using 100 samplings of the data set. Bar = 0.10 estimated substitutions per nucleotide position. *Desulfovibrio desulfuricans*, a member of the *Deltaproteobacteria*, was used to root the tree.

the following additional features. Rods 0.4–0.6 × 1.2–2.5 μm, with rounded ends, often curved, occurring singly, in pairs, or occasionally in chains, with curved cells leading to a spiral appearance. Flagella are not present.

High levels of 16S rRNA sequence similarity (96.6–99.8%) have been found for a group of strains of *O. formigenes* that includes both gastrointestinal and lake sediment strains (Table BXII.β.16).

The major total cellular fatty acids of representative strains of *O. formigenes* are given in Table BXII.β.17. When strains are arranged based on descending values for quantities of 19-carbon cyclopropane ($C_{19:0\ cyclo}$) fatty acids, a separation into two groups is evident. When these fatty acid profiles are compared using a cluster analysis program (Sasser, 1990b), the same grouping is supported (Fig. BXII.β.12). Assignment of strains into Groups I and II based on cellular fatty acid profiles generally agrees with grouping based on 16S rRNA sequences (Fig. BXII.β.11), except for

[a]Fatty acids separated as methyl esters by gas chromatography and identified as described by Sasser (1990a).

[b]nr, not reported.

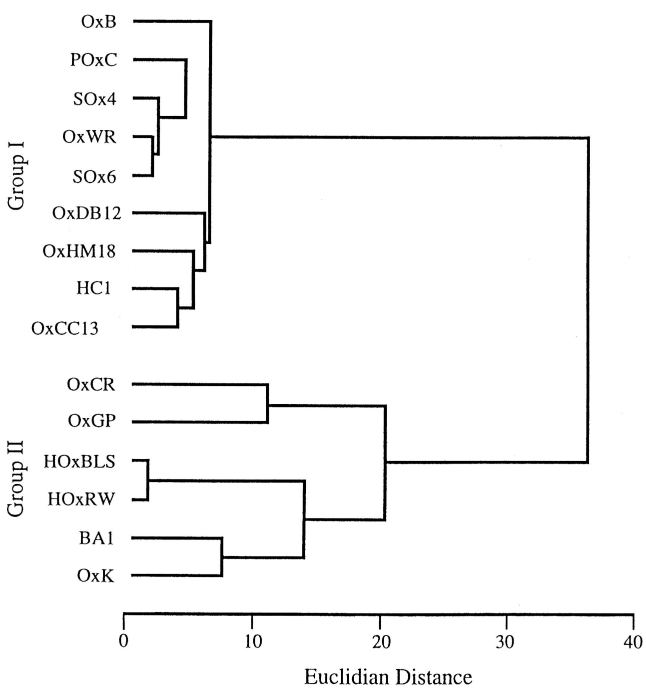

FIGURE BXII.β.12. Computer-generated dendogram (Sasser, 1990b) based on fatty acid profiles of strains of *Oxalobacter formigenes.*

strain OxGP, which fits with Group I based on rRNA sequences but is placed in Group II based on fatty acid profiles. Representative strains from both Group I and Group II contain both 12 and 14-carbon hydroxy fatty acids (Allison et al., 1985a). Comparisons of profiles of cellular proteins separated by polyacrylamide gel electrophoresis also support the distinctions between strains and groupings found by other methods (Jensen and Allison, 1994).

Results of both RFLP and PCR tests with oligonucleotide probes and primers also support the concept that *O. formigenes* strains can be separated into two main groups that fit with the above separations. Further separation of Group II strains into three subgroups has also been suggested (Sidhu et al., 1997a).

The mol% G + C of the DNA is: 48–51 (T_m).

Type strain: OxB, ATCC 35274.

GenBank accession number (16S rRNA): U49757.

Additional Remarks: GenBank accession numbers (16S rRNA) for other strains are U49754 (strain BA4), U49750 (strain HOxBLS), U49751 (strain SOx4), U49752 (strain OxWR), U49753 (strain OxGP), U49754 (strain OxCR), U49755 (strain OxC), U49756 (strain OxK), and U49758 (strain HC1).

2. **Oxalobacter vibrioformis** Dehning and Schink 1990, 320[VP] (Effective publication: Dehning and Schink 1989b, 82.)
vi.bri.o.for' mis. L. v. *vibrare* to vibrate; M.L. masc. n. *vibrio* that which vibrates; L. fem. n. *forma* shape, e.g., a curved cell; M.L. masc. adj. *vibrioformis* shaped like a curved cell.

The characteristics are as described for the genus, with the following additional features. Vibrioid rods 0.4 × 1.8–2.4 μm; motile by 1–2 polar flagella. Cells occur singly, in pairs, or in spiral chains. Growth occurs in freshwater or brackish water mineral medium. Temperature range: 18–35°C; optimum, 30–32°C. pH range, 5.6–8.3; optimum, 6.8–7.0. Catalase negative. No reduction of nitrate, sulfate, sulfite, thiosulfate, or sulfur. Indole is not formed from tryptophan. Does not hydrolyze urea, gelatin, or esculin. Acetate (1–2 mM) is required for growth. Formate is produced from oxalate. Cell yields are 1.2–1.3 g cell (dry wt) per mol of oxalate metabolized in growth medium that does not contain yeast extract and 1.6–1.7 g/mol in the presence of 0.05% yeast extract. The type strain was isolated from freshwater sediments, but similar strains have been isolated from marine sediments (Dehning and Schink, 1989b).

The mol% G + C of the DNA is: 51.6 ± 0.6 (T_m).

Type strain: WoOx3, DSM 5502.

Genus II. **Duganella** *Hiraishi, Shin and Sugiyama 1997b, 1251*[VP]

THE EDITORIAL BOARD

Du.ga.nel′la. M.L. dim. ending *-ella;* M.L. fem. n. *Duganella* named after P.R. Dugan, the American microbiologist who isolated the organism.

Straight or slightly curved rods, 0.6–0.8 × 1.8–3.0 μm. **Motile by single polar flagellum.** Gram negative. Nonsporeforming. **Aerobic,** having a strictly respiratory metabolism with O_2 as the terminal electron acceptor. Nitrate is not used as a terminal electron acceptor. No chemolithotrophic growth occurs with H_2. **In liquid media, either of two types of growth may occur: amorphous flocs (occasionally fingerlike), or dispersed growth with little or no formation of flocs. Colonies on nutrient agar are pale yellow to straw-colored.** Mesophilic. Neutrophilic. Chemoorganotrophic. Growth occurs on organic media or on mineral media supplemented with simple organic compounds. **Catalase and oxidase positive. Acid is produced oxidatively from glucose** and other carbohydrates. **Starch, gelatin, casein, and urea are hydrolyzed.** Major cellular fatty acids are $C_{16:0}$, $C_{16:1}$; $C_{10:0\ 3OH}$ is the major hydroxy fatty acid. Ubiquinone-8 is the sole respiratory quinone. Putrescine and hydroxyputrescine are intracellular polyamines. The genus is classified in the class *Betaproteobacteria*. Isolated from sewage and polluted water.

The mol% G + C of the DNA is: 63–64.

Type species: **Duganella zoogloeoides** Hiraishi, Shin and Sugiyama 1997b, 1251.

DIFFERENTIATION OF THE GENUS *DUGANELLA* FROM OTHER GENERA

Characteristics differentiating the genus *Duganella* from other related genera are listed in Table BXII.β.18.

TAXONOMIC COMMENTS

The type strain of *D. zoogloeoides* (Dugan strain 115) was originally classified in the genus *Zoogloea* as a strain of *Zoogloea ramigera* (Friedman and Dugan 1968). This placement was questioned by Unz (1984), who found extensive phenotypic dissimilarities between strain 115 and the type strain of *Zoogloea ramigera*. Phylogenetic studies by Hiraishi et al. (1997b) based on 16S rDNA sequencing have shown that strain 115 is not closely related to the type strain of *Z. ramigera*, but is instead located in a different cluster, with its closest relatives being the genus *Telluria* and the species *Pseudomonas lemoignei* (for which a new genus, *Paucimonas*, has been proposed by Jendrossek (2001). In this 2nd edition of the *Manual*, the genus *Duganella* is classified in the class *Betaproteobacteria*, order *Burkholderiales*, and the family *Oxalobacteraceae*. Other genera belonging to this family include *Oxalobacter*, *Herbaspirillum*, *Janthinobacterium*, *Massilia*, and *Telluria*.

growth. Forms an ester-like, sweet odor when grown with organic acids. The following carbohydrates are used as carbon sources, and acid is formed from them oxidatively: L-arabinose, D-xylose, D-glucose, D-fructose, D-galactose, D-mannose, maltose, sucrose, cellobiose, lactose, and glycogen. No growth or acid production occurs on D-ribose, L-rhamnose, glycerol, D-mannitol, D-sorbitol, or inositol. The following noncarbohydrates are used: pyruvate, citrate, succinate, fumarate, malate, malonate, tartrate, ethanol, alanine, aspartate, asparagine, glutamate, and proline. No or little growth with formate, acetate, propionate, butyrate, caproate, caprylate, methanol, propanol, benzoate, *p*-hydroxybenzoate, glycine, histidine, arginine, lysine, ornithine, or tryptophan. Putrescine and hydroxyputrescine are intracellular polyamines.

The mol% G + C of the DNA is: 63-64 (method not reported).

Type strain: Dugan 115, ATCC 25935, IAM 12670.

GenBank accession number (16S rRNA): D14256.

Additional Remarks: The type strain shows two types of colonies, designated A and B. Colonies of the A type are glistening, convex, viscous, and cream to straw colored. The organisms show dispersed growth rather than floc formation when cultured in complex peptone-containing media with shaking, but they do produce flocs when cultured in a chemically defined medium supplemented with organic acids. In contrast, colonies of the B type are tough, leathery, dry, wrinkled, and pale yellow. Flocs are produced in both complex and chemically defined media and are amorphous, although occasionally flocs with fingerlike projections occur. The A and B types give 93–102% DNA–DNA hybridization to each other.

Genus III. **Herbaspirillum** *Baldani, Baldani, Seldin and Döbereiner 1986a, 90^VP emend. Baldani, Pot, Kirchhof, Falsen, Baldani, Olivares, Hoste, Kersters, Hartmann, Gillis and Döbereiner 1996, 808*

José Ivo Baldani, Vera Lúcia Divan Baldani and Johanna Döbereiner

Her.ba.spi.ril' lum. L. fem. n. *herba* herbaceous, seed-bearing plant that does not produce persistent woody tissue; M.L. dim. neut. n. *spirillum* small spiral; *Herbaspirillum* small, spiral-shaped bacteria from herbaceous, seed-bearing plants.

Cells are generally **vibrioid**, sometimes spirilloid, approximately **0.6–0.7 μm in diameter**. The cell length varies from 1.5–5.0 μm depending on the culture medium. **Gram negative.** Motile, having 1–3 flagella at one or both poles. The organisms have a strictly **respiratory type of metabolism**, and sugars may be oxidized but not fermented. **The three named species presently included in the genus have the ability to fix atmospheric N_2 under microaerobic conditions** and grow well with N_2 as the sole nitrogen source, even in the presence of 10% sucrose. **Oxidase and urease positive.** Catalase variable or weak. Salts of organic acids such as malate, pyruvate, succinate and fumarate are the favored carbon source for NH_4^+ or N_2-dependent growth. Other carbon sources, such as glycerol, mannitol, D-glucose, and sorbitol, but not sucrose, are also catabolized. Optimal temperature, 30–34°C. **Optimal pH, 5.3–8.0.** Colonies on JNFb agar plates containing three times the usual concentration of bromothymol blue are smooth and white with blue or green centers after one week. Occur mainly in association with **graminaceous plants endophytically colonizing roots, stems and leaves**.

The mol% G + C of the DNA is: 60–65.

Type species: **Herbaspirillum seropedicae** Baldani, Baldani, Seldin and Döbereiner 1986a, 90 emend. Baldani, Pot, Kirchoof, Falsen, Baldani, Olivares, Hoste, Kersters, Hartmann, Gillis and Döbereiner 1996, 808.

Further descriptive information

Morphological features The flagellar arrangement is shown in Figs. BXII.β.13 and BXII.β.14. No lateral flagella have been observed for the species. Cells become very motile when close to air bubbles. Cells become elongated when grown in a semisolid medium containing glucose, galactose, arabinose, mannitol, or glycerol as the sole carbon source in the presence of 20 mM NH_4Cl (Figs. BXII.β.15 and BXII.β.16) (Baldani et al., 1992). With monosaccharides, *H. rubrisubalbicans* cells are more elongated and thinner, whereas *H. seropedicae* cells are wider. With organic acids such as malate, succinate, α-ketoglutarate, and fumarate, these characteristics have not been observed. The size of *H. seropedicae* and *H. rubrisubalbicans* cells are also different when they endophytically colonize sugarcane plant tissues. *H. seropedicae* has a cell size of 1.7 × 0.52 μm, whereas *H. rubrisubalbicans* cells are 2.1 × 0.45 μm (Olivares, 1997).

Cultural characteristics In semisolid JNFb medium[1], *H. seropedicae* and *H. rubrisubalbicans* form a fine white pellicle below the surface of the medium after incubation for 48 h at 30–34°C. The cells remain motile and vibrioid even after 1 week. Very pronounced swarming has been observed for *H. seropedicae* grown on nutrient agar (0.8% agar) plates at 35°C. *H. seropedicae* and *H. rubrisubalbicans* can grow and fix nitrogen in semisolid NFb medium, the medium routinely used to isolate *Azospirillum lipoferum* and *A. brasilense*. On this medium, the pellicles are similar to those of *Azospirillum*, except that the larger cell size of the latter differentiates *Herbaspirillum* cells under the microscope. No nitrogen fixation has been observed for either diazotrophic species grown at temperatures above 38°C, although growth can be observed at 41°C with inorganic nitrogen sources (Baldani et al., 1992).

The colonies are small, smooth, and whitish with blue or green centers when grown on JNFb agar plates containing three times

1. JNFb medium consists of L-malic acid, 5.0; K_2HPO_4, 0.6; KH_2PO_4, 1.8; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 0.1; $CaCl_2 \cdot 2H_2O$, 0.02; trace element solution ($Na_2MoO_4 \cdot 2H_2O$, 0.2 g; $MnSO_4 \cdot H_2O$, 0.235 g; H_3BO_3, 0.28 g; $CuSO_4 \cdot 5H_2O$, 0.008 g; $ZnSO_4 \cdot 7H_2O$, 0.024 g; distilled water, 1000 ml), 2.0 ml; bromthymol blue (0.5% aqueous solution (dissolve in 0.2 N KOH)), 2.0 ml; FeEDTA (1.64% solution), 4.0 ml; vitamin solution (biotin, 0.01 g; pyridoxine, 0.02 g; distilled water, 1000 ml), 1.0 ml; KOH, 4.5; pH adjusted to 5.8 with KOH. Bring the final volume to 1000 ml with distilled water. For a semisolid medium, add 1.75 to 1.9 g agar/l (agar should be dissolved before distribution into vials); for a solid medium, add 15.0 g agar/l.

the usual amount of the bromothymol blue indicator. On BMS agar plates, colonies are moist and small with brown centers. (The recipe for BMS agar is given in the chapter on the genus *Azospirillum* located in the family *Rhodospirillaceae.*)

There is no growth or nitrogen fixation activity in liquid nitrogen-free medium under air (20.9% O_2). However, nitrogenase activity can be detected under an air when grown in liquid JNFb or NFbHP medium supplemented with L-glutamate and L-glutamine, but not with L-serine, L-alanine, or ammonium chloride. (The recipe for NFbHP medium is given in the chapter on the genus *Azospirillum* in the family *Rhodospirillaceae.*) Nitrogen fixation occurs only when the nitrogen source is exhausted from the culture medium. Other nitrogen sources, such as L-histidine, L-lysine, L-arginine, and the amines methylammonium chloride, tetramethylammonium chloride, and ethylenediamine chloride, do not support growth or nitrogen fixation by *H. seropedicae* (Klassen et al., 1997). Strains from this species also assimilate or dissimilate nitrate to nitrite under oxygen limitation, but no NO_3^--

dependent anaerobic growth or visible gas production from nitrate is observed either in solid or semisolid medium. Small amounts of N_2O are detected when 10% acetylene is added. Most strains from *H. rubrisubalbicans* reduce nitrate to nitrite, but denitrification has not been observed.

Compounds that can serve as sole carbon and energy sources for N_2-dependent growth of *H. seropedicae* and *H. rubrisubalbicans* strains include malate, succinate, citrate, α-ketoglutarate, fumarate, pyruvate, *trans*-aconitate, mannitol, glycerol, sorbitol, glucose, galactose, and L-arabinose. *N*-acetylglucosamine is also used as a sole carbon source for N_2-dependent growth by *H. seropedicae* strains. On the other hand, *meso*-erythritol is used by strains of *H. rubrisubalbicans* when ammonium chloride is added to the medium.

Biochemical tests (API 50CH, 50 A, and 50AA kits) reveal that catabolizabled carbon sources can be used to differentiate these species. All tested strains use the following substrates: glycerol, D- and L-arabinose, D-ribose, D-xylose, D-glucose, D-fructose, D-mannose, mannitol, sorbitol, xylitol, D-lyxose, DL-lactate, DL-glycerate, DL-3-hydroxybutyrate, pyruvate, citrate, succinate, fumarate, L-leucine, L-threonine, L-aspartate, L-glutamate, α-ketoglutarate, adonitol, D-galactose, L-fucose, D-and L-arabitol, gluconate, 2-ketogluconate, propionate, isobutyrate, *n*-valerate, isovalerate, D- and L-malate, *meso*-tartrate, butyrate, DL-4-aminobutyrate, aconitate, mesoaconitate, *p*-hydroxybenzoate, L-proline, D-arabinose, 5-ketogluconate, acetate, caprate, amylamine, D-fucose, and tryptamine (Baldani et al., 1996). Whether all of these carbon sources can support N_2-dependent growth has yet to be determined. On the other hand, all tested strains are unable to use the following carbon sources: arbutin, salicin, D-cellobiose, maltose, sucrose, trehalose, inulin, D-tartrate, D-raffinose, starch, L-phenylalanine, DL-5-aminovalerate, betaine, glutarate, L-histidine, L-sorbose, dulcitol, esculin, glycogen, phthalate, oxalate, and maleate.

Strains from this genus have a strictly respiratory metabolism, and sugars are oxidized but not fermented. Acid is produced from L-arabinose under N_2-fixation conditions, although it has also been observed from other carbon sources, such as glucose, fructose, galactose, mannitol, lactose, glycerol, and sorbitol, when using biochemical tests. The efficiency of N_2-fixation for *H. seropedicae* strains as evaluated in semisolid NFb medium is 12–15 mg N_2 per g DL-malate or 13 mg N_2 per g mannitol. Vitamins or other growth substances are not required. The plant-growth substance indoleacetic acid has been detected in strains of *H. seropedicae* and *H. rubrisubalbicans* when tryptophan is added.

Genetic features Many of the *nif* genes (*nif A*, *B*, *HDK*), as well as *glnA* and *B*, and *ntrBC* genes have already been identified in the chromosome of *H. seropedicae* species (Pedrosa et al., 1997). Plasmids have also been detected for some *H. seropedicae* strains, but no function has been ascribed to them (Pedrosa, personal communication).

Plasmids of the IncP1 incompatibility group are stable in *Herbaspirillum seropedicae* and can be transferred to this species by conjugation, electroporation, and transformation (Vande Broek et al., 1996; Pedrosa et al., 1997). Plasmids from this group have also been transferred by conjugation to a strain of *H. rubrisubalbicans* (Gitahy et al., 1997).

Antigenic features Polyclonal antibodies against whole cells of the type species of *H. seropedicae* (strain Z67) and against *H. rubrisubalbicans* strain M4 have been very useful for discriminating the plant tissue colonization by *H. seropedicae* and *H. rubrisubalbicans* when applying immunogold labeling (Olivares et al., 1997). Purified antisera can discriminate among strains of both species by ELISA, and the immunotrapping technique using antibody-specific for *H. seropedicae* has permitted isolation of strains from sugarcane roots grown in the field (Reis et al., 1998).

Antibiotic susceptibility and resistance Strains of *H. seropedicae* and *H. rubrisubalbicans* are resistant to nalidixic acid, penicillin, and low concentrations of novobiocin and rifampicin. They are sensitive to several antibiotics, including streptomycin, kanamycin, spectinomycin, tetracycline, and chloramphenicol (Ureta et al., 1995; Baldani et al., 1986a).

Ecology The majority of the isolates of the genus *Herbaspirillum* has been isolated from graminaceous plants and show the ability to fix nitrogen. On the other hand, it has been shown that strains of *H. rubrisubalbicans* are mild pathogenic agents to some susceptible sugarcane varieties, causing "mottled stripe disease," mainly in crops highly fertilized with nitrogen. Experiments carried out in Brazil have shown that all commercial varieties are resistant to this disease, and neither *H. seropedicae* nor *H. rubrisubalbicans* strains cause the characteristic symptoms when artificially inoculated into leaves by injection (Olivares et al., 1997). In addition, strains of *H. seropedicae* and *H. rubrisubalbicans* cause "red stripe disease" in *Pennisetum purpureum* as well as in sorghum bicolor, although symptoms are very mild in sorghum leaves inoculated artificially with these bacteria (Pimentel et al., 1991; Olivares et al., 1997). However, symptoms are not observed in maize plants inoculated artificially with *H. seropedicae* and *H. rubrisubalbicans* strains (Olivares, 1997).

The ecological distribution of *Herbaspirillum seropedicae* and *H. rubrisubalbicans* has so far been restricted to tropical areas, where they have been found in numbers varying from 10^{2}–10^{7} cells/g of fresh plant tissues. Strains of *H. seropedicae* were first isolated from washed, surface-sterilized roots of maize, sorghum, and rice grown in two different soils in Rio de Janeiro State, as well as from maize plants grown in a Cerrado soil in Brasilia, DF, Brazil (Baldani et al., 1986a). A few isolates have been obtained from rhizosphere soil (Baldani et al., 1986a). Since it is now known that *H. seropedicae* does not survive well in soil and could not be found in 10 different soil samples free of roots collected around Seropédica (Olivares et al., 1996), we suspect that small root pieces were present in the rhizosphere soil utilized by Baldani et al. (1986a). In addition, *H. seropedicae* has been isolated from roots and stems of *Saccharum* spp. and roots of *Echinola crusgalli*, *Pennisetum purpureum*, *Panicum maximum*, *Digitaria decumbens*, *Brachiaria decumbens*, and *Melinis minutiflora* (Olivares et al., 1996). In contrast, *H. rubrisubalbicans* has been isolated from roots, stems, and leaves of sugarcane plants as well as from roots of *Digitaria insularis*, a weed plant grown in the sugarcane field. No isolates of *H. seropedicae* and *H. rubrisubalbicans* could be found in many samples from seven different plant families: Compositae, Molluginaceae, Sterculaceae, Cyperaceae, Portulacaceae, Leguminosae, and Cucurbitaceae (Olivares et al., 1996). One isolate resembling *H. rubrisubalbicans* has been identified in banana plant material (Weber et al., 1997). One isolate of *H. seropedicae* and one resembling *H. rubrisubalbicans* have been identified in banana plant material (Weber et al., 1999).

Electron-microscopic analysis shows that *H. rubrisubalbicans* colonizes the xylem, intercellular, and substomatal cavities of a mottled-stripe-susceptible sugarcane variety, in which the bacteria are restricted to microcolonies encapsulated within membranes of plant cell origin (Olivares et al., 1997; Fig. BXII.β.17). Colonizations in intercellular spaces and xylem have also been found

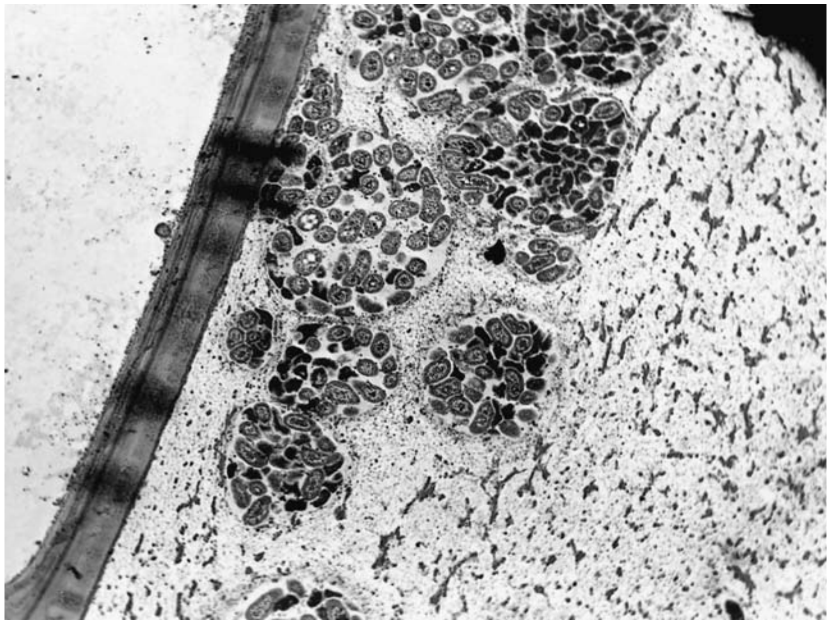

FIGURE BXII.β.17. Transmission electron micrograph (TEM) of xylem vessel from the leaf of a sorghum plant inoculated with *Herbaspirillum rubrisubalbicans* ATCC 19308 showing the microcolonies close to the walls of the vessels and that are surrounded by host-derived gums. (Reprinted with permission from E.K. James and F.L. Olivares, Critical Reviews in Plant Sciences *17:* 77–119, 1997, ©CRC Press, Boca Raton.)

for *Herbaspirillum* spp. in sugar cane roots (Olivares et al., 1997). *H. seropedicae* has also been localized within intercellular cavities of rice seeds and roots (Baldani et al., 1994).

Field inoculation experiments have shown yield increases of maize inoculated with *H. seropedicae* strains (Pereira et al., 1988). Increase of dry weight and grain yield has been observed in rice plants inoculated with selected strains of *H. seropedicae* (Döbereiner and Baldani, 1998).

Enrichment and Isolation Procedures

Serial dilutions (0.1 ml) of root, stem, or leaf samples are inoculated into 10-ml cotton-plugged serum vials containing 5 ml of semisolid JNFb medium and incubated for 1 week at 32°C. Smashed pieces (5–8 mm long) of plant tissues can also be used, but the incubation time should be only 40–48 h. For vials exhibiting a fine white pellicle, cells are examined under the microscope for the presence of small, curved rods (0.6–0.7 × 4–6 μm) that move faster close to air bubbles. After a second transfer to JNFb semisolid medium and incubation for 24–48 h, cultures are streaked out on a solid JNFb medium containing 20 mg/l yeast extract and three times the bromothymol blue concentration of the JNFb medium. On these plates, *H. seropedicae* and *H. rubrisubalbicans* form small, moist colonies with a green or dark blue center (different from the white colonies of *Azospirillum lipoferum* and *A. brasilense*). For final purification, single colonies are again transferred to the JNFb semisolid medium, and cells from the typical pellicle are streaked onto BMS agar plates, on which moist, smooth and small brownish colonies develop. Colonies are selected and stored for further identification (Döbereiner et al., 1995).

Maintenance Procedures

Stock cultures can be maintained on JNFb or BMS medium under a layer of sterilized mineral oil in tubes tightly sealed with rubber caps. Under these conditions, *H. seropedicae* remains viable at room temperature for more than 12 years.

For routine use in the laboratory, it is recommended to maintain duplicate vials and subculture strains from time to time (e.g., every 6 months, with maintenance at room temperature). Strains can also be maintained in glycerol at −20°C by mixing equal volumes of sterilized glycerol and washed, resuspended cells from a 48-h-old culture grown in liquid JNFb medium (containing 20 mg of yeast extract and 5 mM ammonium chloride or sodium glutamate).

Strains can also be kept lyophilized for many years. Cells grown on slant JNFb medium, with malic acid replaced by D-glucose, for 48–72 h at 30°C are suspended in 2 ml of a 10% sucrose solution and 5% peptone in 100 ml water. Aliquots (0.2 ml) are then distributed into lyophilization ampoules and lyophilized.

Procedures for Testing Special Characters

***Meso*-erythritol and *N*-acetylglucosamine as carbon sources for growth that is dependent on nitrogen fixation or inorganic nitrogen** A loopful of culture grown in semisolid JNFb medium is inoculated into a vial of semisolid JNFb medium (in which malate is replaced by 0.5% *meso*-erythritol plus 1 g of NH_4Cl or 0.5% *N*-acetylglucosamine). *H. seropedicae* forms a fine pellicle on the surface of a semisolid medium containing *N*-acetylglucosamine after incubation at 32°C for 48 h, but no growth is observed in the presence of *meso*-erythritol. On the other hand, *H. rubrisubalbicans* forms a typical pellicle in the presence of *meso*-erythritol plus NH_4Cl, but not with *N*-acetylglucosamine as a carbon source. API galleries (API 50CH, API 50AO, and API 50AA; bioMérieux, Montalieu-Vercieu, France) can also be used to distinguish *H. seropedicae* from *H. rubrisubalbicans.*

Oligonucleotide probes Probe HS (5′-GTC CCG GTT TTT GCA TCG A-3′) and probe HR (5′-TAG TCG GTT TTT GCA

TCG A-3′) are species-specific for a highly variable stretch of helix 55–59 of the 23S rRNA of *H. seropedicae* and *H. rubrisubalbicans*. Bulk nucleic acids are isolated from strains, cultivated overnight in DYGS liquid medium, and transferred to a positively charged nylon membrane via spot blotting. Hybridization with radioactive or non-radioactive DIG-labeled probes is performed for 2–12 h (radioactive) or 16 h (nonradioactive) at 52°C according to the method of Kirchhof et al. (1997b). Hybridization signals are detected by autoradiography.

Differentiation of the genus *Herbaspirillum* from other genera

The morphological, physiological and genetic characteristics that differentiate *Herbaspirillum* from other diazotrophic species within the class *Betaproteobacteria* and from *Azospirillum brasilense* are shown in Table BXII.β.19.

Taxonomic Comments

This genus *Herbaspirillum* constitutes a separate rRNA cluster within the class *Betaproteobacteria*. Comparison of many bacteria within this group based on the $T_{m(e)}$ values of the DNA–rRNA hybridization experiments has shown that *Herbaspirillum* has a very close relationship to the genus *Janthinobacterium*. However, *Janthinobacterium* has the lowest $T_{m(e)}$ value within this rRNA cluster and because of its phenotypic distinction from the other members of this rRNA branch, including its inability to fix nitrogen, it has been maintained as a separate genus. The DNA–DNA hybridization experiments also confirm the results, since they show a very low degree of similarity with the *Herbaspirillum* species. More recently, a comparison of the 16S rRNA full sequence from *H. seropedicae* with those of several other non-nitrogen-fixing bacteria from the *Betaproteobacteria* has shown that this species, along with *Oxalobacter formigenes*, forms a separate lineage in the *Betaproteobacteria* (Sievers et al., 1998).

Other nitrogen-fixing bacteria are also found within the *Betaproteobacteria*, including the species *Burkholderia vietnamiensis*, *Azoarcus indigens*, and *Alcaligenes faecalis*. Although they share the ability to fix nitrogen, they have several other distinguishable phenotypes and genetic aspects that maintain them as separate species from the genus *Herbaspirillum*. *B. vietnamiensis* is able to use glucose, caprate, and itaconate as carbon sources, as does *Herbaspirillum*. However, in contrast to the latter genus, it is urease negative, the cells are not curved, the optimal temperature for growth is much lower, and it has been isolated mainly from rhizosphere rice roots. The mol% G + C is 66.9–68.1, which is higher than the 60–65 mol% G + C value established for *Herbaspirillum* species. The genus *Herbaspirillum* has some characteristics similar to those of *Azoarcus indigens*, such as cell shape, vibrioid movement, and an ability to use malic acid. However, *A. indigens* has a much higher oxygen tolerance for N_2 fixation (6.5%), in contrast to the 2.5% observed for the *Herbaspirillum*. In addition, it has a much higher optimal temperature for growth (40°C) and has been found associated only with Kallar grass plants. Although the $T_{m(e)}$ values show that they belong to the same rRNA superfamily, they are quite separate based on the DNA–rRNA hybridization dendrogram and therefore should not be included in the same genus. The other nitrogen-fixing species within the *Betaproteobacteria* has been identified as *Alcaligenes faecalis*. It has also been isolated from rice plants (You et al., 1991) and has an oxygen tolerance for N_2 fixation, size, and mol% G + C very close to those of *Herbaspirillum*.

Due to the similar shape, vibrioid movement, and mol% G

TABLE BXII.β.19. Differential morphological and physiological characteristics of the genus *Herbaspirillum*, selected diazotrophic species within the class *Betaproteobacteria*, and *Azospirillum brasilense* (class *Alphaproteobacteria*)[a]

[b]Data from Reinhold-Hurek et al. (1993b).

[c]Date from Döbereiner (1991).

[d]Data from Gillis et al. (1995).

[e]In liquid medium, the cells possess only single polar flagella, but on agar media, several lateral flagella of shorter wavelength also occur.

[f]According to the experiments carried out by Vande Broek et al. (1996).

[g]A few strains are of clinical origin.

+ C content of DNA, *Herbaspirillum seropedicae* was provisionally placed into the genus *Azospirillum* (Baldani et al., 1984). However, results from RNA–RNA hybridization experiments comparing several strains of *H. seropedicae* with the three known species of *Azospirillum* and other possibly related N_2-fixing bacteria yielded very low RNA similarity values (<20%) (Falk et al., 1986). These differences were also confirmed by analysis of the SDS-PAGE membrane-protein pattern of strains of both genera: a characteristic major band at 37.5 kDa occurs only in *H. seropedicae* strains (Dianese et al., 1989). rRNA sequence analysis has shown that the genus *Herbaspirillum* belongs to the *Betaproteobacteria*, whereas the *Azospirillum* species were grouped into the *Alphaproteobacteria*. Even though *H. seropedicae* species show some physiological and morphological characteristics similar to those of *Azospirillum brasilense*, the genetic data show that it should not be included in the genus *Azospirillum*.

The genus *Herbaspirillum* was expanded when biochemical, DNA–rDNA, and DNA–DNA hybridization studies showed that *Pseudomonas rubrisubalbicans*, the causative agent of the "mottled strip" disease in sugarcane, has a high degree of rRNA similarity to *Herbaspirillum* and should therefore be included in this genus (Gillis et al., 1991). These data were confirmed by additional features of *P. rubrisubalbicans*, including its ability to fix nitrogen, culminating with the reclassification of the species as *Herbaspirillum rubrisubalbicans* (Baldani et al., 1996).

DNA–DNA hybridization studies have shown that there are three distinct groups, i.e., species, of bacteria within the *Herbaspirillum* genus. High values of DNA–DNA hybridization (71–100%) have been observed for *H. seropedicae* and *H. rubrisubalbicans*, and the full sequences of the 16S rRNAs of the type strains from both species show a 99.2% similarity (Kirchhof et al., 2001).

On the basis of physiological properties, phylogenetic analysis comparing 16S rDNA sequences and DNA–DNA hybridization experiments with chromosomal DNA, Kirchhof et al. (2001) created a new species, *Herbaspirillum frisingense*, for nitrogen-fixing bacteria isolated from the C4-fibre plants, *Spartina pectinata, Miscanthus sinensis, Miscanthus sacchariflorus,* and *Pennisetum purpureum.* Nitrogen-fixing capability was examined by PCR amplification of the *nifD* gene and an acetylene reduction assay and was found with all isolates tested. The 16S rDNA sequence similarity to the other two *Herbaspirillum* species is 98.5–99.1%.

Acknowledgments

This chapter is dedicated to the memory of the late Dr. Johanna Döbereiner, the Brazilian soil microbiologist, who, during a long and distinguished career, identified and characterized many novel nitrogen-fixing bacteria associated with graminaceous plants.

Differentiation of the species of the genus *Herbaspirillum*

The differential characteristics of the species *Herbaspirillum* are indicated in Table BXII.β.20. Other characteristics of the species are presented in Table BXII.β.21.

Although the 16S rDNA sequence analysis of *H. seropedicae* and *H. rubrisubalbicans* shows a high degree of similarity between the two (99.2% Kirchhof et al., 2001), analysis of the hypervariable region of the 23S rDNA shows a higher degree of variation, allowing for the design of probes to differentiate between *H. seropedicae* and *H. rubrisubalbicans* (Kirchhof et al., 1997b).

List of species of the genus Herbaspirillum

1. **Herbaspirillum seropedicae** Baldani, Baldani, Seldin and Döbereiner 1986a, 90^{VP} emend. Baldani, Pot, Kirchoof, Falsen, Baldani, Olivares, Hoste, Kersters, Hartmann, Gillis and Döbereiner 1996, 808.
se.ro.ped' i.cae. L. gen. n. *seropedicae* of Seropédica, Rio de Janeiro, Brazil, where the species was first isolated.

The characteristics are as described for the genus and in Tables BXII.β.20 and BXII.β.21.

Cells are vibrioid and sometimes spirilloid and become motile when close to O_2 sources. Two polar flagella are generally found at one or both poles, and pronounced swarming is observed on soft nutrient agar at 35°C. Oxidase, urease, and catalase positive. All strains except LMG 2284 fix nitrogen under microaerobic conditions and grow well with N_2 as a sole nitrogen source. Optimal pH and temperature for N_2-dependent growth in semisolid JNFb medium are 5.8 and 34°C, respectively. N_2-fixation can also occur in liquid medium when L-glutamate or L-glutamine used as the sole nitrogen source is completely exhausted. Colonies on JNFb agar plates containing three times the usual concentration of bromothymol blue are small and moist with a green or dark blue center.

Salts of organic acids such as malate, fumarate, pyruvate, succinate, and *trans*-aconitate are favored carbon sources for both N_2- and NH_4-dependent growth, as are glucose, galactose, and L-arabinose. Fructose is not used for N_2-dependent growth. Growth and N_2 fixation occur in the presence of 10% sucrose. Vitamins and growth substances are not required. Sensitive to chloramphenicol, tetracycline, gentamicin, kanamycin, and streptomycin and resistant to penicillin, nalidixic acids, and low concentrations of novobiocin and rifampicin.

Habitats are roots, stems, and leaves of many members of the family Gramineae, but so far strains have not been isolated from soil, unless sorghum plants are used as trapping hosts. When artificially inoculated into leaves of sor-

TABLE BXII.β.20. Characteristics differentiating the species of the genus *Herbaspirillum*[a]

Characteristic	*H. seropedicae*	*H. frisingense*	*H. rubrisubalbicans*
Usual polar flagella arrangement	2 at one or both poles	Mostly two, occasionally 1 or 3; unipolar	Several polar
Carbon sources used for growth:

Survival in soil	Poor	nd	Poor
Habitat	Tissues of several grasses	Tissue of C-4 fiber plants	Only leaves of sugar cane
Mol% G + C of DNA	64–65	61–65	62–63

[a]For symbols, see standard definitions; nd, not determined; ∓, several strains positive but the majority of strains negative.

[b]Several strains are able to reduce nitrite to N_2O, but the majority of strains are negative.

[c]All species grow poorly in D-fructose when dependent on nitrogen fixation.

ghum, *H. seropedicae* causes a mild symptom of red stripe disease.

The mol% G + C of the DNA is: 64–65 (T_m).

Type strain: Z67, ATCC35892, BR 11175, DSM 6445.

GenBank accession number (16S rRNA): Y10146.

Additional Remarks: Reference strains: ATCC 35893 (BR11177, Z78); ATCC 35894 (BR 11178, Z152).

2. **Herbaspirillum frisingense** Kirchhof, Eckert, Stoffels, Baldani, Reis and Hartmann 2001, 166[VP]
fri.sin.gen' se. frisingense L. gen. n. of Frisinga, now known as Freising, Germany, town where the species was first isolated.

The characteristics are as described for the genus.

Cells are vibrioid rods, but smaller and have a single polar flagellum. This group forms a fine pellicle on the surface of the semisolid NFb or JNFb medium quite similar to that of the other species. Colonies on JNFb agar plates containing three times the concentration of bromthymol blue are small and moist with a green or dark blue center. Oxidase, urease, and catalase positive. Gelatin is not hydrolyzed. All strains catabolize *N*-acetylglucosamine, arabinose, caprate, citrate, glucose, gluconate, malate, mannose, mannitol, and phenylacetate, but not maltose or adipate, as determined by biochemical analyses. All isolates reduce nitrate to nitrite but not to N_2. Possess a cytochrome oxidase. N_2-dependent growth (subsurface pellicle) was also observed with arabinose, *N*-acetylglucosamine, malate, mannitol, and glucose. In contrast to *H. seropedicae*, these isolates do not use L-rhamnose or inositol as sole carbon sources. They also differ from *H. rubrisubalbicans* by the ability to

use *N*-acetylglucosamine but not *meso*-erythritol in the presence of NH_4Cl. Based on the sequence of a highly variable 23S rDNA stretch within domain III, an oligonucleotide probe named beta 20 (5′-GAT ACA AGA ACC GGG AC-3′) is used to distinguish *H. frisingense* from the other species of the genus.

Habitats are roots, stems, and leaves of the C-4 graminaceous plants *Spartina pectinata*, *Miscanthus sinensis*, and *Miscanthus sacchariflorus* grown in Germany and *Pennisetum purpureum* grown in Brazil.

The mol% G + C of the DNA is: 61–65 (T_m).

Type strain: DSM 13128, GSF30.

GenBank accession number (16S rRNA): AJ238358.

Additional remarks: Reference strains: DSM 13130 (strain Mb11) and ATCC 35894 (strain 75B).

3. **Herbaspirillum rubrisubalbicans** (Christopher and Edgerton 1930) Baldani, Pot, Kirchhof, Falsen, Baldani, Olivares, Hoste, Kersters, Hartmann, Gillis and Döbereiner 1996, 809[VP] (*Pseudomonas rubrisubalbicans* (Christopher and Edgerton 1930) Krasil'nikov 1949, 379; *"Phytomonas rubrisubalbicans"* Christopher and Edgerton 1930, 266.)
ru.bri.sub.al′ bi.cans. L. adj. *ruber* red; adj. *subalbicans* whitish; M.L. adj. *rubrisubalbicans* red-whitish, referring to the symptoms of mottled stripe disease.

Cells are slightly curved rods, motile by means of several polar flagella. Poly-β-hydroxybutyrate is accumulated. Colonies on 2% glucose–peptone agar are mucoid and similar to *H. seropedicae* when grown on JNFb agar plates. Oxidase positive. No hydrolysis of gelatin, starch, or Tween 80. Denitrification is negative, although most strains reduce nitrate to nitrite. Optimal pH and temperature for N_2-dependent growth in semisolid JNFb medium are 5.8 and 30°C, respectively, although growth can occur at temperatures as high as 40°C. N_2 is fixed as efficiently as by *H. seropedicae*. The favored carbon sources are those described for *H. seropedicae*. Growth and N_2 fixation occur in the presence of 10% sucrose, although this carbon source is not used (osmotolerance effect). The strains also do not use maltose, cellobiose, raffinose, salicin, and *meso*-inositol. The ability to tolerate high concentrations of these carbon sources was not tested. Sensitive to kanamycin, spectinomycin, and streptomycin and resistant to nalidixic acids and low concentrations of novobiocin and rifampicin.

Occurrence is apparently limited to sugar cane. Causes mottled stripe disease, mainly on sugar cane genotypes from regions in which high-nitrogen fertilizer applications are used. In addition, the organism can cause red stripe disease when artificially inoculated by injection into leaves of *Sorghum vulgare* and *Pennisetum purpureum*.

The mol% G + C of the DNA is: 62–63 (T_m).

Type strain: ATCC 19308, BR11192, DSM 9440, LMG 2286, NCPPB 1027.

GenBank accession number (16S rRNA): AB021424.

Other Organisms

A group, also called EF group 1, comprising two subgroups, 1a (8 strains) and 1b (14 isolates), and showing many physiological and genetics characteristics resembling *Herbaspirillum* was identified during the description of the *H. rubrisubalbicans* species. Subgroup 1a is differentiated from subgroup 1b by its ability to use *meso*-erythritol and benzoate as sole carbon sources. $T_{m(e)}$ (°C) values from the DNA–rRNA hybrids formed by the DNA hybridization of strains from this EF1 group with the 23S rRNA from *H. rubrisubalbicans* strain LMG 2286 vary from 77.0–79.3. These values are very close to those observed when strains of *H. seropedicae* were used (77.1–78.3). Because of the high level of DNA relatedness to the nitrogen-fixing species, this group has been tentatively included in the genus *Herbaspirillum* and has been provisionally called species 3. However, the correct taxonomic position of this group will be published elsewhere (Gillis, personal communication). This species has also been separated from other species based on its antigenic properties (Falsen, 1996). All of the strains are of clinical origin (i.e., wound, urine, otitis, gastric juice, respiratory tract, eye secretion, etc.) except for isolates LMG 2285, LMG 6421, and LMG 6416, which were isolated from sugarcane, sorghum, and maize plants, respectively, and previously described as *Pseudomonas rubrisubalbicans*. None of the strains fix nitrogen. The mol% G + C of the DNA of strain LMG 5523 is 61, as determined by the thermal denaturation method (De Ley and van Muylen, 1963) and calculated by the equation of Marmur and Doty (1962), modified by De Ley et al. (1970a).

Genus IV. Janthinobacterium *De Ley, Segers and Gillis 1978, 164,[AL] emend. Lincoln, Fermor and Tindall 1999, 1586*

MONIQUE GILLIS AND NIALL A. LOGAN

Jan.thin.o.bac.te′ ri.um. L. adj. *janthinus* violet-colored; Gr. n. *bakterion* a small rod; M.L. neut. n. *Janthinobacterium* a small, violet-colored rod.

Round-ended, straight rods, sometimes slightly curved, 0.8–1.5 × 1.8–6.0 μm, occurring singly and sometimes in pairs or short chains. Definite capsules are not evident, but intercellular slime may be produced. No resting stages are known. Gram negative, occasionally showing bipolar or barred staining and lipid inclusions. **Motile. Strict aerobes. Growth occurs from 4°C to about 30°C, with optimum growth at around 25°C.** Optimal pH 7–8, with no growth below pH 5. **Many strains produce the violet pigment violacein,** but strains producing partly pigmented or nonpigmented colonies are often encountered. Colonies on routine solid media are low convex and round. **Aerobic, having a strictly respiratory metabolism with oxygen as the terminal electron acceptor. Oxidase and catalase positive.** Chemoorganotrophs. Growth occurs on ordinary peptone media. Citrate and ammonium ions can be used as sole carbon and nitrogen sources, respectively. Small amounts of acid, but no gas, are produced

from glucose and some other carbohydrates. **The genus is characterized by the following major phospholipids**: phosphatidyl ethanolamine, phosphatidylglycerol, and diphosphatidylglycerol as polar lipids. **The major fatty acids** are $C_{16:0}$, $C_{16:1\ \omega7c}$, and $C_{17:0\ cyclo}$. Only $C_{10:0\ 3OH}$ and $C_{12:0\ 2OH}$ are synthesized; the $C_{10:0\ 3OH}$ are ester- and (presumably) amide-linked, and the $C_{12:0\ 2OH}$ fatty acids are (presumptively) ester-linked. Q-8 is the major respiratory lipoquinone. Occur in soil and water and are common in temperate climates and cold climates, but can also be isolated from diseased mushroom tissue.

The mol% G + C of the DNA is: 61–67.

Type species: **Janthinobacterium lividum** (Eisenberg 1891) De Ley, Segers and Gillis 1978, 164 (*Chromobacterium lividum* Bergey, Harrison, Breed, Hammer and Huntoon 1923a, 119; *Bacillus lividus* Eisenberg 1891, 81.)

Further descriptive information

Pigmentation and colony characteristics The genus *Janthinobacterium* was created to contain the former oxidative, psychrotrophic, violacein-producing species *Chromobacterium lividum* (Sneath, 1984b) and contained solely that species for several years. A second species—*Janthinobacterium agaricidamnosum*—was proposed by Lincoln et al. (1999) based on the results of a polyphasic study on a group of isolates that provoked soft rot on mushrooms. The new species does not form a violet pigment, although in older cultures, a buff, nonfluorescent pigment is seen; the colonies are also slightly mucoid. The texture is more viscous than for the species *J. lividum*. Consequently, the description of the genus has been emended.

The pigment violacein is produced by *J. lividum* on or in media containing tryptophan. It is soluble in ethanol, but not in water or chloroform, and is readily identified by spectrophotometry and by testing with routine reagents (see "Procedures for Testing for Special Characters" in the chapter *Chromobacterium*). Subcultures of pigmented strains may contain partially or completely nonpigmented colonies. A nonpigmented strain is most readily recognized by a colony morphology similar to that of a pigmented strain isolated at the same time under the same conditions. Once it has been confirmed as an oxidase- and catalase-positive, Gram-negative rod, such an isolate should be stained to determine the type of flagellation. If it possesses the characteristic polar and lateral flagella, it should then be subjected to tests that differentiate the four genera *Chromobacterium*, *Iodobacter*, *Janthinobacterium*, and *Vogesella*—all of which belong to the class *Betaproteobacteria* and can produce a violet pigment (Table BXII.β.22). Although young cultures of *Aeromonas*, *Pseudomonas*, and *Vibrio* spp. grown on solid media sometimes produce lateral flagella in addition to their usual polar flagella, they give patterns of results that differ from those for the violet-pigmented organisms in the differential tests.

The characteristic flagellar arrangement in *J. lividum* is best seen with cells from young cultures on solid media. The single polar flagellum is inserted at the tip of the cell, shows long, shallow waves, and often stains faintly. The lateral flagella are usually long and 1–4 in number, although up to eight may occur. They may be inserted subpolarly or laterally, usually show deep, short waves, and stain readily (see the chapter on *Iodobacter*, Fig. BXII.β.71).

Atypical strains of *J. lividum*, characterized by gelatinous, tough colonies and differing from typical *J. lividum* in several biochemical test reactions (Tables BXII.β.22 and BXII.β.24), represented 16% of the *J. lividum* isolates in the studies of Moss and Ryall (1981) and Logan (1989). Atypical strains may prove difficult to subculture or maintain in the laboratory, and until further strains are isolated and studied, *J. lividum* must be regarded as a heterogeneous species. However, Sneath (1984b) has found that the strains with gelatinous colonies (atypical strains) cross-reacted serologically with other *J. lividum* strains and do not notably differ from them in other ways. The similarity between *J. agaricidamnosum* and the atypical *J. lividum* strains has not been studied.

The second species, *J. agaricidamnosum*, causes soft rot disease on *Agaricus bisporus*, the cultivated mushroom. The cells are motile, but the type of flagellation has not been determined. *J. lividum* strains either cause only a slight necrosis on mushroom tissue blocks or have no effect. *J. agaricidamnosum* and representative strains of *J. lividum* have been studied intensively by Lincoln et al. (1999), and chemotaxonomic and phenotypic characteristics have been found to distinguish both species. Unfortunately, the atypical *J. lividum* strains were not included in this study, and thus it is not possible to decide if some of the atypical strains belong in *J. agaricidamnosum*.

Chemotaxonomic features Whole-cell fatty acid analyses (Moss et al., 1980) have been performed on both species and on their phylogenetic neighbors. Special methods were used, which allowed the selective hydrolysis of ester- and amide-linked fatty acids (B. Tindall, personal communication). The respiratory lipoquinones and polar lipids have also been studied (Lincoln et al., 1999).

Sensitivity to antibiotics Members of *J. lividum* are sensitive to a number of antibiotics (Table BXII.β.24). *J. agaricidamnosum* strains are sensitive to erythromycin (15 μg/disc), streptomycin (10 μg/ disc), tetracycline (30 μg/disc), and nalidixic acid (30 μg/disc).

Enrichment and Isolation Procedures

Isolation of *J. lividum* from soil may be accomplished by the method of Corpe (1951). A few crumbs of soil are placed in a Petri dish and 10–25 ml of sterile water is added. About 5–6 grains of heat-sterilized, polished rice are added, and the plates are closed and incubated at 20°C for several weeks. Incubation at 4-10°C may be advantageous. Strains can be isolated by plating from violet patches on the rice onto nutrient agar and incubating at 20°C. Instead of nutrient agar, 0.025% yeast extract in water-agar or a medium consisting of 1% mashed and strained boiled rice in 1.5% water-agar supplemented with L-tryptophan (25 mg/l) may be used to improve pigmentation. *J. lividum* can also be enriched and isolated on the same media as given in detail for *Chromobacterium* (see chapter on *Chromobacterium*). According to Moss and Ryall (1981), *Chromobacterium* spp. grow rapidly and can be selected on a citrate ammonium salt agar medium[1]. Koburger and May (1982) have recovered *J. lividum* from a variety of food samples only on Bennett's agar[2] at 25°C. They found higher counts in water and soil samples on this medium than on the medium of Ryall and Moss (1975) or on *Aeromonas* agar (Rippey and Cabelli, 1979). Maximal numbers of

1. Citrate ammonium salt agar is composed of (g/l): NaCl, 1.0; $MgSO_4 \cdot 7H_2O$, 0.2; $NH_4H_2PO_4$, 1.0; K_2HPO_4, 1.0; Ionoagar no. 2 (Oxoid), 15.

2. Bennett's agar consists of (g/l): tryptose, 5; trehalose, 5; yeast extract, 2; NaCl, 3; KCl, 2; $MgSO_4 \cdot 7H_2O$, 0.2; $FeCl_3 \cdot 6H_2O$, 0.1; bromothymol blue, 0.04.

TABLE BXII.β.22. Patterns of results in tests useful for differentiating typical and atypical strains of *Janthinobacterium lividum* from *Chromobacterium*, *Iodobacter*, and *Vogesella* species[a,b]

[a]Symbols: see standard definitions; nr, data not reported. Numbers in parentheses indicate the % of strains giving a positive reaction.

[b]Data from Logan (1989) with later amendments.

[c]Fluorescence on chalk agar (Starr et al., 1960) is determined with short wavelength illumination. All *Vogesella* strains exhibit very weak fluorescence.

[d]Only tested for the type strain.

[e]Some strains give no reaction in this test.

[f]Occasional strains are oxidative.

[g]Similar patterns of results are obtained with D-cellobiose and D-galactose.

[h]Similar patterns of results are obtained with D-sorbitol.

[i]Negative for the type strain (Grimes et al., 1997).

J. lividum have been isolated at 25°C from turbot gills (Muddaris and Austin, 1988) on a casein–tryptone medium.[3]

J. agaricidamnosum can be isolated by transferring samples of diseased mushroom tissue to sterile 0.25× Ringer's solution and inoculating 10-fold dilution series onto *Pseudomonas* agar F (PAF, Merck) and nutrient agar, with incubation at 25°C for 24 h. Single colonies are isolated from the dilution plates and cultured at 25°C on the appropriate media. Each isolate is first "white line tested" for identity as *P. tolaasii* (Wong and Preece, 1979), a common pathogen for mushrooms, and then tested on mushroom blocks in an initial pathogenicity test (Gandy, 1968). The isolates are plated on *Pseudomonas* isolation agar (PIA, Difco). The cultures are reported to die if left more than 10 d without subculturing.

J. lividum strains have been isolated and identified in microbial mats in Antarctica (Brambilla et al., 2001) and in wet silk thread that became violet in color (Shirata et al., 2000). The question has arisen as to whether violacein can be used to dye natural and synthetic fibers.

J. lividum JAC1 has also been described as producing metallo-β-lactamase upon exposure to β-lactams. The β-lactamase determinant encodes for a new member of the highly divergent subclass B3 lineage of metallo-β-lactamases (Rossolini et al., 2001).

Maintenance Procedures

Janthinobacterium lividum strains may survive for several years in dilute peptone water (0.1% peptone) at room temperature. They can also be preserved indefinitely by lyophilization or by freezing in nutrient broth containing 15% glycerol. Strains of *J. agaricidamnosum* can be stored freeze-dried or in liquid nitrogen. Working cultures must be subcultured weekly.

Procedures for Testing Special Characters

Methods for demonstrating special features in *J. lividum* (production of violacein, flagellar arrangement, growth temperature, oxidase reaction, oxidative attack of glucose, aerobic growth, acid production from carbohydrates, esculin hydrolysis, and lactate

3. Casein–tryptone medium (g/l): $CaCl_2$, 1.0; yeast extract, 1.0; beef extract, 5.0; casein, 6.0; tryptone, 2.0; agar no. 1, 15.0; aged sea water, 750 ml; pH 7.2.

[b]The following tests are negative for all strains: α-xyclodextrin, glycogen, *N*-acetyl-D-glucosamine, adonitol, D-arabitol, cellobiose, *i*-erythritol, α-D-lactose, D-melibiose, methyl-β-D-glucoside, monomethylsuccinate, *cis*-aconitic acid, citric acid, D-galactonic acid lactone, D-galacturonic acid, D-gluconic acid, D-glucosaminic acid, α-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, itaconic acid, quinic acid, D-saccharic acid, sebacic acid, glucuronamide, L-histidine, hydroxyl-L-proline, L-leucine, L-ornithine, L-phenylalanine, L-pyroglutamic acid, DL-carnitine, γ-aminobutyric acid, uridine, thymidine, phenylethylamine, putrescine, 2-amino-ethanol, and 2,3-butanediol.

[c]The following tests are positive for all strains: α-D-glucose, sucrose, methylpyruvate, formic acid, β-hydroxybutyric acid, bromosuccinic acid, alaninamide, L-alanylglycine, glycyl-L-aspartic acid, glycyl-L-glutamic acid, DL-glycerol phosphate, glucose-1-phosphate, and glucose-6-phosphate.

utilization) are described in the chapter on the genus *Chromobacterium*.

Janthinobacterium agaricidamnosum can be tested for pathogenicity on mushroom tissue blocks or on growing mushrooms. In the latter experiments, varying percentages of relative humidity (85–95%) have been applied, leading to the conclusion that there is a general trend in which no disease symptoms appear at below 71.5% relative humidity (Lincoln et al., 1999).

A special technique has been used by Lincoln et al. (1999) to study the release of ester-linked or amide-linked fatty acids.

Differentiation of the genus *Janthinobacterium* from other genera

Table BXII.β.22 presents characteristics differentiating typical and atypical strains of *Janthinobacterium* from the other violet-pigment-producing genera of the class *Betaproteobacteria*—i.e., *Chromobacterium*, *Iodobacter*, and *Vogesella*. The percentage fatty acid composition and some phenotypic characteristics that differentiate the genus *Janthinobacterium* from *Duganella*, *Herbaspirillum*, *Oxalobacter*, *Massilia*, and *Paucimonas* are listed in Table BXII.β.25.

Janthinobacterium is phylogenetically more closely related to the following organisms: *Duganella*, *Herbaspirillum*, *Telluria*, *Oxalobacter*, *Massilia*, and to *Pseudomonas lemoignei*, for which a new genus, *Paucimonas*, has recently been proposed (Jendrossek, 2001). *Oxalobacter* can be differentiated from the other genera by the lower mol% G + C of its DNA (48–51), its obligate anaerobic growth requirement, and its strict use of only oxalate and oxamate as sole sources of carbon for growth. *Telluria* can be differentiated from *Janthinobacterium*, *Duganella*, *Paucimonas*, and *Herbaspirillum* by its relatively high mol% G + C (67–72) and its ability to grow on starch and glycogen. Chemotaxonomically, the genera *Janthinobacterium*, *Paucimonas*, *Duganella*, *Massilia*, and *Herbaspirillum* can be differentiated from each other by their quantitative fatty acid compositions (See Table BXII.β.25). Moreover, *Duganella* is the only member of this group to exhibit flocculent growth; *Massilia* has a tendency to form flocs.

Taxonomic Comments

Sneath (1984b) described the genus *Chromobacterium* as containing two species: *C. violaceum* and *C. lividum*. The former species was fermentative and mesophilic, growing at 37°C, but not at 4°C, whereas the latter species was nonfermentative and psychrotrophic, with growth occurring at 4°C, but not at 37°C. Both species were described based on the numerical analysis of their phenotypic features. Sneath stressed that both groups were phenotypically very different from each other, but kept them in one genus because, at that time, no genomic results were available. Later genomic studies indicated that the two species differ too much to be contained in one genus, and the new genus *Janthinobacterium* was proposed for the former *Chromobacterium lividum* (De Ley et al., 1978; Sneath, 1984b). The phylogenetic affiliation was determined first by rRNA–DNA hybridization (De Ley et al., 1978) and later by 16S rDNA sequence analysis (Lincoln et al., 1999). *Janthinobacterium* is a member of the class *Betaproteobacteria*, in which it constitutes a cluster together with the genera *Herbaspirillum*, (Baldani et al., 1986a, 1996; Kirchhof et al., 2001) *Duganella* (Hiraishi et al., 1997b), *Oxalobacter* (Allison et al., 1985a; Dehning and Schink, 1989b), *Telluria* (Bowman et al., 1993b), *Massilia* (La Scola et al., 1998a), and *Paucimonas* (Jendrossek, 2001). The highest 16S rDNA sequence similarity is found among *Janthinobacterium*, *Herbaspirillum*, and *Duganella* (95–96.4%), raising the question as to whether the latter genera might be merged. Baldani et al. (1996) considered the single violacein-producing species *J. lividum* to be phenotypically different enough from *Herbaspirillum* to remain in a separate genus. With the inclusion of a second species in *Janthinobacterium*, Lincoln et al. (1999) raised this question again and performed a broad chemotaxonomic study within this rRNA cluster. The results obtained indicated clearly that the genera *Herbaspirillum*,

[a]Symbols: see standard definitions; nr, data not reported. Numbers in parentheses indicate the % of strains giving a positive reaction.

Duganella, *Oxalobacter*, and *Paucimonas* share several chemotaxonomic features, but that the genus *Janthinobacterium* has peculiar features that distinguish it from its neighbors and thus deserve to be maintained in a separate genus. Moreover, Lincoln et al. (1999) have shown that isolates from diseased mushrooms share 99% 16S rDNA sequence similarity with *Janthinobacterium lividum*, thereby leading to the inclusion of this non-violacein-producing group in the genus *Janthinobacterium*. The phenotypic (auxanographic) results, DNA–DNA hybridizations (only 35% DNA–DNA hybridization has been reported between the type strains of both species), and chemotaxonomic results (cyclo-fatty acids and polar lipids) have shown that these mushroom isolates belong in a separate species, for which the name *J. agaricidamnosum* was proposed. Consequently, the genus *Janthinobacterium* has been emended to contain these mushroom isolates as a new species.

The 16S rDNA similarity between *Janthinobacterium*, *Duganella*, *Herbaspirillum*, *Paucimonas*, *Telluria*, *Massilia*, and *Oxalobacter* ranges from 92.7–96.4%.

Differentiation of the species of the genus *Janthinobacterium*

The phenotypic and chemotaxonomic features that differentiate *J. lividum* and *J. agaricidamnosum* are given in Table BXII.β.24. Differential tests using the commercial Biolog GN and the API 50CH systems are listed in Tables BXII.β.23 and BXII.β.26.

List of species of the genus Janthinobacterium

1. **Janthinobacterium lividum** (Eisenberg 1891) De Ley, Segers and Gillis 1978, 164[AL] (*Chromobacterium lividum* Bergey, Harrison, Breed, Hammer and Huntoon 1923a, 119; *Bacillus lividus* Eisenberg 1891, 81.)
li'vi.dum. L. adj. *lividum* leaden-colored, dark blue.

The description of *J. lividum* is based on the studies of Leifson (1956), Sneath (1956, 1960), De Ley et al. (1978), and Logan (1989). The characteristics are as described for the genus and in Tables BXII.β.22, BXII.β.23, BXII.β.24, BXII.β.25, and BXII.β.26, with the following additional features. Pigmentation may be produced in concentric rings or in sectors within colonies, and subcultures may contain unpigmented colonies. Colonies may be butyrous, gelatinous, or rubbery or may comprise a gelatinous outer layer with butyrous or mucoid growth beneath. Growth in nutrient broth shows a violet ring at the junction of the liquid surface and the wall of the vessel; strains forming gelatinous or rubbery colonies may form a tough, violet pellicle in broth cultures.

Characteristics differentiating typical strains from atypical strains are listed in Tables BXII.β.22 and BXII.β.24.

Motile by means of a single polar flagellum and usually one or more subpolar or lateral flagella. Indole negative, Voges–Proskauer negative. Nitrate and nitrite are reduced, sometimes with visible gas production. Phosphatase positive. Arylsulfatase negative. Other characteristics are shown in Tables BXII.β.23, BXII.β.24, and BXII.β.25. Resistant to benzylpenicillin (10 μg/ml) and O/129 (2,4-diamino-6,7-diisopropyl pteridine) by disc diffusion method, (50 μg/disc).

Janthinobacterium lividum occurs in soil and water and is common in temperate and cold climates. It occasionally causes food spoilage, and these strains may produce active metalloproteinases (Dainty et al., 1978).

The mol% G + C of the DNA is: 61–67 (T_m).

Type strain: H-24, ATCC 12473, CCM 160, DSM 1522, NCIB 9130, NCTC 9796.

GenBank accession number (16S rRNA): Y08846.

2. **Janthinobacterium agaricidamnosum** Lincoln, Fermor and Tindall 1999, 1577[VP]
a.ga'ri.ci.dam.no.sum. L. masc. n. *agaricus* mushroom; L. adj. *damnosum* damaging; *agaricidamnosum* damaging mushroom.

The description of *J. agaricidamnosum* is based on the studies of Lincoln et al. (1999). The characteristics are as described for the genus and in Tables BXII.β.23, BXII.β.24, BXII.β.25, and BXII.β.26, with the following additional features. Low, convex, round, beige colonies are formed on solid media. Maximum growth temperature, 30°C; minimum, 2°C. No growth occurs below pH 5 or in media containing 2.9% NaCl. Acid is produced from glucose. Indole and Voges–Proskauer negative. Nitrate and nitrite are not reduced. No violet pigment is produced. Resistant to penicillin G (10 μg/disc) and vancomycin (30 μg/disc). The chemical composition is as described for the genus.

The type strain was isolated as the cause of soft rot disease of the cultivated mushroom *A. bisporus.*

The mol% G + C of the DNA is: 64.2 (T_m).

Type strain: W1r3, DSM 9628, NCPPB 3945.

GenBank accession number (16S rRNA): Y08845.

Genus V. **Massilia** *La Scola, Birtles, Mallet and Raoult 2000, 423[VP] (Effective publication: La Scola, Birtles, Mallet and Raoult 1998a, 2852)*

THE EDITORIAL BOARD*

Mas.sil' i.a. L. n. *Massilia* Latin name of Marseille, France.

Gram-negative nonsporeforming motile rods (1.0 × 3.0 μm). **Strictly aerobic**; catalase positive and oxidase negative. **Grow in 3% NaCl.** No denitrification. Produce arginine dihydrolase and urease. Hydrolyze esculin, gelatin, and starch. **No acid from carbohydrates.** Utilize L-alanine, L-arabinose, D-cellobiose, fumarate, D-galacturonate, gentisate, D-glucuronate, α-ketoglutarate, α-lactose, D-malate, L-malate, malonate, maltose, D-mannose, protochachuate, α-L-rhamnose, succinate, D-tagatose, and D-xylose. Does not utilize D-alanine, L-aspartate, citrate, D-fructose, D-galactose, D-glucose, L-glutamate, DL-glycerate, β-hydroxybutyrate, DL-lactate, D-melezitose, mucate, D-saccharate, L-serine, sucrose, L-tartrate, or D-trehalose. Major fatty acids are $C_{16:1\ \omega7c}$, $C_{16:0}$, $C_{18:1}$, $C_{12:0}$, $C_{10:0\ 3OH}$, $C_{14:0}$, and $C_{12:0\ 2OH}$.

The mol% G + C of the DNA is: 64 ± 1.8 (HPLC).

Type species: **Massilia timonae** La Scola, Birtles, Mallet and Raoult 2000, 423 (Effective publication: La Scola, Birtles, Mallet and Raoult 1998a, 2852).

FURTHER DESCRIPTIVE INFORMATION

Colonies are straw-colored; flocs or films form in liquid medium; older cultures at 37°C may contain filamentous cells. Growth occurs on MacConkey agar, Columbia agar containing 5% sheep blood, chocolate agar, and trypticase soy agar.

The organism was isolated from the blood of an immunocompromised patient suffering from meningoencephalitis. The infection was viewed as opportunistic because the 16S rDNA sequence obtained from the organism was most similar to those of the soil microorganisms *Telluria mixta*, *Telluria chitinolytica*, and *Duganella zoogloeoides*, which are not known to be pathogenic to humans. Other characteristics, including biochemical test profiles and mol% G + C of the DNA, were consistent with this relationship.

ENRICHMENT AND ISOLATION PROCEDURES

The organism was isolated from blood using an automated blood culture system (BACTEC NR-860).

**Editorial Note:* The description in this chapter is based on a single strain—the type strain. Lindquist, et al., 2003, J. Clin. Microbiol. *41:* 192–196 reported the isolation of additional strains and proposed an emended species description to include them.

List of species of the genus Massilia

1. **Massilia timonae** La Scola, Birtles, Mallet and Raoult 2000, 423[VP] (Effective publication: La Scola, Birtles, Mallet and Raoult 1998a, 2852)
   ti.mon.ae. L. gen. n. belonging to Timone, because the organism was isolated from a patient at L'Hôpital de la Timone.

   The species description and the genus description are identical.

   The mol% G + C of the DNA is: 64 ± 1.8 (HPLC).
   Type strain: UR/MT95, CIP 105350.
   GenBank accession number (16S rRNA): U54470.

Genus VI. **Telluria** *Bowman, Sly, Hayward, Spiegel and Stackebrandt 1993b, 123[VP]*

LINDSAY I. SLY AND MARK FEGAN

Tel.lu' ri.a. L. fem. n. *Tellus* a Roman goddess of the earth, also the ground or earth; M.L. fem. n. *Telluria* from the earth.

Cells are **rod-shaped**, 2–3 × 0.5–1.0 μm. **Gram negative**. Filamentous cells up to 30 μm long are formed occasionally in older cultures. **Cells occur singly, in pairs, or in short chains**. **Motile**. Exhibit **mixed flagellation**; cells in liquid media possess a single polar flagellum, while on solid media additional lateral flagella of shorter wavelength occur. **Accumulate poly-β-hydroxybutyrate**. **Strictly aerobic**. **Oxidative** metabolism. **Catalase and oxidase positive**. Surface pellicle formed in static liquid cultures. **Chemoheterotrophic**. Unable to grow chemolithotrophically with hydrogen. **Denitrification does not occur**. **Arginine dihydrolase is absent**. Good growth occurs on media containing carbohydrates and an inorganic or organic combined nitrogen source. Poor growth occurs on media lacking carbohydrates. **NaCl sensitive**; completely inhibited by NaCl concentrations greater than 1.5%, and only poor growth occurs at an NaCl concentration of 0.5%. **Utilize complex polysaccharides**, including starch and xylan. Cellulose is not hydrolyzed. Hydrolyze gelatin, casein, DNA, esculin, and Tween 40, Tween 60, and Tween 80. Produce phosphatase and arylsulfatase. Grow well at temperatures between 20° and 45°C and optimally at 30–35°C; optimal growth occurs at pH 7.0. The **major quinone is ubiquinone 8**. Belongs to the *Betaproteobacteria.* The only known habitat is soil, particularly the rhizosphere.

The mol% G + C of the DNA is: 67–72.

Type species: **Telluria mixta** (Bowman, Sly and Hayward 1989) Bowman, Sly, Hayward, Spiegel and Stackebrandt 1993b, 124 (*Pseudomonas mixta* Bowman, Sly and Hayward 1989, 205.)

FURTHER DESCRIPTIVE INFORMATION

The species of *Telluria* are characterized by their ability to degrade a range of complex carbohydrates. *T. mixta* strains are able to degrade dextran, starch, inulin, pectate, and xylan, but are

unable to degrade cellulose or chitin. A few strains attack alginate and xanthan gum. The first isolate of *T. mixta* (*Pseudomonas* sp. ACM 733, UQM 733, ATCC 49107) was isolated from a sugar cane rhizosphere in Queensland, Australia (Richards and Streamer, 1972). A subsequent taxonomic study of similar dextranolytic strains led to the description of *Pseudomonas mixta* (Bowman et al., 1988, 1989), later transferred to the new genus *Telluria* based on phylogenetic evidence (Bowman et al., 1993b). The dextranases and other carbohydrate-degrading enzymes produced by strain UQM 733 have been studied extensively (Richards and Streamer, 1972; Covacevich and Richards, 1978, 1979). The only known strain of *T. chitinolytica* was isolated from soil in Israel and demonstrated to have bionematicidal activity and potential for the biocontrol of the root-knot nematode *Meloidogyne javinica* (Spiegel et al., 1991).

A distinctive morphological characteristic of the genus is mixed flagellation exhibited when cultures are grown on solid agar media (Bowman et al., 1988). Cells possess a single polar flagellum of long wavelength (2.6 μm) and at least two lateral flagella of shorter wavelength (1.2 μm) (Fig. BXII.β.18). Cells usually possess uniform morphology, but occasionally may be distended by PHB inclusions or form longer cells (Fig. BXII.β.19).

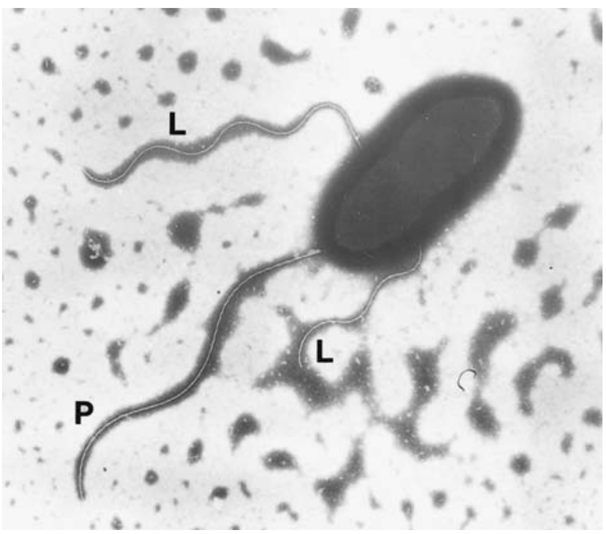

FIGURE BXII.β.18. Electron micrograph of *T. mixta* ACM 1762 showing mixed flagellation. *P*, polar; *L*, lateral flagellum. (Reprinted with permission from J.P. Bowman et al., Systematic and Applied Microbiology *11:* 53– 59, 1988, ©Urban & Fischer Verlag GmbH & Co, KG, Jena, Germany.)

Telluria strains have a predilection for carbohydrates and tricarboxylic cycle intermediates as sources of carbon and energy, although *T. chitinolytica* is slightly less biochemically versatile than *T. mixta*. The spectrum of polysaccharide degradation by *T. chitinolytica* is quite different from that of *T. mixta*, the former able to hydrolyze chitin, but not dextran or pectate (Table BXII.β.27).

Both species utilize D-xylose, L-rhamnose, D-fructose, D-galactose, D-glucose, D-mannose, D-melezitose, maltose, sucrose, cellobiose, trehalose, inulin, starch, xylan, gluconate, 2-ketogluconate, glucuronate, galacturonate, mucate, saccharate, β-hydroxybutyrate, malonate, succinate, DL-lactate, fumarate, DL-malate, pyruvate, L-(+)-tartrate, citrate, D-alanine, L-alanine, L-aspartate, and L-glutamate as sole carbon and energy sources. Unable to utilize D-ribose, acetate, propionate, isobutyrate, valerate, isovalerate, caproate, pelargonate, caprate, oxalate, glutarate, adipate, pimelate, suberate, azelate, sebacate, maleate, D-(−)-tartrate, meso-tartrate, citraconate, itaconate, mesaconate, levulinate, ethanol, propanol, butanol, 1,2-ethanediol, 1,3-propanediol, 2,3-butanediol, adonitol, *meso*-erythritol, *meso*-inositol, sorbitol, anthranilate, *p*-aminobenzoate, benzylamine, sarcosine, betaine, β-ala-

TABLE BXII.β.27. Differential and descriptive characteristics of the species of *Telluria*[a]

Characteristic	*T. mixta*	*T. chitinolytica*
Yellow pigmentation	−	+
Growth at 45°C	−	+
Nitrate reduced to nitrite	d	−
Urease and β-galactosidase activities	+	−
Lecithinase activity (egg yolk)	−	+
Hydrolysis of:		
Chitin and tributyrin	−	+
Dextran, pectate (pH 5 to 8.3), and Tween 20	+	−
Utilization of:		
DL-Arabinose, lactose, dextran, butyrate, DL-glycerate, glycolate, benzoate, *p*-hydroxybenzoate, DL-serine, DL-threonine, L-arginine, L-citrulline, L-ornithine, and L-phenylalanine	+	−
Glycerol and acetamide	−	+
L-Tyrosine, poly-β-hydroxybutyrate, heptanoate, caprylate, mannitol, phenol, *m*-hydroxybenzoate, benzoyl-formate, DL-mandelate, and quinate	d	−
L-Histidine	d	+

[a]Data from Bowman et al. (1988).

nine, DL-2-aminobutyrate, DL-4-aminobutyrate, DL-2-aminovalerate, DL-5-aminovalerate, L-valine, L-proline, L-hydroxyproline, L-glutamine, L-lysine, L-tryptophan, L-methionine, L-cystein, putrescine, spermine, ethanolamine, histamine, α-amylamine, tryptamine, and pantothenate (Bowman et al., 1993b).

Other biochemical differences include a lack of urease and β-galactosidase activities in *T. chitinolytica*, while the lipolytic activity (lecithinase and lipase) of *T. chitinolytica* is more extensive than *T. mixta*. The carbon source utilization pattern of *T. mixta* (57 of 118 compounds utilized) is more extensive that *T. chitinolytica* (36 of 118 compounds utilized). Aromatic compounds are not utilized by *T. chitinolytica* (Bowman et al., 1993b).

Although no further isolations of *Telluria* have been published, a partial 16S rRNA gene sequence of *T. mixta* from a bacterial endophyte in potato was submitted to GenBank (GenBank accession number AF297697) by van Elsas, van Overbeek and Garbeva (MIBU, PRI, Binenhaven 5, Wageningen 6700, The Netherlands) in 2000 supporting the association of the species with the plant rhizosphere.

Enrichment and Isolation Procedures

Cultures of *T. mixta* are best enriched from soil or rhizosphere in a medium containing dextran minerals salts (Blackall et al., 1985; Bowman et al., 1988). Isolation of pure cultures is readily achieved by plating from the enrichment on dextran agar and observing for colonies surrounded by a clear zone after flooding with ethanol indicative of dextran hydrolysis (Bowman et al., 1988). Colonies are circular, low convex, with a rough or smooth surface, white to tan in color, and may have a highly elastic and cartilaginous consistency. *T. chitinolytica* was first isolated from potted soil emended with powdered crustacean shells kept in a glasshouse at 27–29°C for up to 45 d. After enrichment, isolation was made by plating on agar plates containing 0.2% (w/v) colloidal chitin as the sole carbon source and selecting yellow-pigmented colonies producing a halo of chitin degradation (Spiegel et al., 1991). Colonies of *Telluria* on isolation are highly elastic and cartilaginous.

Maintenance Procedures

Media containing carbohydrates are required for good growth and maintenance. Sucrose peptone agar (Hayward, 1964) is a good general medium for maintenance, and good growth occurs on glucose nitrate medium. Dextran agar and chitin agar are also suitable for *T. mixta* and *T. chitinolytica*, respectively, and for checking culture purity (Bowman et al., 1988, 1993b). Cultures may be preserved by cryogenic storage in liquid nitrogen when suspended in sucrose peptone broth containing 10% glycerol, and by freeze drying in glucose peptone broth containing horse serum.

Differentiation of the genus *Telluria* from other genera

The primary characters for differentiation of *Telluria* from other high mol% G + C, strictly oxidative aerobes in the *Betaproteobacteria* are possession of mixed flagellation on solid agar and the inability to grow well on nutrient agar without the addition of carbohydrates. Additional characters useful for differentiation from *Ralstonia*, *Burkholderia*, *Comamonas*, *Delftia*, *Acidovorax*, *Hydrogenophaga*, *Variovorax*, and *Xylophilus* are given in Table BXII.β.28.

Taxonomic Comments

Phylogenetically, the genus *Telluria* belongs to a distinct, well-supported branch in the *Betaproteobacteria* comprising the two species of *Telluria* with 97% rDNA sequence similarity, and the species *Duganella zoogloeoides*, *Janthinobacterium lividum*, *Herbaspirillum* species, and *Paucimonas lemoignei* (Fig. BXII.β.20). The nearest relatives of *Telluria* species are *Duganella zoogloeoides* and *Janthinobacterium lividum*, which are only moderately related at 93% sequence similarity to *Telluria*. These phylogenetic relationships confirm studies by Bowman et al. (1993b), Anzai et al. (2000), and Jendrossek (2001).

Differentiation of the species of the genus *Telluria*

General characteristics of the species are given in the generic description. Differential characteristics of the species of *Telluria* are indicated in Table BXII.β.27, and additional characteristics are provided in the section on further descriptive information.

List of species of the genus Telluria

1. **Telluria mixta** (Bowman, Sly and Hayward 1989) Bowman, Sly, Hayward, Spiegel and Stackebrandt 1993b, 124[VP] (*Pseudomonas mixta* Bowman, Sly and Hayward 1989, 205.)
mix' ta. L. adj. *mixtus* mixed; M.L. fem. adj. *mixta* mixed, referring to mixed flagellation.

Colonies are circular, low convex, with a rough or smooth surface, white to tan in color, and may have a highly elastic and cartilaginous consistency. Unable to grow at 45°C. Nitrate is reduced to nitrite. Urease and β-galactosidase positive. Lecithinase not produced. Dextran, pectate, and Tween 20 are hydrolyzed, but not chitin or tributyrin. DL-Arabinose, lactose, dextran, butyrate, DL-glycerate, glycolate, benzoate, *p*-hydroxybenzoate, DL-serine, DL-threonine, L-arginine, L-citrulline, L-ornithine, and L-phenylalanine are utilized as carbon sources, but not glycerol or acetamide. L-Tyrosine, poly-β-hydroxybutyrate, heptanoate, caprylate, mannitol, phenol, *m*-hydroxybenzoate, benzoylformate, DL-mandelate, and quinate are utilized by most strains. Isolated from various soils in Queensland, Australia.

The mol% G + C of the DNA is: 69 (T_i).
Type strain: ACM 1762, ATCC 49108, UQM 1762.
GenBank accession number (16S rRNA): X65589.

2. **Telluria chitinolytica** Bowman, Sly, Hayward, Spiegel and Stackebrandt 1993b, 124[VP]
chi.tin.o.lyt' i.ca. chitin clinical term for a polysaccharide; Gr. adj. *lytos* soluble; M.L. adj. *lytos* soluble; M.L. fem. adj. *chitinolytica* dissolving chitin.

Colonies are yellow-pigmented and on isolation are highly elastic and cartilaginous. Able to grow at 45°C. Nitrate is not reduced to nitrite. Urease and β-galactosidase negative. Lecithinase is produced. Chitin and tributyrin are

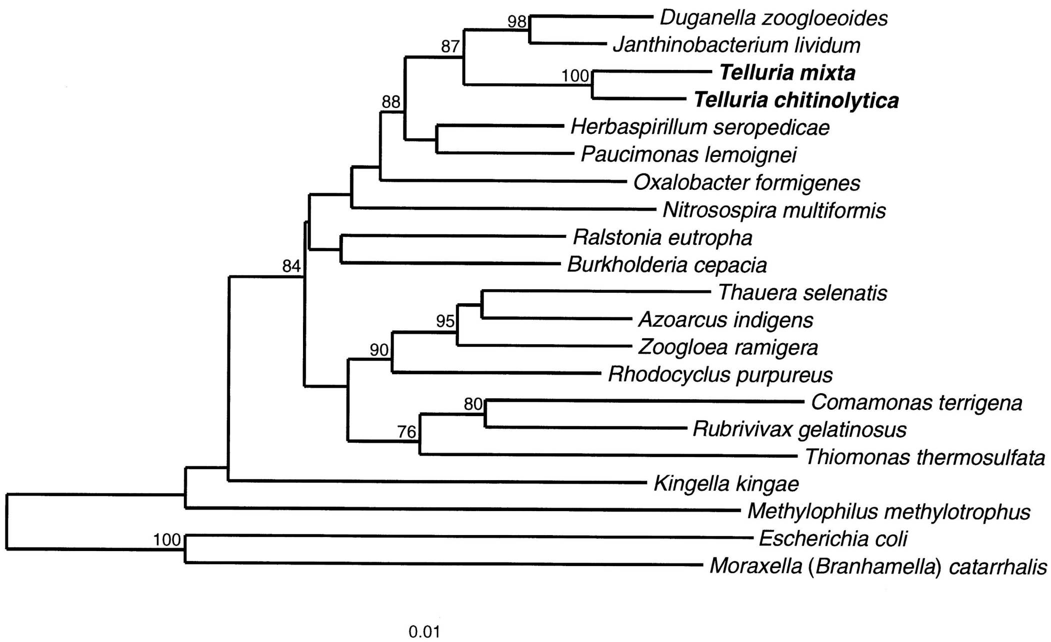

FIGURE BXII.β.20. Neighbor-joining tree reconstructed from 16S rRNA gene sequences using the PHYLIP programs (Felsenstein, 1993) as implemented in the ARB program (Software available from O. Strunk and W. Ludwig: ARB: a software environment for sequence data). Bootstrap values of 100 resamplings are shown at the branch points. Scale bar represents 1 nucleotide substitution per 100 nucleotide positions. The tree was constructed using the following sequences: *Duganella zoogloeoides* IAM 12670^T, D14256; *Janthinobacterium lividum* DSM 1522^T, Y08846; *Telluria mixta* ACM 1762^T, X65589; *Telluria chitinolytica* ACM 3522^T, X65590; *Herbaspirillum seropedicae* ATCC 35892^T (DSM 6445^T), Y10146; *Paucimonas lemoignei* ATCC 17989^T, AB021375; *Oxalobacter formigenes* OxB^T, U49757; *Nitrosospira multiformis* ATCC 25196^T, L35509; *Ralstonia eutropha* ATCC 17697^T, 335 (Stanier), M32021; *Burkholderia cepacia* ATCC 25416^T, M22518; *Thauera selenatis* ATCC 55363^T, X68491; *Azoarcus indigens* VB 32^T, L15531; *Zoogloea ramigera* ATCC 19544^T (NCIMB 10706^T) X74913; *Rhodocyclus purpureus* DSM 168^T, M34132; *Comamonas terrigena* IMI 359870^T, AF078772; *Rubrivivax gelatinosus* ATCC 17011^T (DSM 1709^T) D16213; *Thiomonas thermosulfata* ATCC 51520^T, U27839; *Kingella kingae* ATCC 23330^T, M22467; *Methylophilus methylotrophus* AS1^T, M29021; *Escherichia coli* ATCC 11775^T, X80725; *Moraxella catarrhalis* ATCC 25238^T, U10876.

hydrolyzed, but not dextran, pectate, or Tween 20. Glycerol and acetamide are utilized as carbon sources, but not DL-arabinose, lactose, dextran, butyrate, DL-glycerate, glycolate, benzoate, *p*-hydroxybenzoate, DL-serine, DL-threonine, L-arginine, L-citrulline, L-ornithine, and L-phenylalanine. L-tyrosine, poly-β-hydroxybutyrate, heptanoate, caprylate, man-

nitol, phenol, *m*-hydroxybenzoate, benzoyl-formate, DL-mandelate, and quinate are not utilized. The type strain was isolated from a loamy soil from Bet Dagan, Israel.

The mol% G + C of the DNA is: 72 (T_i).
Type strain: ACM 3522, CNCM I-804.
GenBank accession number (16S rRNA): X65590.

Family III. **Alcaligenaceae** De Ley, Segers, Kersters, Mannheim and Lievens 1986, 412[VP]

HANS-JÜRGEN BUSSE AND GEORG AULING

Al.cal.li.ge.na' ce.ae. M.L. masc. n. *Alcaligenes* type genus of the family; M.L. masc. pl. n. *Alcaligenaceae* the *Alcaligenes* family.

Rods or coccobacilli 0.2–1.0 × 0.5–2.6 μm, occurring singly, in pairs, or rarely in chains. **Gram negative**. No resting stages are known. Motile by peritrichous flagella or nonmotile (*Bordetella parapertussis* and *Bordetella pertussis*). Aerobic, having a **strictly respiratory** type of metabolism with oxygen as the terminal electron acceptor. Some strains can use nitrate or nitrite as an alternative electron acceptor, allowing growth to occur anaerobically. Optimal temperature, 30–37°C. Colonies are usually nonpigmented. Most species are oxidase and catalase positive. Alkaline reaction in litmus milk. Gelatin not hydrolyzed. **Chemoorganotrophic**. Most species utilize a variety of organic acids and amino acids as carbon sources. Carbohydrates are usually not utilized. *Achromobacter xylosoxidans* subsp. *xylosoxidans* produces acid from D-glucose and D-xylose and utilizes both of these carbohydrates as carbon sources. Some species require nicotinamide, organic sulfur (e.g., cysteine), and organic nitrogen (amino acids).

As demonstrated by DNA–rRNA hybridization experiments (De Ley et al., 1986) and 16S rDNA gene sequence analyses (Vandamme et al., 1996a), the family *Alcaligenaceae* belongs to the *Betaproteobacteria*. In general, species of the family *Alcaligenaceae* are characterized by **ubiquinone-8** (Q-8) as the major isoprenoid quinone (Fletcher et al., 1987; Oyaizu-Masuchi and Komagata, 1988). Species analyzed for their polyamine content contain **putrescine** as the major compound and the β-subclass-specific polyamine **2-hydroxyputrescine** (HPUT) (Busse and Auling, 1988; Hamana and Takeuchi, 1998). All species contain in their fatty acid profile the major compounds **hexadecanoate** ($C_{16:0}$) and **cycloheptadecanoate** ($C_{17:0\ cyclo}$), but *Bordetella pertussis* lacks the acid $C_{17:0\ cyclo}$ (Oyaizu-Masuchi and Komagata, 1988; Vancanneyt et al., 1995; Weyant et al., 1995a; Vandamme et al., 1996a).

Species of the genera *Alcaligenes* and *Achromobacter* occur in soil, water, and the hospital environment and have been isolated from human clinical material. Species of the genus *Bordetella* have been isolated from humans and warm-blooded animals but not all are pathogenic for warm-blooded animals (*Bordetella trematum*). The single species of the genus *Pigmentiphaga* has been isolated from soil.

The mol% G + C of the DNA is: 56–70.
Type genus: **Alcaligenes** Castellani and Chalmers 1919, 936.

FURTHER DESCRIPTIVE INFORMATION

The family *Alcaligenaceae* was proposed by De Ley et al. (1986) to encompass the genera *Alcaligenes* and *Bordetella*, which were shown by DNA–rRNA hybridization to group in one cluster within the *Betaproteobacteria*. Phylogenetic analyses based on 16S rDNA sequence data confirm this clustering (Weyant et al., 1995a). Recently, the species *Alcaligenes denitrificans*, *Alcaligenes xylosoxidans*, and *Alcaligenes piechaudii* have been reclassified in the genus *Achromobacter* (Yabuuchi et al., 1998a). Sequence alignment to 120 primary structures of 23S rDNAs from other members of the domain *Bacteria* representing all known phyla confirmed a closer relationship between *Bordetella* species and the type species of the genus, *Alcaligenes faecalis*, in a stable subtree comprising the *Betaproteobacteria* (Ludwig et al., 1995). In this context it is of interest that species of both *Achromobacter* and *Bordetella* produce the macrocyclic siderophore alcaligin, which was originally isolated from *Alcaligenes xylosoxidans* (Nishio et al., 1988; Nishio and Ishida, 1990), and the alcaligin biosynthesis genes have been characterized in *Bordetella pertussis* (Kang et al., 1996).

On the other hand, 16S rDNA sequence data also demonstrate the distance of certain species to the family *Alcaligenaceae*, previously transferred from the genus *Alcaligenes* to other genera outside the family (Auling et al., 1988; Willems et al., 1991a; Dobson et al., 1993; Meyer et al., 1993; Yabuuchi et al., 1995; Dobson and Franzmann, 1996), such as *Ralstonia eutropha* (basonym *Alcaligenes eutrophus*), *Variovorax paradoxus* (basonym *Alcaligenes paradoxus*), *Halomonas aquamarina* (basonym *Alcaligenes aquamarinus*; basonym *Deleya aquamarina*), *Halomonas cupida* (basonym *Alcaligenes cupidus*; basonym *Deleya cupida*), *Halomonas pacifica* (basonym *Alcaligenes pacificus*; basonym *Deleya pacifica*), *Halomonas venusta* (basonym *Alcaligenes venustus*; basonym *Deleya venusta*), and *Carbophilus carboxidus* (formerly *"Alcaligenes carboxidus"*). The species reclassified as members of the genera *Ralstonia*, *Halomonas*, and *Carbophilus* can be easily distinguished from the genus *Alcaligenes* based on their fatty acid profiles, quinones, and/or polyamine patterns (Table BXII.β.29). *V. paradoxus* might be distinguished from members of the family *Alcaligenaceae* by its yellow pigmentation, utilization of the carbon sources D-galactose, L-arabinose, D-mannitol, and *p*-hydroxybenzoate, and the presence of urease (Kersters and De Ley, 1984b). Results from DNA–rRNA hybridization studies have demonstrated that *Alcaligenes latus* is most likely misnamed and a member of an as yet undescribed genus (Willems et al., 1991b). Differentiation of *A. latus* from the species of the genus *Alcaligenes* may be achieved by its ability to utilize maltose, sucrose, 2-ketogluconate, *p*-hydroxybenzoate, butylamine, betaine, sarcosine, and creatine as a carbon source, by chemolithotrophic growth with molecular hydrogen, and by hydrolysis of gelatin, starch, and Tween 80 (Kersters and De Ley, 1984b).

The genus *Bordetella* consists of seven species: *B. pertussis* (Moreno-López, 1952), *B. parapertussis* (Eldering and Kendrick, 1938), *B. bronchiseptica* (Moreno-López, 1952), *B. avium* (Kersters et al., 1984), *B. hinzii* (Vandamme et al., 1995c), *B. holmesii* (Weyant et al., 1995a), and *B. trematum* (Vandamme et al., 1996a). DNA–DNA hybridization (Kloos et al., 1981), multilocus enzyme electrophoresis (Musser et al., 1986), ERIC-PCR, and ARDRA (Vandamme et al., 1997a) studies have shown that the species *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* are closely related and may be considered different subspecies of a single species. In contrast, macrorestriction digests resolved by pulsed-field gel electrophoresis (Khattak and Matthews, 1993), whole-cell protein electrophoresis, and fatty acid profiles (Vancanneyt et al., 1995) generated species-specific profiles for these three species, supporting their present status as different species. Interestingly, it has been independently shown by two groups (Vancanneyt et al., 1995; Weyant et al., 1995a) that *B. pertussis* lacks the fatty acid $C_{17:0\ cyclo}$, which is a predominant compound in the fatty acid profile of the majority of members of the family. Thus, the important human pathogen *B. pertussis* can be easily identified by fatty acid analysis. The taxonomic status of the remaining species *B. avium*, *B. hinzii*, *B. holmesii*, and *B. trematum* is not a matter of discussion. These four species are phenotypically and genotypically sufficiently distinct from each other and from the other three species to justify their status as single species (Vandamme et al., 1997a).

Until the recent reclassification of the species *Alcaligenes denitrificans*, *Alcaligenes xylosoxidans*, and *Alcaligenes piechaudii* to the genus *Achromobacter* as *Achromobacter xylosoxidans* subsp. *denitrificans*, *Achromobacter xylosoxidans* subsp. *xylosoxidans*, and *Achromobacter piechaudii* (Yabuuchi et al., 1998a), taxonomic confusion arose from the phylogenetic clustering of species within the family. Based on 16S rDNA sequence comparisons, the species *Achromobacter xylosoxidans* subsp. *denitrificans*, *Achromobacter xylosoxidans* subsp. *xylosoxidans*, and *Achromobacter piechaudii* are more closely related to the type species of the genus *Bordetella* than to the type species of the genus *Alcaligenes*, *Alcaligenes faecalis* (Fig. BXII.β.21). Likewise, the newly described species *Alcaligenes defragrans* (Foss et al., 1998a) is phylogenetically clearly separated from all genera within the family *Alcaligenaceae* (Blümel et al., 2001b). Thus, it is most likely that *A. defragrans* will be reclassified as a member of a new genus within the family. The DNA base ratios reflect the separate position of *A. faecalis*. While *A. xylosoxidans* subsp. *denitrificans*, *A. xylosoxidans* subsp. *xylosoxidans*, *A. ruhlandii*, *A. piechaudii*, and *A. defragrans* have a mol% G + C content (64–70%) in the range of *Bordetella* species (62–70%), a lower DNA base ratio of 56–60% has been reported for *A. faecalis* (De Ley et al., 1986). Thus, the generic homogeneity within the family has been enhanced by removal of *A. denitrificans*, *A. xylosoxidans*, and *A. piechaudii* from the genus *Alcaligenes*. From the phylogenetic point of view, it would be acceptable to transfer the species *A. xylosoxidans* subsp. *denitrificans*, *A. xylosoxidans* subsp. *xylosoxidans*, *A. piechaudii*, and *A. defragrans* into the genus *Bordetella*. One major obstacle to this reclassification is the definition of the genus *Bordetella*, which describes its members as mammalian parasites and pathogens living among epithelial cilia of the respiratory tract (Pittman, 1984b). However, no association with the respiratory tract of any of the *Alcaligenes* and *Achromobacter* species in question has been described so far. Only *Achromobacter xylosoxidans* subsp. *xylosoxidans* is an important opportunistic pathogen as concluded from numerous reports (Reverdy et al., 1984; Chandrasekar et al., 1986; Reina et al., 1988; Schoch and Cunha, 1988; Legrand and Anaissie, 1992; Cheron et al., 1994; Dunne and Maisch, 1995; Knippschild et al., 1996). The species *A. ruhlandii* and *A. defragrans* have not been isolated from clinical specimens (Foss et al., 1998a). In the last decade, new *Bordetella* species were isolated from the respiratory tract of birds, human blood cultures, ear infections, and wounds of humans (*B. avium* [Kersters et al., 1984], *B. hinzii* [Vandamme et al., 1995c], *B. holmesii* [Weyant et al., 1995a], and *B. trematum* [Vandamme et al., 1996a]). However, no pathogenic significance was demonstrated for *B. trematum*, and that of *B. holmesii* might be limited to opportunistic infections. *B. avium* is a pathogen only for animals. An eventual emendation of *Bordetella* to a more broadly defined genus that is not restricted to obligate pathogens that thrive between epithelial cilia of the respiratory tract would be an alternative to solve discrepancies between phylogeny and taxonomy. This would allow inclusion of the species *A. xylosoxidans* subsp. *denitrificans*, *A. xylosoxidans* subsp. *xylosoxidans*, and *A. piechaudii*, often isolated from clinical specimens, and even *A. ruhlandii*, into a redefined genus *Bordetella*.

Very recently, the genus *Pigmentiphaga* with the single species *Pigmentiphaga kullae* has been proposed as a new genus of the family *Alcaligenaceae* (Blümel et al., 2001b). The single strain of *P. kullae* was isolated after an aerobic enrichment with the azo compound 1-(4′-carboxyphenylazo)-4-naphthol as sole source of carbon and energy (Kulla et al., 1984). Analysis of the 16S rDNA sequence (95–96% similarity with members of the family *Alcaligenaceae*), designation of signature nucleotides, and chemotaxonomic characteristics (presence of ubiquinone Q-8, the polyamines putrescine and 2-hydroxyputrescine, and the fatty acids $C_{16:0}$ and $C_{17:0\ cyclo}$) placed *P. kullae* unambiguously within the family *Alcaligenaceae*.

Some taxonomic comments have to be addressed regarding *Taylorella equigenitalis*, *Taylorella asinigenitalis*, and *Pelistega europaea*. *T. equigenitalis* was originally described as *Haemophilus equigenitalis* (Taylor et al., 1978). A reinvestigation of the taxonomic position of *H. equigenitalis* based on phenotypic data, DNA base composition, and DNA–DNA hybridization data led to its transfer to the new genus *Taylorella*, as its type species *T. equigenitalis* (Sugimoto et al., 1983). The second species of this genus, *T. asinigenitalis*, shares 97.6% 16S rDNA sequence similarity with strains of *Taylorella equigenitalis* (Jang et al., 2001). 16S rDNA sequence analyses (Bleumink-Pluym et al., 1993; Jang et al., 2001) demonstrated that the genera *Pelistega*, *Alcaligenes*, *Achromobacter*, and *Bordetella* are the closest phylogenetic relatives of the genus *Taylorella*. As deduced from phylogenetic analyses based on 16S rDNA sequences, *T. equigenitalis* and *A. faecalis* share approximately the same distance to certain *Bordetella* species and *A. xylosoxidans* subsp. *xylosoxidans* (Bleumink-Pluym et al., 1993; Weyant et al., 1995a). These data indicate that the genus *Taylorella* may represent another genus within the family *Alcaligenaceae*. However, its inclusion in the family is not clearly supported by other data. *Taylorella* species have been shown to have a DNA base composition of ~38 mol% G + C. This value is substantially lower than the mol% G + C content of *A. faecalis*, which is known to have the lowest mol% G + C content (57.4% as determined for the type strain) within the family. Likewise, the fatty acid profile of *Taylorella* species with the major compounds $C_{18:1}$, $C_{16:0}$, $C_{18:0}$, and $C_{14:0\ 3OH}$ (Rossau et al., 1987; Jang et al., 2001) does not reflect the characteristics of the family, i.e., the compound $C_{17:0\ cyclo}$ (Table BXII.β.29) is missing and the predominant compound, $C_{18:1}$, is not a major fatty acid in the profile of the family members. However, the presence of $C_{16:0}$ and $C_{14:0\ 3OH}$ fatty acids

TABLE BXII.β.29. [j]Data from Auling et al. (1988); Meyer et al. (1993).

[k]The fatty acid composition was analyzed from biomass that was grown under denitrifying conditions with acetate as the sole carbon source.

[l]In the original paper (Vandamme et al., 1995c) the authors pointed out that the microbial identification system (Microbial ID, Inc., Newark, Delaware) used for identification of fatty acids cannot distinguish between the two acids $C_{16:1\ iso}$ and $C_{14:0\ 3OH}$. Since branched-chain fatty acids have not been reported in *Alcaligenes* or *Bordetella* strains or are present only in trace amounts, the peak designated summed in feature 3 most probably corresponds to $C_{14:0\ 3OH}$.

[m]The values in brackets indicate the differing results as determined by Willems et al. (1989).

[n]PUT, putrescine; HPUT, 2-hydroxyputrescine; SPD, spermidine; HSPD, *sym*-homospermidine.

as major compounds in *Taylorella* species is characteristic of all validly described species of the family *Alcaligenaceae.*

The closest phylogenetic relative of *Taylorella* is *Pelistega europaea* (Vandamme et al., 1998). Members of this species were reported to have a low mol% G + C content of genomic DNA (42–43%), and a fatty acid profile with the predominant acids $C_{18:1}$, $C_{16:1}$, $C_{16:0}$, summed feature 3 ($C_{14:0\ 3OH}$ or $C_{16:1\ iso\ I}$ or both), and $C_{14:0}$. *P. europaea* can be distinguished from members of the genus *Taylorella* based on 16S rDNA sequences dissimilarities (5.2%), and by qualitative and quantitative differences in the fatty acid profile and biochemical traits. To substantiate the allocation of *Taylorella* and *P. europaea* to an enlarged family *Alcaligenaceae,* the definition of signature nucleotides in the 16S rDNA sequence might be the most promising approach.

The genus *Sutterella* might be another member of the family *Alcaligenaceae* as deduced from 16S rDNA sequences of its single species *S. wadsworthensis* (Wexler et al., 1996a). This microaerophilic/anaerobic species has $C_{16:0}$ and $C_{16:1\ \omega7c}$ acids and summed feature 10 ($C_{18:1\ \omega7c,\ 9t,\ 12c}$ and/or an unknown peak). This profile and the relatively low mol% G + C content (36.5%) remind us of traits in members of *Taylorella* and *Pelistega.* Surprisingly, neither $C_{14:0\ 3OH}$ fatty acid present in all other members of the family *Alcaligenaceae* nor any other hydroxy fatty acid commonly associated to LPS of Gram-negative bacteria has been reported. On the other hand, inclusion of *Sutterella* into an emended family *Alcaligenaceae* appears questionable due to its phylogenetic equidistance (16S rDNA sequences similarities of 88–90%) to members of the family including *Taylorella* and *Pelistega* and to other members of the *Betaproteobacteria* such as *Ralstonia, Herbaspirillum,* and *Roseateles.*

Pathogenicity Strains of *A. faecalis, A. xylosoxidans* subsp. *denitrificans,* and *A. piechaudii* are frequently isolated from clinical specimens, and so they can be regarded as opportunistic pathogens (Kiredjian et al., 1981). Only *A. xylosoxidans* subsp. *xylosoxidans* is considered to be of clinical relevance. This species has been recognized as a causative agent of various human infections, mostly in immunocompromised hosts, i.e., patients with underlying diseases including endocarditis, meningitis, and ventriculitis after neurosurgery, pneumonia, bacteremia osteomyelitis, arthritis, and peritonitis (Shigeta et al., 1978; Reverdy et al., 1984; San Miguel et al., 1991; Legrand and Anaissie, 1992; Walsh et al., 1993). Several outbreaks of hospital-acquired infections have been observed in intensive care units or postsurgical recovery areas due to contamination with *A. xylosoxidans* subsp. *xylosoxidans* of antiseptic solutions (Shigeta et al., 1978), nonbacteriostatic solutions used in diagnostic tracer procedures (McGuckin et al., 1982), dialysis fluids (Reverdy et al., 1984), intravascular pressure transducers (Gahrn-Hansen et al., 1988), and a diagnostic contrast solution (Reina et al., 1988). Strains of *A. xylosoxidans* subsp. *xylosoxidans* have been reported to be susceptible to amoxicillin/clavulanic acid, piperacillin, piperacillin/tazobactam, azlocillin, ceftazidime, and imipenem, and resistant to cefazolin, cefuroxime, gentamicin, tobramycin, netilmicin, amikacin, tetracycline, ofloxacin, and ciproflxacin (Knippschild and Ansorg, 1998). The increasing recovery of this species from clinical specimens might be related to the extensive use of third-generation antibiotics such as cephalosporins and fluoroquinolones not effective against *A. xylosoxidans* subsp. *xylosoxidans* (Glupczynski et al., 1988; Mensah et al., 1989). No pathogenic potential has been reported for *A. ruhlandii, A. defragrans,* or *P. kullae.*

The genus *Bordetella* consists of several pathogenic bacteria. These bacteria produce many virulence related factors, among which there are several toxins such as the pertussis toxin (PTX) that is produced only by *B. pertussis,* the adenylate cyclase toxin (CYA), and several adhesins such as the filamentous hemagglutinin (FHA), the pertactin (PRN), and the fimbriae (Weiss, 1992). *B. pertussis* is the etiological agent of whooping cough

(Weiss and Hewlett, 1986). *B. parapertussis*, which causes a milder form of whooping cough, has been assumed as a strictly human pathogen (Hewlett, 1990), but it has been isolated from both healthy sheep and sheep affected with chronic nonprogressive pneumonia (Cullinane et al., 1987; Chen et al., 1988a; Porter et al., 1994). *B. bronchiseptica* is found in a wide range of animals, and it is associated with atrophic rhinitis in swine and kennel cough in dogs (Goodnow, 1980; Harkness and Wagner, 1995; Keil and Fenwick, 1998; Speakman et al., 1999). *B. avium* is a pathogen of birds and causes rhinotracheitis (turkey coryza) in turkey poults (Simmons and Gray, 1979; Simmons et al., 1979; Saif et al., 1980; Arp and Cheville, 1984; Kersters et al., 1984). Only recently, *B. hinzii* (Vandamme et al., 1995c) has been reported as the causative agent of fatal septicemia (Kattar et al., 2000). *B. holmesii* has been associated most often with septicemia in patients with underlying conditions (Lindquist et al., 1995; Weyant et al., 1995a; Morris and Meyers, 1998; Tang et al., 1998). It also has been isolated from sputum from one patient with respiratory symptoms. *B. trematum* has been isolated from wounds and ear infections, but its pathogenic significance is unknown (Vandamme et al., 1996a).

T. equigenitalis is considered a commensal or opportunistic pathogen. It colonizes the urogenital membranes of the clitoral sinuses and fossa, urethra, and cervix of mares, and the urethra, urethral fosses, and penile sheath of stallions. So far, only infections of mares have been reported where *T. equigenitalis* causes vaginal discharge, infertility, or early abortion (Wada et al., 1983). *T. equigenitalis* is moderately resistant to a limited number of antibiotics including clindamycin, lincomycin, trimethoprim, and sulfamethoxazole but sensitive to penicillin G, ampicillin, carbenicillin, cephaloridine, cephalothin, erythromycin, tetracycline, kanamycin, gentamicin, chloramphenicol, and polymyxin B (Sugimoto et al., 1983). *T. asinigenitalis* is not reported to cause disease in jacks or mares (Jang et al., 2001).

Pelistega europaea strains have been mainly isolated from lungs, air sac exudate, and trachea mucosa and less frequently from other organs such as liver and spleen of pigeons.

Sutterella wadsworthensis has been isolated from infections of gastrointestinal origin (Finegold and Jousimies-Somer, 1997; Jousimies-Somer, 1997). The majority of *Sutterella* strains are susceptible to amoxicillin/clavulanate, ticarcillin/clavulanate, cefoxitin, ceftriaxone, clindamycin, piperacillin/tazobactam, ceftizoxime, ciprofloxacin, trovafloxacin, azithromycin, clarithromycin, erythromycin, and roxithromycin.

Taxonomic Comments

The numerous reclassifications between the two genera *Alcaligenes* and *Achromobacter* suggest a common discussion of their history.

The type species of the genus *Alcaligenes* is *A. faecalis* Castellani and Chalmers 1919. This species also encompasses strains originally described as *"Pseudomonas odorans"* (Málek and Kazdová-Košiskova, 1946) Málek et al., 1963, *"A. odorans* var. viridans" Mitchell and Clarke, 1965 and *"Achromobacter arsenoxydans-tres"* Turner, 1954.

Based on the phylogenetic relationships within the family *Alcaligenaceae*, *A. faecalis* can be considered as the only representative of the genus *Alcaligenes sensu stricto*. Recently, a strain accumulating poly-β-hydroxybutyrate from acetone-butanol bioprocess residues was shown to be closely related with *A. faecalis* DSM 30030^T (Schroll et al., 2001a). This strain shared 98.7% 16S rDNA sequence similarity, 56% DNA relatedness, and an almost identical protein pattern with the type strain of *A. faecalis*. Since it could only be distinguished from *A. faecalis* DSM 30030^T based on few physiological and biochemical traits and the extremely low content of the diagnostic polyamine 2-hydroxyputrescine, it was described as a subspecies of *A. faecalis*, *A. faecalis* subsp. *parafaecalis*. As a result of this study, the species *A. faecalis* is subdivided into the two subspecies *A. faecalis* subsp. *faecalis* and *A. faecalis* subsp. *parafaecalis*.

A. defragrans has been described as a new species (Foss et al., 1998a), encompassing four strains isolated on the alkenoic monoterpenes (+)-menthene, α-pinene, 2-carene, and α-phellandrene, respectively, as the sole source of carbon and energy under denitrifying conditions. 16S rDNA sequence data indicate that *A. defragrans* occupies a separate position within the *Alcaligenaceae*. Thus, future reclassification of this species in a new genus is most likely. In agreement with a proposal of a new genus for *A. defragrans* is its unusual fatty acid profile. In contrast to the fatty acid profiles of *Alcaligenes*, *Achromobacter*, and *Bordetella* species, *A. defragrans* was reported to contain significant amounts of dodecanal and to lack $C_{12:0\ 2OH}$ acid. However, the fatty acid profiles of strains of this species show the characteristics of the members of the family, the predominant acids $C_{16:0}$ and $C_{17:0\ cyclo}$, and the presence of the hydroxy acid $C_{14:0\ 3OH}$. Unfortunately, the fatty acid profile of *A. defragrans* was not obtained from cells grown on the commonly used trypticase soy agar. Thus, it cannot be compared directly with other profiles of species within the family *Alcaligenaceae* available from the literature and from the MIDI fatty acid identification system (Microbial ID, Newark, NJ, USA).

The type species of the genus *Achromobacter* is *A. xylosoxidans* (ex Yabuuchi and Ohyama 1971; Yabuuchi and Yano 1981) Yabuuchi et al. 1998a. The history of the two subspecies *Achromobacter xylosoxidans* subsp. *denitrificans* (formerly *Alcaligenes denitrificans* subsp. *denitrificans*) and *Achromobacter xylosoxidans* subsp. *xylosoxidans* (formerly *Alcaligenes denitrificans* subsp. *xylosoxidans*) has been reviewed in detail by Kersters and De Ley (1984b) and will be only summarized here. The name *Alcaligenes denitrificans* was proposed by Leifson and Hugh (1954a) to accommodate two strains that reduce nitrate to nitrite and gas. Based on biochemical and nutritional characteristics, Hendrie et al. (1974) proposed that *A. denitrificans* was a subjective synonym of *A. faecalis* Castellani and Chalmers 1919. The name was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980) and thus did not have standing in bacterial nomenclature. The name *A. denitrificans* was revived by Rüger and Tan (1983) to separate the original type strain of *A. denitrificans* (Leifson and Hugh, 1954a) from the species *A. faecalis*, based on DNA base composition, DNA reassociation, and nitrate reduction. In the first edition of *Bergey's Manual of Systematic Bacteriology*, *A. denitrificans* was named *A. denitrificans* subsp. *denitrificans*, *Achromobacter xylosoxidans* as *A. denitrificans* subsp. *xylosoxidans*, and *A. ruhlandii* was included in this second subspecies (Kersters and De Ley, 1984b). *Achromobacter xylosoxidans* was originally described by Yabuuchi and Ohyama (1971). Since this name was omitted from the Approved Lists of Bacterial names (Skerman et al., 1980), it had no standing in bacterial nomenclature. Thus, the name was revived by Yabuuchi and Yano (1981). Due to its high degree of similarity in the rRNA cistron to *A. denitrificans* subsp. *denitrificans*, Kersters and De Ley (1984b) proposed including as a second subspecies in *A. denitrificans*, namely *A. denitrificans* subsp. *xylosoxidans*. Additionally, the hydrogen-oxidizing species *A. ruhlandii* (Packer and Vishniac, 1955; Aragno and Schlegel,

1977), which appears in the Approved Lists, was transferred to *A. denitrificans* subsp. *xylosoxidans*, based on its similarity in genotypic and phenotypic features, and its indistinguishability from this subspecies in protein electrophoregrams.

Since the species epithet *xylosoxidans* had priority, Kiredjian et al. (1986) proposed the new combinations *A. xylosoxidans* subsp. *denitrificans* and *A. xylosoxidans* subsp. *xylosoxidans*. Vandamme et al. (1996a) demonstrated that strains of *A. xylosoxidans* subsp. *denitrificans* and *A. xylosoxidans* subsp. *xylosoxidans* can be readily distinguished by their whole-cell protein patterns, fatty acid components, and other phenotypic characteristics. These authors proposed that *A. xylosoxidans* subsp. *denitrificans* and *A. xylosoxidans* subsp. *xylosoxidans* should be elevated to species rank as *A. denitrificans* and *A. xylosoxidans*, respectively. Yabuuchi et al. (1998a) proposed combining *A. denitrificans* and *A. xylosoxidans* in a single species, *Achromobacter xylosoxidans*, with the two subspecies *Achromobacter xylosoxidans* subsp. *denitrificans* and *Achromobacter xylosoxidans* subsp. *xylosoxidans*, based on 63.4% DNA relatedness and 98.7% 16S rDNA sequence similarity between the type strains of the two subspecies. This proposal ignores the distinguishing characteristics reported by Vandamme et al. (1998) and thus creates a heterogeneous species.

The names *Alcaligenes denitrificans*, *Alcaligenes xylosoxidans* subsp. *denitrificans*, *Alcaligenes denitrificans* subsp. *denitrificans* and *Achromobacter xylosoxidans*, *Alcaligenes xylosoxidans*, *Alcaligenes xylosoxidans* subsp. *xylosoxidans*, and *Alcaligenes denitrificans* subsp. *xylosoxidans* are senior synonyms of the validated names *Achromobacter xylosoxidans* subsp. *denitrificans* and *Achromobacter xylosoxidans* subsp. *xylosoxidans*, respectively, as proposed by Yabuuchi et al. (1998a). Based on the low degree of DNA relatedness with other members of the genus *Achromobacter*, Yabuuchi et al. (1998a) also proposed the new species *Achromobacter ruhlandii* to accommodate the hydrogen-oxidizing strain of *Achromobacter xylosoxidans* originally described as *"Hydrogenomonas ruhlandii"* (Packer and Vishniac, 1955; Aragno and Schlegel, 1977).

The third species, *A. piechaudii*, encompasses isolates from human clinical material from different geographical regions (Kiredjian et al., 1986), as well as strains originally named *A. faecalis* CIB 60.75 and *"Achromobacter iophagus"* (Kiredjian et al., 1981; Holmes and Dawson, 1983), which were shown to be phenotypically and genotypically distinct from the other species transferred to the genus *Achromobacter*.

The marine *Alcaligenes* species *A. aestus*, *A. pacificus*, *A. cupidus*, and *A. venustus* have been reclassified and described as species of the new genus *Deleya* as *D. aesta*, *D. pacifica*, *D. cupida*, and *D. venusta* (Baumann et al., 1983). Akagawa and Yamasato (1989) showed that *A. aquamarinus* is another member of the genus *Deleya*. They also demonstrated that the type strains of *A. aquamarinus*, *A. faecalis* subsp. *homari* (Austin et al., 1981), and *D. aesta* are members of the same species, and due to priority of the species epithet *aquamarina* they were reclassified in the species *Deleya aquamarina*. Meanwhile, members of the genus *Deleya* have been transferred to the genus *Halomonas*, and the new combinations *H. aquamarina*, *H. pacifica*, *H. cupida*, and *H. venusta* have been proposed for the marine *Alcaligenes* species (Dobson and Franzmann, 1996).

Genus I. **Alcaligenes** *Castellani and Chalmers 1919, 936*[AL]

Hans-Jürgen Busse and Georg Auling

Al.ca.li′ ge.nes. Arabic *al* the; Arabic n. *galiy* the ash of saltwort; French n. *alcali* alkali; Gr. v. *gennaio* to produce; M.L. masc. n. *Alcaligenes* alkali-producing (bacteria).

Rods or coccobacilli, 0.5–1.2 × 1.0–3.0 µm, usually occurring singly. Resting stages not known. **Gram negative**. **Motile** with one to nine **peritrichous** flagella. **Obligately aerobic**, possessing a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Some strains are capable of anaerobic respiration in the presence of nitrate or nitrite. Optimal growth temperature: 20–37°C. Colonies on nutrient agar are **nonpigmented**. **Oxidase positive**. **Catalase positive**. Indole not produced. Cellulose, esculin, gelatin, and DNA usually not hydrolyzed. **Chemoorganotrophic, using a variety of organic acids and amino acids as carbon sources. Alkali produced** from several organic salts and amides. Carbohydrates usually not utilized. **Characteristic fatty acids are $C_{17:0\ cyclo}$, $C_{16:0}$, $C_{14:0\ 3OH}$, $C_{16:1}$, and $C_{12:0\ 2OH}$. Ubiquinone Q-8**. **Polyamine patterns with the predominant compound putrescine and the unusual diamine 2-hydroxyputrescine.** Isolated from water, soil, and clinical specimens such as blood, spinal fluid, pleural fluid, peritoneal fluid, pus, urine, stools, and swabs of eyes, ears, and pharynxes. Frequently found in unsterilized distilled water and in chlorhexidine solutions in hospitals. Occasionally causing opportunistic infections in humans.

The mol% G + C of the DNA is: 56–60.

Type species: **Alcaligenes faecalis** Castellani and Chalmers 1919, 936[AL] (*Achromobacter arsenoxydans-tres* Turner 1954, 475; *"Pseudomonas odorans"* (Málek and Kazdová-Košiskova 1946; Málek, Radochová and Lysenko 1963, 353; *"Alcaligenes odorans* var. viridans" Mitchell and Clarke 1965, 347.

Further descriptive information

For a broad and an extensive view the reader is referred to the excellent treatment of the genus by Kersters and De Ley (1984b) except for those characteristics that became available since the first edition of *Bergey's Manual of Systematic Bacteriology*. However, since the Kersters and De Ley publication, many of the xenobiotic-degrading soil bacteria, especially some of the strains well known for plasmid-encoded pathways that were originally allocated to *Alcaligenes* species, have been transferred to other genera

(Busse and Auling, 1992, cf. also the family *Alcaligenaceae* in this volume).

Dimethyl disulfide-producing bacteria have been isolated from activated sludge and some of them were phenotypically allocated to the genus *Alcaligenes* (Tomita et al., 1987). In the same study pure cultures from the authentic genus *Alcaligenes* were also shown to produce dimethyl disulfide from DL-methionine and *S*-methyl-L-cysteine. More recently, an *Alcaligenes*-like dimethyl sulfide-producing marine isolate, phenotypically identified (Vitek), was shown to contain a dimethylsulfoniopropionate lyase (de Souza and Yoch, 1995). This enzyme was purified and the authors argued that the K_m value and other properties observed may reflect the greater potential of facultative anaerobes over aerobes to metabolize lower levels of dimethylsulfoniopropionate in anoxic zones of seawater and salt marshes.

List of species of the genus Alcaligenes

1. **Alcaligenes faecalis** Castellani and Chalmers 1919, 936[AL] (*Achromobacter arsenoxydans-tres* Turner 1954, 475; *"Pseudomonas odorans"* (Málek and Kazdová-Košiskova 1946; Málek, Radochová and Lysenko 1963, 353; *"Alcaligenes odorans* var. viridans" Mitchell and Clarke 1965, 347.)
fae.ca′lis. L. n. *faex, faecis* dregs; M.L. adj. *faecalis* fecal.

The species *Alcaligenes faecalis* is subdivided into the two subspecies, *A. faecalis* subsp. *faecalis* and *A. faecalis* subsp. *parafaecalis*.

The mol% G + C of the DNA is: 56–60 (T_m, Bd).

a. **Alcaligenes faecalis** *subsp.* **faecalis** Castellani and Chalmers 1919, 936[AL]

The description of *Alcaligenes faecalis* subsp. *faecalis* is based on that given by Kersters and De Ley (1984b) for *A. faecalis*. This subspecies is the type subspecies of *Alcaligenes faecalis* and contains the type strain of the species. The morphological characteristics are as described for the genus. Colonies on nutrient agar are nonpigmented to grayish white, translucent to opaque, flat to low convex, margin usually entire, usually smooth, sometimes dull or rough. Most strains form colonies with a thin, spreading irregular edge. Some strains previously named *"A. odorans"* (Málek and Kazdová-Koziškova, 1946; Málek et al., 1963), produce a characteristic aromatic fruity odor and/or a green discoloration on blood agar. Those strains producing the latter characteristic were previously named " *A. odorans* var. viridans" (Mitchell and Clarke, 1965).

Physiological and nutritional characteristics of *A. faecalis* are presented in Table BXII.β.29 of the chapter *Alcaligenaceae* and Tables BXII.β.30 and BXII.β.31 of this chapter. Carbohydrates are not utilized as sole carbon sources. Good growth is obtained on several organic acids and amino acids. Instead of using a monoamine oxidase, *Alcaligenes faecalis* initiates catabolism of aromatic amines alternatively by an aromatic amine dehydrogenase that is structurally similar to methylamine dehydrogenase and possesses the same tryptophan tryptophylquinone prosthetic group as the latter (Govindaraj et al., 1994). Chemolithotrophic growth using hydrogen gas has not been demonstrated.

Nitrite, but not nitrate, is reduced. Anaerobic respiration with nitrite, but not with nitrate, as a sole electron acceptor is possible for most strains. Some strains oxidize arsenite. *Alcaligenes faecalis* is among the bacterial taxa that are able to combine aerobic denitrification and heterotrophic nitrification (van Niel et al., 1992; Anderson et al., 1993) and that may contribute to biogenic emissions of NO and N_2O into the atmosphere even when growing logarithmically (Papen et al., 1989; Otte et al., 1996). Since *Alcaligenes faecalis* is commonly found in soil, water, and waste water treatment plants, bacteria of this species, enriched by the denitrification process of activated sludge, may be responsible for significant trace gas emissions of suboptimally functioning systems of waste water treatment. Among a large collection of isolates from biofilters for off-gas treatment of animal-rendering plant emissions, 21 bacteria were allocated by a polyphasic taxonomic approach to either *Alcaligenes faecalis* or a new taxon (cluster J) within the family *Alcaligenaceae* (Ahrens et al., 1997).

Degradation of microbial reserve polymers such as poly-(3-hydroxybutyrate) (PHB) is known to occur in marine environments and a PHB depolymerase was purified and characterized from a marine bacterium, *Alcaligenes faecalis* strain AE122 (Kita et al., 1995). From activated sludge an *Alcaligenes faecalis* strain, T1, was isolated that can hydrolyze not only water-insoluble PHB but also water-soluble D(−)-3-hydroxybutyrate oligomeric esters. The PHB depolymerase of this strain was cloned, and the structure and function of its three domains (catalytic, substrate-binding, and fibronectin type-like) were studied (Saito et al., 1989; Nojiri and Saito, 1997). Resting cells of *Alcaligenes faecalis* ATCC 8750 have been described as producing *R*-(−)-mandelic acid from mandelonitrile for synthesis of semisynthetic cephalosporins (Yamamoto et al., 1991). D-Aminoacylase with high stereospecificity has been purified from *Alcaligenes faecalis* strain DA1 (Yang et al., 1991b).

A. faecalis subsp. *faecalis* has a fatty acid profile consisting of $C_{17:0\ cyclo}$, $C_{16:0}$, $C_{14:0\ 3OH}$, $C_{18:1}$, $C_{12:0\ 2OH}$, $C_{16:1\ \omega 7c}$, $C_{12:0}$, $C_{19:0\ cyclo}$, $C_{14:0}$, and an unknown fatty acid (Vandamme et al., 1995c); phosphatidylethanolamine, phosphatidylglycerol, and an ornithine lipid (Yabuuchi et al., 1995), and an ubiquinone Q-8 (Lipski et al., 1992) are present; the polyamine pattern contains the predominant compound putrescine and the unusual 2-hydroxyputrescine (Busse and Auling, 1988).

Isolated from soil, water, feces, urine, blood, sputum, wounds, pleural fluid, nematodes, and insects.

The mol% G + C of the DNA is: 55.9–59.4 (T_m, Bd) (De Ley et al., 1970b; Pichinoty et al., 1978).

Type strain: ATCC 8750, CCM 1052, CCUG 1325, CIP 60.80, DSM 30030, IAM 12586, IFO 13111, IMET 10443, JCM 1472, LMG 1229, NCDO 868, NCIB 8156.

GenBank accession number (16S rRNA): M22508.

para.fae.ca'lis. Gr. prep. *para* along side of, resembling; M.L. adj. *faecalis* specific epithet; M.L. *parafaecalis* intended to mean alongside of the species *A. faecalis*.

The description of this subspecies is taken from Schroll et al. (2001a). Cells are Gram negative, rod shaped, 0.75–1.0 × 1.5–3.0 μm, nonsporeforming, and motile. Colonies on standard bacteriological media are circular, entire, low convex, and smooth with a thin spreading irregular edge; diameter is up to 2.0 mm after 1 d incubation at 37°C. The following tests were positive: oxidase activity, catalase activity, alkalization, growth on MacConkey agar, citrate utilization, acetoin production, gelatin liquefaction at 37°C, assimilation of gentisate; enzymatic activities as follows: L-alanine aminopeptidase, alkaline phosphatase, esterase (C_4), leucine arylamidase, valine arylamidase, acid phosphatase, weak reactions for esterase lipase (C_8), lipase (C_{14}), naphthol-AS-BI-phosphohydrolase. No growth at 42°C or on MacConkey agar. Acid is not produced in Hugh/Leifson's glucose O-F medium, and L-histidine, L-tryptophan, and benzoate are not assimilated. Lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, indole production, H_2S production, nitrate reduction, nitrite reduction, urease activity, acetoin production, gelatin liquefaction at 28°C, hydrolysis of Tween 80 and casein, DNase activity, cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosamidase, α-mannosidase, and α-fucosidase are negative. The following compounds are assimilated (as tested by growth in M9 medium): acetate, propionate, butyrate, valerate, heptanoate, γ-hydroxybutyric acid, γ-butyrolactone, L-lactate, citrate, ethanol. By using the Biolog GN system the following reactions are positive: Tween 40, Tween 80, methylpyruvate, mono-methyl pyruvate, acetic acid, *cis*-aconitic acid, citric acid, formic acid; α-, β-, and γ-hydroxybutyric acid, *p*-hydroxyphenyl acetic acid, α-ketobutyric acid, D,L-lactic acid, malonic acid, propionic acid, succinic acid, bromosuccinic acid, succinamic acid, alaninamide, D-alanine, L-alanine, L-glutamic acid, L-leucine, L-phenylalanine, L-proline, urocanic acid, and phenylethylamine; weak reactions are observed for glycogen, L-alanylglycine, L-asparagine, L-aspartic acid, glycyl-L-glutamic acid, L-pyroglutamic acid, D-serine, L-threonine, and inosine. The following compounds are not assimilated (as tested by growth in M9 medium): 1,4 butandiol, 2,3 butandiol, methanol, 1-butanol, 2-butanol, 1-hexanol, glycerol, acetone, and tartric acid. Using the Biolog GN system, the following reactions are negative: α-cyclodextrin, dextrin, *N*-acetylglucosamine, adonitol, L-arabinose, D-arabitol, cellobiose, *i*-erythritol, D-fructose, L-fucose, D-galactose, gentiobiose, α-D-glucose, *meso*-inositol, α-D-lactose, lactulose, maltose, D-mannitol, D-mannose, D-melibiose, β-methyl-D-glucoside, D-psicose, D-raffinose, L-rhamnose, D-sorbitol, sucrose, D-trehalose, turanose, xylitol, D-galactonic acid lactone, D-galacturonic acid, D-gluconic acid, D-glucosaminic acid, D-glucuronic acid, itaconic acid, α-ketoglutaric acid, quinic acid, D-saccharic acid, sebacic acid, glucuronamide, glycyl-L-aspartic acid, L-histidine, hydroxy-L-proline, L-ornithine, L-pyroglutamic acid, L-serine, D,L-carnitine, γ-amino butyric acid, uridine, thymidine, putrescine, 2-amino ethanol, 2,3 butanediol, glycerol, D,L-α-glycerol phosphate, glucose-1-phosphate, and glucose-6-phosphate.

A. faecalis subsp. *parafaecalis* has a fatty acid profile consisting of $C_{16:0}$, $C_{16:1}$, $C_{17:0\ cyclo}$, $C_{18:1\ \omega7c/9t}$, $C_{14:0\ 3OH}$, $C_{14:0}$, $C_{12:0\ 2OH}$, $C_{12:0}$, $C_{18:0}$, $C_{15:0}$, and $C_{17:0}$; a ubiquinone Q-8; and a polyamine pattern with putrescine as the predominant compound and only trace amounts of the *Betaproteobacteria*-specific polyamine 2-hydroxyputrescine.

Isolated from water (garden pond, Lower Austria; Austria).

The mol% G + C of the DNA is: 56 (T_m).

Type strain: G, CIP 106866, DSM 13975.

GenBank accession number (16S rRNA): AJ242986.

2. **Alcaligenes defragrans** Foss, Heyen and Harder 1998b, 1083[VP] (Effective publication: Foss, Heyen and Harder 1998a, 243.)

de.fra.grans. L. prep. *de* away, from; L. adj. *fragrans* sweet scented; M.L. defragrans to annihilate fragrance, referring to the capacity to degrade monoterpenes.

The morphological characteristics are as described for the genus. The facultatively anaerobic chemoorganotrophic metabolism is strictly oxidative. Oxygen, nitrate, nitrite, or dinitrogen oxide can serve as electron acceptor. Under denitrifying conditions, acetate, propionate, butyrate, hexanoate, heptanoate, octanoate, pyruvate, malate, succinate, fumarate, 3-methylbutyrate, glutarate, glutamate, alanine, valine, ethanol, and the monoterpenes (+)-ρ-menth-1-ene, (+)-limonene, (−)-α-phellandrene, α-terpinene, γ-terpinene, (+)-sabinene, (+)-2-carene, (+)-3-carene, (−)-α-pinene, (−)-β-pinene, terpinolene, (+)-α-terpineol, and

(+)-terpinen-4-ol are used as carbon and energy sources. The majority of strains grow on myrcene, arginine, and gluconate. Under denitrifying conditions no growth occurs on D-glucose, D-fructose, D-sorbitol, *meso*-inositol, D-ribose, D-arabinose, D-xylose, D-saccharose, D-trehalose, D-cellobiose, ascorbate, phenylalanine, formate, L-tartrate, adipate, pimelate, suberate, sebacate, itaconate, methanol, cyclohexanol, cyclohexane-1,2-diol, cyclohexane-1,4-diol, decane, hexadecane, heptamethylnonane, cyclohexane, benzoate, toluene, 2,6-dimethyloctane, 3,7-dimethyl-1-octene, (−)-β-citronellene, 3,7-dimethyloctanol-1, (−)-β-citronellol, geraniol, nerol, linalol (+)-*trans*-isolimonene, ρ-cymene, (+)-perilla alcohol, (−)-carveol, (+)-dihydrocarveol, menthol, menthone, (+)-isopulegol, (+)-isomenthol, (+)-pulegone, (−)-carvone, (+)-dihydrocarvone, (−)-*trans*-pinane, eucalyptol, (−)-*cis*-myrtanol, (+)-*trans*-myrtanol, (−)-myrtenol, (+)-isopinocampheol, (−)-borneol, (+)-fenchol, (α+β)-thujone, (+)-fenchone, (−)-verbenone, (+)-camphor, and pine needle oil.

When grown on monoterpene and nitrogen, no vitamins are needed, and growth occurs at 15–40°C in the range of pH 5.9–8.4; pH-optimum is at 6.3–7.8.

The whole cell fatty acid profile is strongly dependent on the culture conditions. When grown under denitrifying conditions on monoterpene, the fatty acid profile is characterized by the predominant acids $C_{16:0}$ and $C_{17:0\ cyclo}$ and varying amounts of dodecanal, $C_{12:0}$, $C_{14:0}$, $C_{14:0\ 3OH}$, $C_{15:0}$, $C_{16:1}$, $C_{18:1}$, and $C_{19:0\ cyclo}$. When acetate is the only carbon and energy source $C_{16:1}$, $C_{16:0}$, $C_{17:0\ cyclo}$, and $C_{18:1}$ are the predominant fatty acids.

The species *Alcaligenes defragrans* was proposed by Foss et al. (1998a) to encompass four monoterpenes degrading strains. 16S rDNA sequence comparisons indicate that *A. defragrans* is more closely related to *Bordetella* and *Achromobacter* than *A. faecalis.* This relatedness is also reflected by its DNA base ratio, which is in the range of *Achromobacter* and *Bordetella.*

Isolated from activated sludge and a forest ditch.

The mol% G + C of the DNA is: 66.9 (HPLC).

Type strain: 54Pin, DSM12141.

GenBank accession number (16S rRNA): AJ005447.

Additional Remarks: Other representative culture collection strains belonging to this taxon: DSM 12142 (62Car), DSM 12143 (65Phen), DSM 12144 (51Men) (*Alcaligenes defragrans*).

Species Incertae Sedis

1. **Alcaligenes latus** Palleroni and Palleroni 1978, 423[AL]
la' tus. L. adj. *latus* broad.

The cells are short to coccoid rods, 1.2–1.4 × 1.6–2.4 μm, occurring singly, in pairs, or in short chains. Gram negative. Motile by means of 5–10 peritrichous flagella. The cells are frequently heavily granulated. Under autotrophic growth conditions on a solid mineral medium colonies are round, grayish pink, and opaque (Palleroni and Palleroni, 1978). Colonies are wrinkled in fresh isolates but can become smooth upon subcultivation.

Facultatively chemolithotrophic in an atmosphere containing hydrogen, oxygen, and carbon dioxide. Can grow with dinitrogen as sole nitrogen source (H.G. Schlegel, personal communication). Physiological and nutritional characteristics are given in Table BXII.β.29 of *Alcaligenaceae* and Table BXII.β.30 of this chapter. Optimal growth temperature is about 35°C. A membrane-bound hydrogenase, but no soluble, NAD-reducing hydrogenase has been found in three strains of *A. latus* (Palleroni and Palleroni, 1978). *meta*-Hydroxybenzoate is metabolized via the gentisate pathway and protocatechuate is degraded by *meta*-cleavage when grown on *p*-hydroxybenzoate or quinate.

Three strains were isolated from soil (Palleroni and Palleroni, 1978). The fatty acid profile is characterized by the following compounds: $C_{16:1}$, $C_{18:1}$, $C_{16:0}$, $C_{18:0}$, $C_{14:0}$, $C_{12:0}$, $C_{17:0\ cyclo}$, $C_{17:0}$, $C_{15:0}$, $C_{10:0\ 3OH}$, and $C_{14:1}$ and the major respiratory quinone is ubiquinone Q-8 (Oyaizu-Masuchi and Komagata, 1988).

The mol% G + C of the DNA is: 69.1–71.1 (Bd, T_m) (Palleroni and Palleroni, 1978; Kersters and De Ley, 1984b).

Type strain: Palleroni H-4, ATCC 29712, CIP 10345, DSM 1122.

GenBank accession number (16S rRNA): D88007.

The species *Alcaligenes latus* was proposed by Palleroni and Palleroni (1978) to encompass hydrogen oxidizing, peritrichously flagellated bacteria. DNA–rRNA hybridization studies revealed that this species is most closely related to *Rubrivivax gelatinosus* and *Leptothrix discophora* (Willems et al., 1991b), and distant from the family *Alcaligenaceae.* Thus, *A. latus* cannot be considered as a member of the genus or even of the family. It is most likely that *A. latus* is a member of a genus that has not yet been described. The species description of *A. latus* is a revised version of that given by Kersters and De Ley (1984b).

Genus II. **Achromobacter** *Yabuuchi and Yano 1981, 477[VP] emend. Yabuuchi, Kawamura, Kosako and Ezaki 1998a, 1083*

HANS-JÜRGEN BUSSE AND GEORG AULING

A.chro.mo.bac' ter. Gr. adj. *achromus* colorless; M.L. n. *bacter* the masc. equivalent of Gr. neut. n. *bactrum* a rod or staff; M.L. masc. n. *Achromobacter* colorless rodlet.

Straight rods, 0.8–1.2 × 2.5–3.0 μm with rounded ends. **Gram negative**. Nonsporeforming. **Motile** with 1–20 sheathed flagella arranged **peritrichously**. **Obligately aerobic** and nonfermentative. Some strains are capable of anaerobic respiration with nitrate as the electron acceptor. They perform nitrate respiration combined with nitrite and nitrous oxide respiration. Some strains are facultative lithoautotrophic hydrogen-oxidizers. **Oxidase positive**. **Catalase positive**. Urease, DNase, phenylalanine deaminase, lysine and ornithine decarboxylase, arginine dihydrolase, and gelatinase negative. Nonhalophilic, nonhemolytic, nonpigmented. **Chemoorganotrophic, using a variety of organic acids and amino acids as carbon sources.** Carbohydrates usually not utilized. *Achromobacter xylosoxidans* subsp. *xylosoxidans* and *Achromobacter ruhlandii* utilize D-glucose as sole carbon source and produce acid from D-glucose, D-arabinose, and D-xylose. **Those strains analyzed contain the characteristic fatty acids $C_{17:0\ cyclo}$,**

$C_{16:0}$, $C_{14:0\ 3OH}$, $C_{16:1}$, $C_{12:0\ 2OH}$, and **ubiquinone Q-8.** The **polyamine patterns** display **putrescine** as the major compound and contain the unusual diamine **2-hydroxyputrescine**.

Isolated from water, soil; also from hospital environment and human clinical specimens with pathological significance or as contaminants.

The mol% G + C of the DNA is: 65–68.

Type species: **Achromobacter xylosoxidans** Yabuuchi and Yano 1981, 477.

FURTHER READING

De Ley, J., P. Segers, K. Kersters, W. Mannheim and A. Lievens. 1986. Intrageneric and intergeneric similarities of the *Bordetella* ribosomal ribonucleic acid cistrons: proposal for a new family, *Alcaligenaceae*. Int. J. Syst. Bacteriol. *36*: 405–414.

List of species of the genus Achromobacter

1. **Achromobacter xylosoxidans** (ex Yabuuchi and Ohyama 1971) Yabuuchi and Yano 1981, 477[VP] emend. Yabuuchi, Kawamura, Kosako and Ezaki 1998a, 436.
xy.los.ox′.i.dans. Gr. n. *xylon* wood, xylose, wood sugar; Gr. adj. *oxys* sharp, acid; L. part. *dans* giving; M.L. pres part. *oxydans* acid-giving, oxidizing; M.L. *xylosoxydans* oxidizing xylose.

The description is taken from Yabuuchi et al. (1998a). The morphological characteristics are as described for the genus. Colonies on nutrient agar are circular, nonpigmented to grayish white, translucent to opaque, flat to convex, usually smooth, sometimes dull or rough, margin usually entire. On heart infusion agar colonies are 1 mm in diameter, low convex with entire margin, moist, and with a glistening surface. Grows anaerobically in the presence of nitrate or nitrite by denitrification. In the API 20NE test citrate, adipic acid, DL-malic acid, and phenylacetate are assimilated. Assimilation of gluconate, capric acid, and glucose is variable. L-arabinose, D-mannitol, D-mannose, maltose, and *N*-acetyl-D-glucosamine are not assimilated.

The mol% G + C of the DNA is: 63.9–69.8 (Bd, T_m).

a. **Achromobacter xylosoxidans** *subsp.* **xylosoxidans** (ex Yabuuchi and Ohyama 1971) Yabuuchi and Yano 1981, 477[VP] (*Alcaligenes denitrificans* subsp. *xylosoxidans* (Yabuuchi and Yano 1981) Kersters and De Ley 1984b, 367; *Alcaligenes xylosoxidans* subsp. *xylosoxidans* (Yabuuchi and Yano 1981) Kiredjian, Holmes, Kersters, Guilvout and De Ley 1986, 285.)

If not stated otherwise, the description is taken from Kersters and De Ley (1984b) and Yabuuchi et al. (1998a). Nearly all strains utilize D-glucose, D-xylose, D-gluconate, adipate, and pimelate as sole carbon sources and characteristically form acid from D-xylose in the O/F medium of Hugh and Leifson (1953). Further characteristics are shown in Table BXII.β.30.

A plasmid-encoded resistance by two distinct nickel resistance loci (high- and low-level) against nickel, cobalt, and cadmium has been described for strain *Achromobacter xylosoxidans* 31A (Schmidt et al., 1991; Schmidt and Schlegel, 1994), originally isolated from a copper galvanization tank. Maintenance of the biodegradation capacities of *A. xylosoxidans* and other Gram-negative aerobic bacteria containing large plasmids during long-term preservation was studied and protective agents have been described (Lang and Malik, 1996).

Mostly isolated from clinical specimens such as blood, sputum, wounds, purulent ear discharge, spinal fluid, cerebral tissue, urine, feces, and, in a few cases, also from disinfectant solutions.

The fatty acid profile is characterized by the following compounds: $C_{16:0}$, $C_{17:0\ cyclo}$, $C_{14:0\ 3OH}$, $C_{16:1}$, $C_{14:0\ 2OH}$, $C_{12:0\ 2OH}$, $C_{16:0\ 2OH}$, $C_{18:0}$, $C_{14:0}$, and $C_{19:0\ cyclo}$ (Vandamme et al., 1995c). Phosphatidylethanolamine, phosphatidylglycerol, and diphosphadidylglycerol are the major compounds in the polar lipid profile (Yabuuchi et al., 1974). The polyamine pattern contains two major compounds: putrescine and the unusual 2-hydroxyputrescine (Busse and Auling, 1988).

The mol% G + C of the DNA is: 66.9–69.8 (T_m) (De Ley et al., 1970b; Yabuuchi et al., 1974; Holmes et al., 1977b).

Type strain: Hugh 2838, ATCC 27061, CIP 71.32, Yabuuchi KM 543, NCTC 10807.

GenBank accession number (16S rRNA): X59163, D88005.

Additional Remarks: The type strain was proposed as the type strain for *Achromobacter xylosoxidans* by Yabuuchi and Ohyama (1971). Other representative culture collection strains belonging to this taxon: CIP 58.72 and CIP 61.20 (formerly *A. denitrificans*). In the near future Coyne et al. will propose the reclassification of *Alcaligenes denitrificans* as *Achromobacter denitrificans* (Int. J. Syst. Evol. Microbiol., in press, 2003).

b. **Achromobacter xylosoxidans** *subsp.* **denitrificans** (Rüger and Tan 1983) Yabuuchi, Kawamura, Kosako and Ezaki 1998b, 1083[VP] (Effective publication: Yabuuchi, Kawamura, Kosako and Ezaki 1998a, 436) (*Alcaligenes denitrificans* Rüger and Tan 1983, 88; *Alcaligenes denitrificans* subsp. *denitrificans* Rüger and Tan 1983; *Alcaligenes xylosoxidans* subsp. *denitrificans* (Rüger and Tan 1983) Kiredjian, Holmes, Kersters, Guilvout and De Ley 1986, 285.)
de.ni.tri′fi.cans. L. prep. *de* away, from; L. n. *nitrum* soda; M.L. n. *nitrum* nitrate; M.L. v. *denitrificans* to denitrify; M.L. pres. part. *denitrificans* denitrifying.

If not stated otherwise the description is taken from Kersters and De Ley (1984b) and Yabuuchi et al. (1998a). Physiological and nutritional characteristics of the species are presented in Table BXII.β.29 of *Alcaligenaceae* and Table BXII.β.30 of this chapter. Most strains characteristically use *meso*-tartrate, itaconate, adipate, pimelate, and other dicarboxylic acids as sole carbon sources. Some strains are auxotrophic and require organic nitrogenous compounds for growth. Nitrates and nitrites are usually reduced. Most strains carry out an anaerobic respiration in the presence of nitrate and nitrite.

The fatty acid profile is characterized by the following compounds: $C_{16:0}$, $C_{17:0\ cyclo}$, $C_{14:0\ 3OH}$, $C_{14:0}$, $C_{16:1}$, $C_{12:0\ 2OH}$, $C_{18:1}$, $C_{12:0}$, $C_{18:0}$, $C_{16:0\ 2OH}$, and $C_{19:0\ cyclo}$ (Vandamme et al., 1995c). Ubiquinone Q-8 is the predominant respiratory quinone (Lipski et al., 1992); the poly-

amine pattern contains two major compounds: putrescine and the unusual 2-hydroxyputrescine (Busse and Auling, 1988).

Isolated from soil, and a variety of clinical specimens such as feces, urine, blood, pleural fluid, purulent ear discharges, prostatic secretions, and throat swabs.

Strains of *A. xylosoxidans* subsp. *denitrificans* or *A. xylosoxidans* subsp. *xylosoxidans* have been isolated from soil and examined for presence of D-aminoacylase in order to produce D-amino acids from *N*-acetyl-DL-amino acids enzymatically. The presence of D-aminoacylase appeared not to be a general characteristic of members of the genus, although inducible D-aminoacylases with high stereospecificity and higher specific activity than those described from *Pseudomonas* and *Streptomyces* were found (Moriguchi and Ideta, 1988; Tsai et al., 1988). A novel cyanide-hydrolyzing enzyme from *A. xylosoxidans* subsp. *denitrificans* has been described (Ingvorsen et al., 1991). Recently a gene from *A. xylosoxidans* subsp. *denitrificans* has been analyzed that confers albicidin resistance by reversible antibiotic binding. This gene appears to be a useful candidate for transfer to plants to protect plastid DNA replication from inhibition by albicidin phytotoxins involved in sugarcane leaf scald disease (Basnayake and Birch, 1995). Uptake of chloro-substituted benzoic acids that are formed as dead-end metabolites by polychlorinated biphenyl-degrading microorganisms has been studied in *A. xylosoxidans* subsp. *denitrificans* (Miguez et al., 1995). *A. xylosoxidans* subsp. *denitrificans* was shown to mineralize the structurally related chlorinated phenoxy alkanoics, including 2,4-dichlorophenoxyacetic acid (2,4-D), 2-methyl-4-chlorophenoxyacetic acid (MCPA), and 2-(2-methyl-4-chlorophenoxy) propionic acid (mecoprop), which are among the most widely used herbicides to control broad-leafed weeds in cereal crops throughout the world. The strain described uses the *ortho*-pathway for biodegradation (Tett et al., 1994, 1997). Reductive dechlorination of 2,4-dichlorobenzoate and hydrolytic dehalogenation of 4-halo-substituted aromatics has been studied with *A. xylosoxidans* subsp. *denitrificans* NTB-1 (van der Tweel et al., 1987). Gene transfer of plasmid-encoded 2,2-dichloropropionate halidohydrolase from *A. xylosoxidans* subsp. *denitrificans* to other soil bacteria has been demonstrated using a soil microcosm (Brokamp and Schmidt, 1991). Recently the plasmid (pFL40)-encoded D,L-haloalkanoic acid dehydrogenase gene (*dhlIV*) was sequenced and expressed in members of the *Gammaproteobacteria* (Brokamp et al., 1997). Gas-phase methyl ethylketone biodegradation in a novel type of bioreactor was demonstrated with a bacterial consortium dominated by *A. xylosoxidans* subsp. *denitrificans*, run under non-axenic conditions (Agathos et al., 1997).

The mol% G + C of the DNA is: 63.9–68.9 (T_m, Bd) (De Ley et al., 1970b; Pichinoty et al., 1978).

Type strain: Hugh 12, ATCC 15173, CIP 77.15, DSM 30026, NCTC 8582.

GenBank accession number (16S rRNA): M22509.

Additional Remarks: Other representative culture collection strains belonging to this taxon are ATCC 13138, CIP 60.81 (*A. xylosoxidans* subsp. *denitrificans*).

2. **Achromobacter piechaudii** (Kiredjian, Holmes, Kersters, Guilvout and De Ley 1986) Yabuuchi, Kawamura, Kosako and Ezaki 1998b, 1083^{VP} (Effective publication: Yabuuchi, Kawamura, Kosako and Ezaki 1998a, 436) (*Alcaligenes piechaudii* Kiredjian, Holmes, Kersters, Guilvout and De Ley 1986, 285.)
pie.chau' di.i. M.L. gen. n. *piechaudii* from Piechaud, to honor M. Piechaud, a bacteriologist at the Institut Pasteur, Paris, France.

The description is taken from the original paper. Gram-negative, obligately aerobic, straight rods, 0.5–1.0 × 1.0–1.5 µm, which have parallel sides and rounded ends. Cells occur singly and are nonsporulating and noncapsulated. Cells are motile by means of two to eight peritrichous flagella, which have one or two wavelengths. At the optimal temperature (28–30°C) visible growth within 24 h. Liquid cultures (in nutrient broth medium) are uniformly turbid; cultures on trypticase soy agar produce small smooth colonies (diameter, 0.2 mm). Colonies are 1 mm in diameter after 48 h of incubation; no pigments or odor produced. Circular, smooth, entire colonies on nutrient agar after 24 h of growth. Colonies are nonhemolytic on 5% (v/v) horse blood agar. The organisms are nonfluorescent on King medium B and do not produce a brown diffusible melanin-like pigment on tyrosine agar. Growth without NaCl in peptone–water medium and at a maximum NaCl concentration of 7% (w/v). Alkaline reaction in glucose oxidation–fermentation medium. Catalase positive. Oxidase positive. Hydrolyzes tributyrin and tyrosine but not gelatin, Tween 20, Tween 80, esculin, or starch. Casein is not digested. Extracellular deoxyribonuclease or opalescence on lecithovitellin agar is not produced. Does not produce indole, urease, arginine desimidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, β-D-galactosidase (as determined by the *o*-nitrophenyl-β-D-galactopyranoside test) or phosphatase. Reduces nitrate but not nitrite; no anaerobic respiration in the presence of nitrate or nitrite. Produces hydrogen sulfide, as determined by the lead acetate paper method, but not as determined by the triple-sugar-iron agar method. Does not reduce thiosulfate. Grows on β-hydroxybutyrate (with production of lipid inclusion granules), on cetrimide, and on MacConkey agar. Produces alkali on Christensen citrate (as determined by the NCTC method; Kiredjian et al., 1986). Utilizes citrate (Simmons medium) as determined by the IP (Kiredjian et al., 1986) method but not as determined by the NCTC method; does not utilize malonate (as determined by the NCTC method). Oxidizes gluconate as determined by the IP method but not as determined by the NCTC method. Tolerates KCN at a concentration of 0.0075%. Does not produce 3-ketolactose. Does not reduce selenite and does not deaminate histidine, leucine, phenylalanine, or tryptophan. In minimal synthetic medium *n*-valerate, isovalerate, D-gluconate, mesaconate, and itaconate are assimilated. Does not assimilate carbohydrates in minimal synthetic medium. Produces acid in ammonium salt medium under aerobic conditions from ethanol. Does not produce acid in ammonium salt medium under aerobic conditions from D-glucose, adonitol, L-arabinose, D-cellobiose, dulcitol, D-fructose, glycerol, *m*-inositol, lactose, maltose, mannitol, raffinose, L-rhamnose, salicin, D-sorbitol, sucrose, trehalose, or D-xylose. Does not produce

acid from 10% (w/v) D-glucose or 10% (w/v) lactose. Does not produce acid or gas from D-glucose in peptone–water medium.

Hydrolyzes the following substrates (determined by using API ZYM galleries): L-leucyl-2-naphthylamide, glycyl-β-naphthylamide, L-aspartyl-β-naphthylamide, arginyl-β-naphthylamide, L-alanyl-β-naphthylamide, and L-leucyl-glycyl-β-naphthylamide. Does not hydrolyze the following substrates (determined by using API ZYM galleries): 2-naphthyl phosphate (at pH 8.5), 2-naphthyl caprylate, 2-naphthyl myristate, L-valyl-2-naphthylamide, L-cystyl-2-naphthylamide, *N*-benzoyl-DL-arginine-2-naphthylamide, *N*-glutaryl-phenylalanine-2-naphthylamide, naphthol-AS-B1-phosphodiamide, 6-bromo-2-naphthyl-α-D-galactopyranoside, 2-naphthyl-β-D-galactopyranoside, naphthol-AS-BI-β-D-glucuronic acid, 2-naphthyl-α-D-glucopyranoside, 6-bromo-2-naphthyl-β-D-glucopyranoside, 1-naphthyl-*N*-acetyl-β-D-glucosaminide, 6-bromo-2-naphthyl-α-D-mannopyranoside, 2-naphthyl-α-L-fucopyranoside, α-D-galactopyranoside, β-D-galactopyranoside, β-D-galactopyranoside-6-phosphate, α-L-arabinofuranoside, α-D-glucopyranoside, β-D-glucopyranoside, β-D-galacturonide, β-D-glucuronide, α-maltoside, β-maltoside, *N*-acetyl-α-D-glucosaminide, *N*-acetyl-β-D-glucosaminide, α-L-fucopyranoside, β-D-fucopyranoside, β-D-lactoside, α-D-mannopyranoside, β-D-mannopyranoside, α-D-xylopyranoside, β-D-xylopyranoside, L-tyrosyl-β-naphthylamide, L-phenylalanyl-β-naphthylamide, L-hydroxyprolyl-β-naphthylamide, L-histidyl-β-naphthylamide, *N*-benzoyl-L-leucyl-β-naphthylamide, *S*-benzoyl-L-cysteyl-β-naphthylamide, glycyl-L-prolyl-β-naphthylamide, *N*-carbobenzoxy-L-arginine-4-methoxy-β-naphthylamide hydrochloride, L-isoleucyl-β-naphthylamide, L-prolyl-β-naphthylamide hydrochloride, L-threonyl-β-naphthylamide, L-tryptophyl-β-naphthylamide and *N*-carbobenzoxy-glycyl-glycyl-L-arginine-β-naphthylamide.

Growth occurs at room temperature and 37°C but not at 5° or 42°C (optimal growth temperature 28–30°C). Although strains of *A. piechaudii* have been recovered mainly from human clinical material, few clinical details are available, so the clinical significance of the species is not yet determined.

The fatty acid profile is characterized by the following compounds: $C_{17:0\ cyclo}$, $C_{16:0}$, $C_{14:0\ 3OH}$, $C_{14:0}$, $C_{18:1}$, $C_{16:1}$, $C_{12:0\ 2OH}$, $C_{18:0}$, $C_{16:0\ 2OH}$, and $C_{19:0\ cyclo}$ (Vandamme et al., 1995c); the polyamine patterns contains two major compounds: putrescine and the unusual 2-hydroxyputrescine (Hamana and Takeuchi, 1998).

The mol% G + C of the DNA is: 64–65 (T_m).

Type strain: Hugh 366-5, CIP 60.75ATCC 43552, IAM 12591, LMG 1873.

GenBank accession number (16S rRNA): AB010841.

Additional Remarks: Other representative culture collection strains belonging to this taxon are LMG 6100 (CIP 55774), LMG 2828 (AB118), LMG 1861 (NCMB 1051), LMG 6102 (CL544/75), LMG 6101 (CL807/79), LMG 6103 (CL237/83).

3. **Achromobacter ruhlandii** (Aragno and Schlegel 1977) Yabuuchi, Kawamura, Kosako and Ezaki 1998b, 1083^{VP} (Effective publication: Yabuuchi, Kawamura, Kosako and Ezaki 1998a, 436) (*Alcaligenes ruhlandii* (Packer and Vishniac 1955) Aragno and Schlegel 1977, 280.)
ruh.lan′di.i. M.L. gen. n. *ruhlandii* of Ruhland, named for the German microbiologist W. Ruhland, who studied the physiology of the hydrogen bacteria.

Cells are Gram-negative, nonsporeforming rods. Nonfermentative, nonhemolytic, and nonhalophilic. Growth occurs on MacConkey agar, in the presence of 5% NaCl, and at 41°C. Catalase and oxidase positive. Simmons' citrate medium is alkalized within 2 d and malonate broth within 3 d of incubation. Nitrate is reduced to nitrite. Gas is not produced in nitrate broth. Oxidatively acid is produced in OF medium from D-arabinose within 2 d and from L-arabinose, glucose, D-ribose, and D-xylose within 3 d of incubation. No acid is produced from fructose, galactose, cellobiose, lactose, maltose, melibiose, sucrose, trehalose, raffinose, melezitose, glycerol, adonitol, dulcitol, inositol, mannitol, sorbitol, salicin, and inulin. Acylamidase test is positive within 3 d of incubation. Urease, phenylalanine deaminase, and DNase are negative. Esculin, gelatin, starch, and Tween 80 are not hydrolyzed. Lysine and ornithine decarboxylase and arginine dihydrolase are negative. No pigments are produced. Glucose, adipic acid, capric acid, malic acid, citrate, gluconate, and phenylacetate are assimilated.

Isolated from soil. The polyamine pattern contains two major compounds: putrescine and the unusual 2-hydroxyputrescine (Busse and Auling, 1988).

The only available strain, *A. ruhlandii* ATCC 15749 (DSM 653), can grow autotrophically with hydrogen. Hydrogen-oxidizing strains similar to the only available strain of the species *A. ruhlandii* or other autohydrogenotrophic denitrifying members of the genus *Achromobacter* could not be isolated from autohydrogenotrophic pilot-reactors for denitrification of drinking water (Vanbrabant, et al., 1993; Auling and Luo, unpublished results).

The mol% G + C of the DNA is: 68.1 (T_m) (De Ley et al., 1986) and 67.7 (HPLC) (Yabuuchi et al., 1998a).

Type strain: ATCC 15749, DSM 653, IAM 12600.

GenBank accession number (16S rRNA): AB010840.

Other Organisms

For *Achromobacter* species (formerly assigned to the genus *Alcaligenes*) a significant environmental role on biodegradation of aromatic or halogenated compounds, even in the deep subsurface (Boivin-Jahns et al., 1995), is proposed by reports on isolation of strains, tentatively assigned to *A. xylosoxidans* (Ewers et al., 1990) and *A. denitrificans* (Weissenfels et al., 1990). The descriptive information is limited to the three species comprising the genus *Achromobacter*—*A. xylosoxidans, A. piechaudii*, and *A. ruhlandii*—and close relatives. Nevertheless, strains preliminarily identified as members of the genus *Alcaligenes* are still awaiting final taxonomic characterization, although published and named. Thus, care has to be taken when extrapolating the properties of such interesting strains to the whole species or even the genus.

The main phylogenetic aspects have been treated in the description of the family. DNA–DNA hybridizations indicated the emergence of an additional species in the neighborhood of *A. denitrificans* that may be centered around a strain O-1 able to degrade sulfonated aromatic compounds (Jahnke et al., 1990). The G + C content (66.1 mol%) of *Alcaligenes* sp. strain O-1

corresponds to that of the species. The DNA relatedness values obtained (51% to the type strain of *A. xylosoxidans* subsp. *xylosoxidans* and 40% to the type strain of *A. xylosoxidans* subsp. *denitrificans*) would justify a status as a separate species. Polyclonal antibodies raised against strain O-1 displayed the highest cross-reactivity with *A. xylosoxidans.* Thus, *Alcaligenes* O-1 can be considered as another species of the genus *Achromobacter. Alcaligenes* sp. strain O-1 contains a 117-MDa conjugative plasmid (pSAH) encoding mineralization of sulfonated aromatic compounds. The conjugative transfer of the toluene transposon Tn 4651 from *Pseudomonas putida* harboring plasmid pWW0, the archetypal TOL plasmid (Assinder and Williams, 1990), into plasmid pSAH extends the expression range of the TOL catabolic genes (degradation of 3-methylbenzoic acid) to the genus *Achromobacter* (Jahnke et al., 1993). A chlorobenzoate transposon (Tn5271) from the indigenous plasmid pBRC60 in *Alcaligenes* sp. strain BR60, isolated from runoff waters adjacent to a chlorobenzoate contaminated landfill, has been intensively studied genetically, although the taxonomic characterization of the host strain is still lacking (Windham et al., 1994).

The expression of xenobiotic-degrading genes using naphthalene as substrate has been investigated in *Alcaligenes* sp. (strain NP-Alk) versus *Pseudomonas putida* ATCC 17484, using these microorganisms as models for bioremediation of contaminated environments by either indigenous bacteria or strains released into an ecosystem (Guerin and Boyd, 1995).

The two biodegradative isolates, strain A3-C, able to degrade naphthalene sulfonic acid (Brilon et al., 1981), and strain B1, able to mineralize toluene sulfonic acid (Thurnheer et al., 1986), were identified as members of *A. denitrificans*, or classified within the genus *Alcaligenes* close to *A. denitrificans*, respectively (Busse et al., 1992).

Another strain (L6), from a collection of aerobic isolates proficient of 3-chlorobenzoate degradation under reduced oxygen partial pressures by metabolization via gentisate or the protocatechuate pathway, was allocated to the genus *Alcaligenes* by 16S rDNA sequencing (Krooneman et al., 1996). The authors demonstrated an increased oxygen affinity of strain L6 in studies with continuous culture, as is expected for organisms that are involved in metabolism of aromatic compounds and play an important role in determining the fate of haloaromatics at oxic-anoxic interfaces. Given their previous allocation to *A. denitrificans* or *A. xylosoxidans*, the strains A3-C, B1, and L6 are considered members of the genus *Achromobacter.*

Genus III. **Bordetella** *Moreno-López 1952, 178*[AL]

Gary N. Sanden and Robbin S. Weyant

Bor.de.tel′ la. M.L. dim ending *-ella;* M.L. fem. n. *Bordetella* named after Jules Bordet, who with O. Gengou first isolated the organism causing pertussis.

Minute coccobacillus, 0.2–0.5 µm in diameter and 0.5–2.0 µm in length, often bipolar stained, and arranged singly or in pairs, more rarely in chains. Gram negative. **Nonmotile** or **motile** by peritrichous flagella. **Strictly aerobic. Optimal temperature, 35–37°C.** Colonies on Bordet–Gengou medium are smooth, convex, pearly, glistening, nearly transparent, and surrounded by a zone of hemolysis without definite periphery. **Respiratory metabolism.** Chemoorganotrophic. **Require nicotinamide, organic sulfur** (e.g., cysteine), and **organic nitrogen** (amino acids). **Utilize oxidatively** glutamic acid, proline, alanine, aspartic acid, and serine, with production of ammonia and CO_2. Litmus milk is made alkaline. Mammalian and avian parasite and pathogen. Most species localize and multiply among the epithelial cilia of the respiratory tract.

The mol% G + C of the DNA is: 66–70.

Type species: **Bordetella pertussis** (Bergey, Harrison, Breed, Hammer and Huntoon 1923a) Moreno-López 1952, 178 (Microbe de coqueluche Bordet and Gengou 1906, 731; *Haemophilus pertussis* Bergey, Harrison, Breed, Hammer and Huntoon 1923a, 269.)

Further descriptive information

Phylogeny and taxonomy The genus *Bordetella*, along with the closely related genus *Alcaligenes*, constitute the family *Alcaligenaceae* of the *Betaproteobacteria.* The close association of these genera has been demonstrated by phenotypic analysis, which identified *Alcaligenes* as the nearest neighbor to *Bordetella* and most closely associated strains of this genus with *B. bronchiseptica* (Johnson and Sneath, 1973). DNA–rRNA hybridization and G + C content confirm this association, together with their mutual divergence from other taxa (De Ley et al., 1986).

Historically, it has been difficult to differentiate between *Bordetella* and *Alcaligenes* based on phenotype because of the low reactivity and common responses in many tests. Formerly, *Bordetella* spp. were regarded as pathogens of the upper respiratory tract of humans and animals and *Alcaligenes* spp. as aquatic and terrestrial saprophytes. This distinction, based on ecological niche, has been confounded by recent revelations in phylogeny, reclassification of some *Alcaligenes* spp., and the designation of novel *Bordetella* spp. that are not etiologic agents of respiratory diseases.

The genus *Bordetella* contains seven species: *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, *B. avium*, *B. hinzii*, *B. holmesii*, and *B. trematum.* Various methods have been used to derive phylogeny within the genus including analyses of phenotypic characteristics, DNA base composition, nucleic acid hybridization, multilocus enzyme electrophoresis (MEE), gene-sequence analyses, and the distribution and copy numbers of insertion sequences (Johnson and Sneath, 1973; Kloos et al., 1979; Kiredjian et al., 1981; Kersters et al., 1984; De Ley et al., 1986; van der Zee et al., 1997). In 1973, Johnson and Sneath described a numerical taxonomic study of *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* based on 134 characteristics. They showed that the test strains aligned into three highly similar clusters corresponding to the respective species. Differentiation based on whole-cell protein and fatty acid analysis also supported the species status of these taxa (Vancanneyt et al., 1995). DNA hybridization results subsequently yielded similar clustering, but the tested isolates were sufficiently related

as to constitute a single genomospecies (Kloos et al., 1979; Weyant et al., 1995a). Evaluations of the DNA base composition, DNA–rRNA hybridization results (De Ley et al., 1986), sequence similarity among the 23S rRNA genes (Muller and Hildebrandt, 1993), and genetic relatedness measured by multilocus enzyme electrophoresis (Musser et al., 1986) also supported the single-species concept. Conversely, lipopolysaccharide expression is nomenspecies-specific (van den Akker, 1998), and macro-restriction profiling of genomic DNA with a rarely cutting endonuclease demonstrated heterogeneity among the three species *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* (Khattak and Mathews, 1993). Although strains were more highly related within a given species, sufficient variability to discriminate between epidemiologically unrelated *B. pertussis* isolates has been documented.

Gene sequence analysis (Marchitto et al., 1987; Muller and Hildebrandt, 1993) and the data supporting the single-species concept suggest a relatively recent evolutionary origin and a common ancestor for *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* (Mooi et al., 1987; van der Zee, 1997). However, further elucidating the relationships within the genus was contentious until recently. *B. pertussis* and *B. parapertussis* were most closely related by the phenotypic characteristics evaluated (Johnson and Sneath, 1973). Sequence variations among pertussis toxin operons provided evidence for the evolution of *B. parapertussis* and then *B. bronchiseptica* from a common ancestor through *B. pertussis* (Arico and Rappuoli, 1987). DNA–rRNA hybridization studies separated *B. pertussis* and *B. bronchiseptica* with *B. parapertussis* between and overlapping them (De Ley et al., 1986). DNA hybridization (Kloos et al., 1979), multilocus enzyme electrophoresis (MEE) (Musser et al., 1986), and susceptibility to lytic bacteriophage (Rauch and Pickett, 1961) suggested that *B. parapertussis* is more highly related to *B. bronchiseptica* than to *B. pertussis*. The restricted diversity exhibited by MEE evaluations of *B. pertussis* and *B. parapertussis* isolates implies a shared ancestor (Musser et al., 1986). The comparatively greater heterogeneity found in *B. bronchiseptica* genetic structure, despite its general clonal nature, is consistent with an older lineage from which *B. pertussis* and *B. parapertussis* derived by host adaptation (Musser et al., 1986, 1987). Maximum parsimony evaluation of data from MEE and pertussis toxin operon sequences (Altschul, 1989) grouped all *B. pertussis* strains together with a unique common ancestor and designated *B. parapertussis* as a subtype of *B. bronchiseptica*.

MEE and DNA polymorphisms mediated by insertion sequence elements have recently yielded additional insights into phylogenetic relationships among *Bordetella* spp. (van der Zee et al., 1996, 1997). The distinction between sheep and human isolates of *B. parapertussis*, first based on differences in phenotype and electrophoretic types (Porter et al., 1994), and later reinforced by LPS expression (van den Akker, 1998), was confirmed by typing with insertion elements (van der Zee et al., 1996). In addition, this latter technique showed that transmission between the human and ovine populations was unlikely, and that the human strains were less divergent, suggesting that they evolved from *B. bronchiseptica* independently and more recently than sheep isolates.

Evaluation of 188 *Bordetella* isolates by MEE and the distribution of three insertion elements clarified the evolution and host adaptation in this genus (van der Zee et al., 1997). In general, host adaptation has restricted *B. pertussis* to humans and *B. parapertussis* to humans and sheep. Although some *B. bronchiseptica* clones tended to be more host- and geographically specific than others, it infects a much greater diversity of hosts, conforming with the greater genotypic diversity calculated for this species. Computer analyses of MEE along with distributions and sequences of insertion elements verified that *B. pertussis* and *B. parapertussis* descended from alternative clones of *B. bronchiseptica*, with *B. pertussis* infecting humans first. Indeed, *B. parapertussis* seems to have adapted to humans relatively recently from a *B. bronchiseptica* clade exclusive to pigs. In contrast, ovine strains of *B. parapertussis* most likely adapted to their host earlier.

Organisms belonging to four additional taxa are highly related to the historically recognized *Bordetella* spp. Among these were isolates classified as *Bordetella* or *Alcaligenes* causing an acute respiratory disease in birds that is symptomatically and pathologically analogous to pertussis in humans (Hinz et al., 1978; Simmons et al., 1981; Rimler and Semmons, 1983). The initial confusion over classifying such isolates was most likely due to their inactivity in conventional biochemical assays. Subsequently, several phenotypic approaches as well as DNA base composition and DNA–rRNA hybridization were used to assign such strains isolated from birds and causing coryza (rhinotracheitis) in turkey poults to a genotypically and phenotypically homogeneous fourth species, *B. avium* (Kersters et al., 1984). The DNA base composition of these strains was lower than those reported for the other *Bordetella* species and for the *Alcaligenes denitrificans*–*Achromobacter xylosoxidans* group (Kersters et al., 1984; De Ley et al., 1986). However, the 6.7 mol% G + C difference was reportedly insufficient to preclude *B. avium* from the genus, especially given the level of relatedness indicated by phenotypic properties, including isoprenoid quinone content (Fletcher et al., 1987), distinctive cellular fatty acid profiles (Moore et al., 1987), and DNA–rRNA hybridization (Kersters et al., 1984). Numerical analysis of phenotypic features related *B. avium* most closely to *B. parapertussis* (De Ley et al., 1986).

Bordetella holmesii was characterized in 1995 (Weyant et al., 1995a). Fifteen isolates representing this species were cultured from the blood of mostly young adults with underlying debilitations between 1983 and 1992. Initially referred to as CDC nonoxidizer group 2 (NO-2) based on common phenotypic characteristics, their cellular fatty acid profiles, 16S rRNA sequences, mol% G + C, and ubiquinone 8 content suggested close relatedness to the genus *Bordetella*. This was confirmed with DNA relatedness experiments that showed that these strains were sufficiently related as to constitute a single species (Wayne et al., 1987) and supported their placement within *Bordetella*. More recently, *B. holmesii*-like organisms were cultured from the sputum of a patient with acute pulmonary edema and bronchitis (Tang et al., 1998) and from 33 nasopharyngeal specimens collected from the nasopharynx of patients with cough illness as part of an active pertussis surveillance program (Yih et al., 1999). Additional studies are needed to define the role of *B. holmesii* in respiratory disease.

A sixth species is composed of isolates sharing similar features and resembling *B. avium* on biochemical assays that were cultured from the respiratory tracts of poultry and two human clinical specimens (Vandamme et al., 1995c). Although initially isolated in diverse geographical areas from turkeys and chickens with respiratory illness, there is insufficient evidence to attribute an etiologic role for these strains (Berkhoff and Riddle, 1984). Conversely, the human isolates from blood and sputum specimens were associated with bacteremia in an immunocompromised patient (Cookson et al., 1994; Vandamme et al., 1995c) and pulmonary complications in a cystic fibrosis patient (Funke et al., 1996), respectively. A third human strain was cultured from

human sputum, but no clinical significance could be assigned due to lack of clinical data (Kiredjian et al., 1981). Twelve isolates from poultry and two from humans were evaluated by nucleic acid composition and hybridizations, and their phenotypic characteristics, including protein and fatty acid analysis. These results revealed that these strains are a new species, *Bordetella hinzii* (Vandamme et al., 1995c).

Previous efforts to characterize atypical members of the *Bordetella–Alcaligenes* group led to the evaluation of a collection of 10 isolates recovered from wounds and chronic otitis media (Dorittke et al., 1995; Vandamme et al., 1996a). Comparison of protein electrophoretic patterns of these isolates disclosed highly similar patterns that were distinguishable from the protein profiles of representative strains of the *Alcaligenaceae*. DNA base composition and hybridization analyses confirmed the homogeneity of this group. DNA–rRNA hybridization results placed these strains within the *Alcaligenaceae* and aligned a representative strain more closely to the *Bordetella* than the *Alcaligenes* type species. Consequently, the species has been named *Bordetella trematum* (Vandamme et al., 1996a).

Cellular morphology *Bordetella* cells usually appear as minute coccobacilli 0.2–0.5 × 0.5–2.0 µm. Cells of degraded strains may appear slightly larger. *B. trematum* cells may be slightly larger (0.5–0.6 × 1.0–2.4 µm) than those of the other species. Capsules have been observed with *B. pertussis*, *B. bronchiseptica*, and *B. trematum* (Lawson, 1940; Nakase, 1957; Vandamme et al., 1996a). Peritrichous flagella are observed on cells of the motile species, *B. bronchiseptica*, *B. avium*, *B. trematum*, and *B. hinzii*. Labow and Mosley have measured the periodic structure of *B. bronchiseptica* flagella as 19.0 by 13.9 nm (Labaw and Mosley, 1955). Pili-like filaments have been observed on cells of *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, and *B. avium* (Morse and Morse, 1970; Jackwood and Saif, 1987). Similar investigations have not as yet been reported for the more recently described species.

Nutrition and growth conditions Bordetellae are obligate aerobes with an optimal growth temperature range of 30–37°C. The metabolism of these organisms is based on the oxidation of amino acids. Carbohydrates are generally not utilized. Nicotinamide, organic nitrogen, and organic sulfur (cystine, cysteine, or glutathione) are required for growth (Weiss, 1992). With the exception of *B. pertussis*, growth can be obtained on a wide variety of culture media, including trypticase soy agar with 5% sheep blood, heart infusion agar with or without 5% rabbit blood, MacConkey agar, and peptone agar. Cultivation of *B. pertussis* is more difficult because of its susceptibility to various compounds (unsaturated fatty acids, colloidal sulfur, or sulfides) found in most growth media. Charcoal horse blood agar and Bordet–Gengou agar contain adsorbants for these inhibitors and allow for the growth of *B. pertussis* (Hoppe, 1988; Weyant et al., 1996). Charcoal horse blood agar has a longer shelf-life than Bordet–Gengou agar and is superior in its ability to support *B. pertussis* growth (Hoppe, 1988). Two chemically defined media, Stainer-Scholte broth and cyclodextrin solid medium (Aoyama et al., 1986), have also been developed to support the growth of *B. pertussis*.

Colonial morphology The time of development and the size of colonies differ among the species. *B. pertussis* is the most fastidious, with 3–6 d required for the development of pinpoint colonies on Bordet–Gengou medium. Colonies have a characteristic narrow zone of hemolysis and are usually convex and glistening, with an entire edge. Colony diameter rarely exceeds 3 mm. *B. parapertussis* and *B. holmesii* produce slightly larger convex, semi-opaque colonies at 2–3 d of incubation. Diffuse zones of browning may be observed around *B. parapertussis* and *B. holmesii* colonies, especially in media supplemented with tyrosine. Strains of the other *Bordetella* species usually produce colonies within 2 d of incubation. *B. bronchiseptica* colonies on MacConkey agar are reddish and surrounded by a small red zone with amber discoloration of the underlying medium. *B. trematum* strains produce convex, circular, and grayish cream white colonies with entire edges on blood agar (Vandamme et al., 1996a). Multiple colony types each have been described for *B. avium* and *B. hinzii*. For *B. avium*, type I colonies are small pearl-like with entire edges and glistening surfaces and <1 mm in diameter after 24 h of incubation. Type II colonies are larger, circular, and convex with entire edges and smooth surfaces. Colony types are usually strain-specific and stable (Kersters et al., 1984). A third colony type, characterized by a crenated edge and a flat surface with a wrinkled or ground-glass appearance, has also been described (Jackwood et al., 1991). Some strains of *B. hinzii* produce round, raised, glistening, grayish colonies about 2 mm in diameter at 48 h of incubation. Other strains produce flat, dry, crinkled colonies with diameters up to 5 mm at 48 h of incubation (Vandamme et al., 1995c).

Pathogenicity *Bordetella* species are responsible for respiratory tract infections in humans and various other warm-blooded animals. These organisms have a significant public health and economic impact. *B. pertussis* causes pertussis (whooping cough) in humans. This disease is characterized by violent paroxysms of coughing followed by a loud inspiratory "whoop" (von Lichtenberg, 1984). The incubation period is between 7 and 10 d. The disease is highly communicable, with person-to-person transmission occurring via aerosolized droplet nuclei. Pertussis infections result in over 350,000 deaths annually (Cherry, 1996; Hoppe, 1999).

Current pertussis-containing vaccines are effective in preventing or attenuating severe pertussis after three or more doses. Because vaccine-induced immunity wanes with time and vaccination does not protect from *B. pertussis* infection, vaccinees of any age may contribute to the reservoir of endemic pertussis. Booster immunizations may be licensed for adolescents and adults in the near future and have the potential to decrease pertussis morbidity in these populations. This strategy may also reduce transmission to young infants, reducing morbidity and mortality among this highly susceptible group (Guris et al., 1999; Centers for Disease Control and Prevention, 2001).

B. parapertussis causes a milder pertussis-like disease in humans and also causes chronic progressive pneumonia in sheep (Martin, 1996; Hoppe, 1999). Studies in mice and specific pathogen-free lambs indicate that prior inoculation with *B. parapertussis* predisposes these animals to pneumonia caused by *Mannheimia* species (previously *Pasteurella haemolytica* complex) (Porter et al., 1995a, c). Pulsed-field gel electrophoresis of cellular DNA, cellular fatty acid profiles, and LPS characterization with monoclonal antibodies have been used to differentiate human from ovine isolates of *B. parapertussis* (Porter et al., 1995b, 1996).

Bordetella avium and *Bordetella bronchiseptica* are predominately animal pathogens. *B. avium* causes coryza or rhinotracheitis in birds, particularly turkeys (Arp and Cheville, 1984; Skeeles and Arp, 1997). This disease is of significant economic concern to worldwide agriculture (Blackall and Doheny, 1987; Skeeles and Arp, 1997). *B. bronchiseptica* causes respiratory tract infections in various animals, including swine, dogs, guinea pigs, rabbits, cats,

and horses (Roop, 1984). In swine, two forms of infection are recognized: atrophic rhinitis and bronchopneumonia in piglets. Atrophic rhinitis is a disease characterized by an initial episode of acute rhinitis, which is followed by chronic atrophy of the turbinate bones and deformity of the face. More severe cases of this disease are associated with dual infection by *B. bronchiseptica* and *Pasteurella multocida* (Rutter, 1985). Dogs (kennel cough) and guinea pigs in group housing are susceptible to outbreaks of respiratory infections caused by *B. bronchiseptica* (Bemis et al., 1977; Goodnow, 1980). *B. bronchiseptica* has also been isolated as a commensal organism in the upper respiratory tract of humans and has been implicated in infections of severely immunocompromised individuals (Woolfrey and Moody, 1991).

An extensive body of literature has been written to describe pathogenic mechanisms associated with *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, and *B. avium* (Wardlaw and Parton, 1988; Weiss, 1992; Parton, 1996). These species show a tropism for ciliated respiratory epithelial cells. Once attachment is achieved, various other virulence factors are produced that mediate damage and loss of ciliated cells and, in advanced cases, systemic pathology (Table BXII.β.32). Pili or fimbriae play a significant role in the early stages of pathogenesis. The major fimbrial subunits, agglutinogen 2/fimbria 2 and fimbria 3, mediate binding to host tissues (Miller et al., 1943; Sako, 1947; Preston, 1963; Preston and Stanbridge, 1972; Stanbridge and Preston, 1974; Preston et al., 1982, 1990; Mooi et al., 1992; Willems et al., 1992b; Hewlett, 1997; Preston and Matthews, 1998). Pertactin is a nonfimbrial surface protein associated with attachment (Charles et al., 1989, 1994; Hewlett, 1997). Nonsurface factors involved in the attachment process include tracheal colonization factor, serum resistance factor, and filamentous hemagglutinin (Van't Wout et al., 1992; Fernandez and Weiss, 1994; Finn and Stevens, 1995; Hewlett, 1997; Liu et al., 1997; Cotter et al., 1998).

Pertussis toxin is a complex protein that has attachment properties as well as other virulence functions (Katada and Ui, 1982; Pittman, 1984a; Weiss and Hewlett, 1986; Relman et al., 1990b; Sato and Sato, 1990; Granstrom et al., 1991; Van't Wout et al., 1992; Sandros and Tuomanen, 1993; Trollfors et al., 1995; Hewlett, 1997; Ui, 1998; Williamson and Matthews, 1999). The toxin contains two functional subunits: the B subunit facilitates binding to host cells and introduction of the enzymatically active A subunit into the host cell cytoplasm. The A subunit then acts as an ADP-ribosyltransferase that modifies and inactivates host cell G proteins. Other postattachment virulence factors include dermonecrotic toxin, which is a potent vasoconstrictor associated with ischaemia and skin necrosis in experimental animals (Livey and Wardlaw, 1984); tracheal cytotoxin, which inhibits DNA synthesis in ciliated epithelial cells (Goldman et al., 1982; Luker et al., 1993); adenylate cyclase toxin/hemolysin, which produces unregulated adenylate cyclase activity in host cells (Wolff et al., 1980; Hanski and Farfel, 1985; Friedman et al., 1987; Glaser et al., 1988; Gueirard et al., 1998; Harvill et al., 1999); and lipopolysaccharide, which produces endotoxin-like effects (Allen et al., 1998).

The expression of virulence in *B. pertussis*, *B. parapertussis*, *B. bronchiseptica*, and *B. avium* is an elegantly regulated phenomenon. In the premolecular era it was observed that *B. pertussis* isolates underwent a phase variation from a virulent (phase I) to avirulent (phase IV) phenotype in guinea pigs with passage *in vitro* (Leslie and Gardner, 1931; Pittman, 1984a). This reduction in virulence was accompanied by changes in colonial morphology and serologic activity. Phase variation occurs with a frequency of 1 per 10^3–10^6 organisms and is generally irreversible *in vitro*. The molecular basis for phase variation was described by Weiss et al., who demonstrated by transposon insertion experiments that pertussis toxin, adenylate cyclase toxin/hemolysis, filamentous hemagglutinin, and dermatonecrotic toxin were all regulated by a single regulatory locus, designated *bvg* (Weiss et al., 1983; Weiss and Falkow, 1984). Mutations or deletions affecting the *bvg* locus result in phase variation. The expression of virulence factors is also affected by growth conditions, including temperature and salt concentration (Lacy, 1960). Unlike phase variation, this phenomenon, designated antigenic modulation, is freely reversible.

The pathogenic mechanisms and clinical significance of the more recently described *Bordetella* species have not yet been worked out. *B. hinzii* has been isolated from human and avian sources. Studies by Blackall and Doheny (1987) and Jackwood et al. (1985) suggest that this species is not a significant avian pathogen. In humans, *B. hinzii* has been isolated from the blood of a human immunodeficiency virus-infected patient and the sputa of two patients, one of whom had cystic fibrosis (Cookson et al., 1994; Vandamme et al., 1995c; Funke et al., 1996). *Bordetella holmesii* has been isolated from human blood cultures and from nasopharyngeal specimens of patients suspected of having pertussis (Lindquist et al., 1995; Weyant et al., 1995a; Mazengia et al., 2000). Some of the patients with positive blood cultures had been previously splenectomized (Lindquist et al., 1995; Weyant et al., 1995a). *Bordetella trematum* has been isolated from human wound and otitis media specimens (Vandamme et al., 1996a).

Ecology *Bordetella* species are isolated from warm-blooded animals, including humans. Until recently, the habitat of this genus was thought to be limited to the respiratory tract of the host. However, *B. holmesii* and *B. hinzii* have been isolated from human blood, and *B. trematum* has been isolated from various human wound cultures (Vandamme et al., 1995c, 1996a; Weyant et al., 1995a). The phenotypic similarity of *B. bronchiseptica*, *B. trematum*, and *B. hinzii* to the free-living *Alcaligenes* species suggests the potential for their isolation from the natural environment, although this has yet to be documented.

Isolation and direct detection procedures Bordetellae are commonly isolated from human specimens, and suspected cases of pertussis should have a nasopharyngeal aspirate or swab obtained from the posterior nasopharynx for culture for *B. pertussis* and *B. parapertussis*. Nasopharyngeal aspirates have similar or higher rates of recovery for *B. pertussis* than nasopharyngeal swabs, but recovery from throat and anterior nasal swabs is unacceptably low (Hoppe and Weiss, 1987; Halperin et al.,1989; Hallander et al., 1993; Bejuk et al., 1995). An enriched agar medium optimizes recovery of *B. pertussis* on primary culture. Modified B-G medium (Kendrick and Eldering, 1969) and charcoal agar with horse blood (Regan and Lowe, 1977) are most commonly used for primary isolation: the former allows for detecting hemolytic activity of *Bordetella* spp., the latter is reportedly more sensitive (Muller et al., 1997a). Supplemental antibiotics (penicillin at 0.25–0.5 U/ml for B–G and cephalexin at 40 μg/ml for charcoal-horse blood agar) are effective in inhibiting the growth of some normal nasopharyngeal flora. Plates incubated at 36° ± 1°C under ambient air and high humidity are examined daily until positive or for 7 d. Other primary isolation media (Lautrop, 1960; Imaizumi et al., 1983) have been proposed, but

TABLE BXII.β.32. Virulence factors of *Bordetella pertussis* and other *Bordetella* species

Virulence factors[a]	Molecular mass (kDA)	Mechanism of action	Stage of infection	Protective immunity	Location and other features	*bvg* regulated	Expression in other *Bordetella* sp.[b]
Agglutinogen2/fimbria 2	22	Fim2 binds heparin; fimD binds heparin and integrin VLA-5	A	+	Located on fimbriae (major subunit); confers protective immunity against serotypes 1 and 2	−	Bp, Bb, Baa
Agglutinin 3			A	+	Either a somatic or fimbrial antigen; confers protective immunity against serotypes 1 and 3	−	Bp, Bb, Baa
Fimbria 3	21.5	FimD binds to heparin and integrin VLA-5	A	+	Major fimbrial subunit	+	Bp, Bb, Baa
P.69 Pertactin	69	RGD motif, probably binds CR3	A	+	Somatic antigen	+	Bp, Bb
Pertussis Toxin	Subunits of 26, 22, 22, 12, 12, 11	Binds ciliated epithelium and macrophages; mimics selectins and upregulates macrophage CR3 for FHA binding; ADP ribosylation of cellular G proteins	A,D,L,S	+	Synergistic adhesin with FHA	+	−
Filamentous hemagglutinin	220	Binds both the bacterium and macrophage CR3 to facilitate phagocytosis	A	−	Secreted; synergistic adhesin with PT	+	Bp, Bb
Adenylate cyclase/hemolysin	45	ATP hydrolysis with raised intracellular cAMP in macrophages and lymphocytes; induces apoptosis	D,L,S	−	Secreted by type I pathway requiring CyaB, D and E proteins; activated by eucaryotic calmodulin	+	Bp, Bb
Tracheal cytotoxin	921	DNA inhibition in ciliated epithelium	D,L	−	A muramyl peptide, derived from bacterial peptoglycan	−	Bp, Bb, ba
Dermonecrotic toxin	102 with subunits of 30, 24	Inhibition of Na^+-K^+ ATPase; vasoconstriction	L,S		Localized to the bacterial cytoplasm; part of molecule probably exposed at cell surface		Bp, Bb, Ba
Lipopolysaccharide		Endotoxin-like effects; pyrogenic, sensitization to histamine	L.S		Two lipids, A and X; two different oligosaccharides, I and II		Bp, Bb, Ba
Tracheal colonization factor	64	Tcf binding, probably mediated by RGD motif	A		Secreted by type IV pathway	+	−
Serum resistance factor	BrkA: 103; BRKB: 32		D		Secreted by type IV pathway		−

[a]Fim2, fimbria 2; Fim3, fimbria 3; FHA, filamentous hemagglutination; PT, pertussis toxin; tcf, tracheal colonization factor; ATP, adenosine triphosphate; ATPase, adenosine triphosphatase; VLA-5, very-late antigen 5; CR3, complement receptor 3; ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; brk, *Bordetella* resistance to killing; RGD, Arg-Gly-Asp sequence; A, attachment; D, evasion of host defense; L, local effects; S, systemic effects.

[b]Bp, *B. parapertussis*; Bb, *B. bronchiseptica*; Ba, *B. avium*; fimbriae are produced by *B. parapertussis*, *B. bronchiseptica*, and *B. avium*, but are antigenically distant from *B. pertussis* fimbriae.

are not widely used. If direct inoculation of a selective medium is not possible, swab specimens can be placed in Regan–Lowe transport medium (one-half strength charcoal agar supplemented with horse blood and cephalexin) (Regan and Lowe, 1977). Some investigators recommend incubating the specimen (swab in the transport medium) before transport to the laboratory because incubating the specimen before transport reportedly allows for growth of *B. pertussis* (Strebel et al., 1993). Others suggest that this practice can decrease the yield of *Bordetella* spp. due to overgrowth by normal flora and recommend storage and transport at 4°C (Morrill et al., 1988). Culture of *B. pertussis* and *B. parapertussis* is optimal at 35–36°C, aerobically (without CO_2), and with sufficient humidity to avoid desiccation. Cultures can be incubated for up to 7 d; *B. pertussis* rarely is visible before 3–4 d, but *B. parapertussis* is commonly discernible at least 24 h earlier.

Numerous studies have demonstrated the potential for polymerase chain reaction (PCR) assays to detect *Bordetella* cells with greater sensitivity and more rapidly than by culture. However, no specific technique for PCR is universally accepted or validated among laboratories. In addition, there is no quality assurance program for PCR. The use of PCR without culture negatively impacts the monitoring of cases of disease, recruitment of isolates for epidemiologic studies, and surveillance for antibiotic resis-

tance. For these reasons, PCR currently is best used as a presumptive assay in conjunction with culture under the conditions described in Meade and Bollen (1994).

Commercially available direct fluorescence assay (DFA) tests have been developed to detect *B. pertussis* in clinical specimens (Preston, 1970; Gilligan and Fisher, 1984; Ewanowich et al., 1993). Although these tests have been widely used to screen patients for *B. pertussis* infection, problems with specificity have been noted. Cross-reactions with normal nasopharyngeal flora accounted for false-positive results in up to 85% of tests (Ewanowich et al., 1993) and led to substantial unnecessary public health intervention. For the best results, DFA tests require care in all technical aspects and experienced personnel for their interpretation. If used, they should always be accompanied by a specimen for culture. Health care and public health workers can weigh the benefit of a presumptive diagnosis with the disadvantage of a high percentage of false-positive results. A mouse monoclonal antibody (BL-5)-based DFA test recently become available (Accu-MabTM, Biotex Laboratories Inc., Edmonton, Canada). Initial evaluation demonstrated 65% sensitivity and 99% specificity when compared with culture (McNicol et al., 1995). Further testing is necessary to confirm these results. The technical requirements and the careful standardization required for previous commercially available DFA tests also apply to this new monoclonal DFA; patients should also be cultured for isolation of *B. pertussis*.

Detection of antibodies to *B. pertussis* in humans Several strategies have been used to measure the immune responses to *B. pertussis* in patients and in vaccinees, including serum antibodies that agglutinate *B. pertussis* cells and a cytopathogenic assay for antibodies that neutralize pertussis toxin (PT). The predictive values of these assays for infection or protection are unacceptably low. Recent reports show promise in defining the role of serum bactericidal antibodies in pertussis immunity, but additional studies are needed. Enzyme-linked immunosorbent assays (ELISA) have provided the most sensitive and specific results, but the materials and methods required for them are not uniform. These tests also fail to relate a specific antibody to a specific protective function. None of the techniques has been validated between laboratories or been approved for diagnostic use in the United States. Currently, the most generally accepted serologic criterion for diagnosis of pertussis is the use of ELISA to demonstrate a significant increase in serum antibody concentrations against PT between acute and convalescent specimens. Anti-PT concentrations in convalescent sera may have diagnostic relevance in populations with known age-related prevalence of these antibodies, or in investigations where the prevalence among controls matched to cases by age and vaccination status can be determined. For individual patients, serology generally is regarded as an adjunct to culture rather than a method for primary diagnosis.

Antibiotic susceptibility Erythromycin is the antibiotic treatment of choice for *B. pertussis* infections (Hoppe et al., 1992). However, in recent years, erythromycin-resistant strains have been recovered (Lewis et al., 1995; Korgenski and Daly, 1997). The prevalence of these strains is not known but available evidence suggests that it is low. One of the erythromycin-resistant isolates was susceptible to trimethoprim-sulfamethoxazole (TMP-SMX), but cross-resistance to clarithromycin and clindamycin was demonstrated in the other. Susceptibility testing to a macrolide and to TMP-SMX can be considered for strains isolated from patients receiving at least 7 d of prophylaxis, or for purposes of surveillance, but is not necessary for all patients. Disk-diffusion or E-Test (Korgenski and Daly, 1997) on charcoal agar containing horse blood have typically been used to screen for antibiotic susceptibilities of *B. pertussis*. There is less experience determining the minimum inhibitory concentrations (MIC) by agar dilution. Hoppe and Paulus suggest using Mueller-Hinton broth and agar with defibrinated horse blood and high inoculums of the test bacteria (Hoppe and Paulus, 1998). Erythromycin, TMP-SMX, and fluoroquinolones have high *in vitro* activities against *B. parapertussis* (Kurzynski et al., 1988; Hoppe and Simon, 1990; Hoppe and Tschirner, 1997).

In vitro antibiotic susceptibility studies with *B. bronchiseptica* indicate a resistance pattern similar to that observed with other nonfermentative Gram-negative bacilli (Kurzynski et al., 1988; Mortensen et al., 1989; Woolfrey and Moody, 1991). Strains of this species are usually sensitive to aminoglycosides, antipseudomonal penicillins, such as azlocillin, mezlocillin, and piperacillin, and broad-spectrum cephalothins, such as cefoperazone. High levels of resistance are usually seen with erythromycin and first- and second-generation penicillins and cephalosporins. Resistance to TMP-SMX and tetracyclines is variable. *In vitro* studies with *B. avium* show an overall lower level of antimicrobial resistance than with *B. bronchiseptica* (Mortensen et al., 1989). Strains of this species are usually sensitive to aminoglycosides, ampicillin, antipseudomonal penicillins, and tetracycline. Sensitivity to first- and second-generation cephalosporins is variable, and most strains are resistant to erythromycin and TMP-SMX (Mortensen et al., 1989; Blackall et al., 1995). *B. hinzii* has been reported to be susceptible to aminoglycosides and TMP-SMX, but resistant to ampicillin, erythromycin, and tetracycline (Blackall et al., 1995; Funke et al., 1996). Susceptibility studies with *B. holmesii* and *B. trematum* suffer from a lack of confirmed strains. Lindquist et al. (1995) described a single *B. holmesii* strain with disk diffusion results suggesting susceptibility to a wide range of agents, including aminoglycosides, TMP-SMX, tetracycline, ciprofloxacin, antipseudomonal penicillins, and ceftazidime.

Maintenance Procedures

For temporary preservation, *B. bronchiseptica*, *B. avium*, *B. hinzii*, *B. holmesii*, and *B. trematum* may be stored as stabs in motility medium containing 0.4% agar (Weyant et al., 1996). Screw-capped 15 × 125-mm tubes containing 8 ml of medium are inoculated with fresh agar-grown cultures by stabbing with a sterile needle or loop to approximately 2 cm below the agar surface. The tubes are then incubated at 35–37°C overnight with the caps loosened to allow for air exchange and then stored at room temperature with the caps tightened. *B. pertussis* and *B. parapertussis* may be grown and stored on B-G slants in closed containers at 4–6°C. Stored under these conditions, most strains will remain viable for 2–3 weeks. For permanent storage, fresh agar-grown cultures may be suspended in sterile skim milk of 10% powdered milk and freeze-dried (Novotny and Brookes, 1975). Alternatively, strains may be preserved by suspending fresh agar-grown cultures in defibrinated rabbit blood or 0.05 M Tris-HCl buffer (pH 7.6) with 20% glycerol and freezing in liquid nitrogen (Novotny and Brookes, 1975; Weyant et al., 1996).

Differentiation of the genus *Bordetella* from other genera

Phenotypic characteristics useful in the differentiation of *Bordetella* species are given in Table BXII.β.33. Although *Bordetella* species are highly related at the phylogenetic level, they are phenotypically heterogeneous. *B. pertussis* fails to grow on most com-

monly used growth media due to inhibition by various medium constituents including unsaturated fatty acids and metal ions (Rowatt, 1957). This characteristic is not observed with the other *Bordetella* species, although *B. holmesii* and *B. parapertussis* do not grow as rapidly on most media as do *B. bronchiseptica*, *B. avium*, *B. hinzii*, and *B. trematum*. *B. holmesii* and *B. parapertussis* also produce a characteristic brown diffusible pigment in heart infusion broth with tyrosine and are oxidase-negative. Urease activity is useful in differentiating *B. holmesii* from *B. parapertussis*. Of the four more rapidly growing species, *B. trematum* is unique in producing a negative oxidase reaction. The citrate, nitrate, and urease tests are useful in differentiating between *B. bronchiseptica*, *B. avium*, and *B. hinzii*. A more complete phenotypic characterization of the species of *Bordetella* is given in Table BXII.β.34.

Tests useful in differentiating *Bordetella* from other phenotypically similar genera are also given in Table BXII.β.33. From a phylogenetic prospective, *Bordetella*, *Achromobacter*, and *Alcaligenes* are closely related. This relatedness is reflected in the high level of phenotypic similarity observed between *Alcaligenes* and *Achromobacter* species and the motile and more rapidly growing species of *Bordetella* (*B. bronchiseptica*, *B. avium*, *B. hinzii*, and *B. trematum*). Historically, the ability of *Bordetella* to colonize mammalian and avian respiratory tracts was useful in differentiating these genera; however, the more recently described species—*B. holmesii*, *B. hinzii*, and *B. trematum*—have been isolated from nonrespiratory sources. *Brucella* species, *Haemophilus* species, and asaccharolytic *Acinetobacter* species share phenotypic similarities with *B. pertussis*, *B. parapertussis*, and *B. holmesii*, and also may be isolated from clinical specimens. The requirement for X and/or V factors differentiates *Haemophilus* from *Bordetella*. Growth on blood agar, brown diffusible pigment production, and acidification of carbohydrates are useful in differentiating *Brucella* from nonmotile *Bordetella* species. Cellular fatty acid profiles have also been used successfully to differentiate among these organisms (Moore et al., 1987; Cookson et al., 1994; Vandamme et al., 1995c, 1996a; Weyant et al., 1995a; Funke et al., 1996). The predominant cellular fatty acids associated with each of these taxa are given in Table BXII.β.33.

Taxonomic Comments

Tang et al. (1998) have described a series of *Bordetella holmesii*-like strains associated with septicemia, endocarditis, and respiratory failure in humans. These isolates are phenotypically consistent with *B. holmesii* and have 99.8% 16S rRNA gene sequence similarity. Additional studies will be required to determine the taxonomic status of these strains.

Acknowledgments

This chapter is based in part on the genus *Bordetella* chapter of the 1st edition of *Bergey's Manual of Systematic Bacteriology*, authored by Dr. Margaret Pittman.

List of species of the genus Bordetella

1. **Bordetella pertussis** (Bergey, Harrison, Breed, Hammer and Huntoon 1923a) Moreno-López 1952, 178[AL] (Microbe de coqueluche Bordet and Gengou 1906, 731; *Haemophilus pertussis* Bergey, Harrison, Breed, Hammer and Huntoon 1923a, 269.)
per.tus′ sis. L. pref. *per* very, severe; L. n. *tussis* cough; M.L. gen. n. *pertussis* of a severe cough, of whooping cough.

Minute coccobacillus, 0.2–0.5 × 0.5–1.0 µm in length, encapsulated or surrounded by a slime sheath composed of extruded filaments or secreted blebs. Potato–glycerol–blood agar (Bordet–Gengou) has been preferred for primary isolation. Colonies are minute in size and are surrounded by a zone of hemolysis on media containing about 20% blood. Uniqueness in slow rate of growth and susceptibility to growth inhibitors are associated with the production of pertussis toxin. A defined broth medium may be used for mass growth. No pellicle is formed. Physiological and nutritional characteristics are presented in Tables BXII.β.33 and BXII.β.34. Parasitic, pathogenic, found only in the respiratory tract of humans, where it is the cause of pertussis (whooping cough).

The mol% G + C of the DNA is: 66–70 (T_m).

Type strain: 18-232 , ATCC 9797, DSM 5571.

GenBank accession number (16S rRNA): U04950.

2. **Bordetella avium** Kersters, Hinz, Hertle, Segers, Lievens, Siegmann and De Ley 1984, 65[VP]
a′ vi.um. L. n. *avis* bird; L. gen. pl. n. *avium* of birds.

The morphology is as described for the genus. Colonies appear earlier on Bordet–Gengou medium and are larger than those of *B. pertussis* or *B. parapertussis*. Grows on MacConkey agar. The physiological and nutritional characteristics are presented in Tables BXII.β.33 and BXII.β.34. Found in avian species and pathogenic for turkey poults.

The mol% G + C of the DNA is: 61.6–62.6 (T_m).

Type strain: Hinz 591-77, ATCC 35086, DSM 11332, LMG 1852.

GenBank accession number (16S rRNA): U04947.

3. **Bordetella bronchiseptica** (Ferry 1912) Moreno-López 1952, 178[AL] (*Bacillus bronchicanis* Ferry 1911, 404; *Bacillus bronchisepticus* Ferry 1912, 377.)
bron.chi.sep′ ti.ca. Gr. n. *bronchus* the trachea; Gr. adj. *septicus* putrefactive, septic; M.L. fem. adj. *bronchiseptica* intended to mean with an infected bronchus.

The morphology is as described for the genus. Colonies appear earlier on Bordet–Gengou medium and are larger than those of *B. pertussis* or *B. parapertussis*. Grows on MacConkey agar. A pellicle forms on liquid media. The physiological and nutritional characteristics are presented in Tables BXII.β.33 and BXII.β.34. Parasitic, pathogenic, found in the respiratory tract of domestic and wild mammalian animals (dogs, swine, guinea pigs, rabbits, raccoons, etc.), causes kennel cough in dogs.

The mol% G + C of the DNA is: 67–69 (T_m).

Type strain: 71, ATCC 19395, NCTC 452.

GenBank accession number (16S rRNA): U04948.

4. **Bordetella hinzii** Vandamme, Hommez, Vancanneyt, Monsieurs, Hoste, Cookson, Wirsing von König, Kersters and Blackall 1995c, 43[VP]
hin′ zi.i. N.L. gen. n. *hinzii* of Hinz, named in honor of K.-H. Hinz.

The cellular morphology is as described for the genus. Two distinct colony types occur. Some strains produce round, raised, glistening, grayish colonies about 2 mm in diameter following 48 h of incubation at 37°C in air containing 5% CO_2. Under the same conditions other strains produce flat, dry, crinkled colonies that are up to 5 mm in diameter. The physiological and nutritional characteristics are presented in Tables BXII.β.33 and BXII.β.34. Strains have been isolated from respiratory tracts of turkeys and chickens. Pathogenic in humans, with strains isolated in blood and sputum specimens. The type strain was isolated from a chicken trachea in Australia.

The mol% G + C of the DNA is: 65–67 (T_m).

Type strain: TC58, LMG 13501, ATCC 51783, CIP 104527, DSM 11333, LMG 13501.

GenBank accession number (16S rRNA): AF177667.

5. **Bordetella holmesii** Weyant, Hollis, Weaver, Amin, Steigerwalt, O' Connor, Whitney, Daneshvar, Moss and Brenner 1995b, 619[VP] (Effective publication: Weyant, Hollis, Weaver, Amin, Steigerwalt, O' Connor, Whitney, Daneshvar, Moss and Brenner 1995a, 6.)
holmes′ i.i. N.L. gen. n. *holmesii* named in honor of B. Holmes.

Cellular morphology is as described for the genus. Growth characteristics on blood agar are similar to those of *B. parapertussis*. Growth occurs on MacConkey agar at between 3 and 7 days of incubation at 35°C. The physiological and nutritional characteristics are presented in Tables BXII.β.33 and BXII.β.34. Strains have been isolated from blood and upper respiratory tract cultures of humans. The type strain was isolated from human blood.

The mol% G + C of the DNA is: 61.5–62.3 (T_m).

Type strain: ATCC 51541, CDC F5101.

GenBank accession number (16S rRNA): U04820.

6. **Bordetella parapertussis** (Eldering and Kendrick 1938) Moreno-López 1952, 178[AL] (*Bacillus parapertussis* Eldering and Kendrick 1938, 571.)
pa.ra.per.tus′ sis. Gr. prep. *para* resembling; M.L. n. *pertussis* the specific epithet of *Bordetella pertussis*; M.L. adj. *parapertussis* resembling *Bordetella pertussis*.

The morphology is similar to that of *B. pertussis*. Colonies are slightly larger and appear earlier on Bordet–Gengou medium than *B. pertussis*. Growth on peptone agar is accompanied by a brown discoloration of the medium that is

attributed to the action of tyrosinase on the tyrosine in the medium (Ensminger, 1953). A pellicle forms on liquid media. Growth is more rapid than with *B. pertussis*. The physiological and nutritional characteristics are presented in Tables BXII.β.33 and BXII.β.34. Parasitic, pathogenic, found in the respiratory tract of humans and sheep. Causes a milder pertussis-like syndrome in humans and chronic progressive pneumonia in ovines.

The mol% G + C of the DNA is: 66–70 (T_m).

Type strain: 522, ATCC 15311, NCTC 5952.

GenBank accession number (16S rRNA): U04949.

7. **Bordetella trematum** Vandamme, Heyndrickx, Vancanneyt, Hoste, De Vos, Falsen, Kersters and Hinz 1996a, 857[VP]
tre.ma' tum. Gr. neut. n. *trema* referring to something pierced or penetrated, an aperture, or a gap; N.L. gen. pl. n. *trematum* pertaining to penetrated or open things, referring to the presence of these bacteria in wounds and other exposed parts of the human body.

Cellular morphology is as described for the genus. Strains do not require special growth factors and grow on conventional media. Colonies may be observed at 16–24 h of incubation at 37°C under aerobic conditions. The physiological and nutritional characteristics are presented in Tables BXII.β.33 and BXII.β.34. Strains have been isolated from wound and ear infections of humans.

The mol% G + C of the DNA is: 64–65 (T_m).

Type strain: CCUG 32381, DSM 11334, LMG 13506.

GenBank accession number (16S rRNA): AJ277798.

Genus IV. **Derxia** *Jensen, Petersen, De and Bhattacharya 1960, 193*[AL]

CHRISTINA KENNEDY

Derx' i.a. M.L. fem. n. *Derxia* named after the Dutch microbiologist H.G. Derx (1894–1953).

Cells are rod-shaped with rounded ends, 1.0–1.2 μm × 3.0–6.0 μm, occurring singly or in short chains. **Cells are rather pleomorphic**, depending on age and the medium. In aging cultures cells often remain together forming long filaments of sometimes locally swollen or distorted cells. Some cells may assume very large lengths (up to 30 μm). **Young cells have a homogeneous cytoplasm; older cells show typical large refractile bodies—probably poly-β-hydroxybutyrate—throughout the whole cell**. Resting stages are not known. Gram negative. **Motile by a short polar flagellum**; motile cells are numerous in liquid glucose media containing combined nitrogen, but rare on nitrogen-deficient solid media. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **N_2 is fixed under aerobic or microaerobic conditions**. Optimal temperature, 25–35°C; growth is slow at 15°C, feeble at 40°C; no growth at 50°C. **Growth occurs between pH 5.5 and ~9.0**; no growth at pH 4.4. **Broth cultures turn into a gelatinous mass**, but growth near the surface is more luxuriant and forms a thick, tough pellicle. **Colonies on agar media are at first slimy and semitransparent, later massive and opaque, highly raised with a wrinkled surface**. **Older colonies develop a dark mahogany-brown color**. **Catalase negative**. A wide range of sugars, alcohols, and organic acids are oxidized mostly to CO_2 and a small amount of acid, probably acetic, when growing in an alkaline medium. **Can grow as a facultative hydrogen autotroph**. **Found in tropical soils** (Asia, Africa, South America).

The mol% G + C of the DNA is: 69.2–72.6.

Type species: **Derxia gummosa** Jensen, Petersen, De and Bhattacharya 1960, 193.

FURTHER DESCRIPTIVE INFORMATION

The description, above and below, of the genus, as given by J.-H. Becking in the 1st edition of the *Manual* remains largely unchanged; information has been updated.*

Cell morphology The appearance of cells from young cultures is depicted in Fig. BXII.β.22. Older cells on sugar-rich media contain large refractile bodies. On glucose–peptone agar especially, very elongated cells are produced containing many refractile and misshapen bodies (Becking, 1984b). The refractile material is probably poly-β-hydroxybutyrate since it stains with Sudan III and Sudan black, but some vacuoles do not stain (Becking, 1984b). On nitrogen-free glucose agar older cells undergo shrinkage and are finally enclosed by a slime envelope (Fig. BXII.β.23).

Motile cells may become numerous in liquid glucose medium containing ammonia or glutamate as the nitrogen source. The cells usually have a single polar flagellum, but some may have a flagellum at each pole. According to Thompson and Skerman (1979), the single polar flagellum is less than a full wave and is less than 3 μm in length.

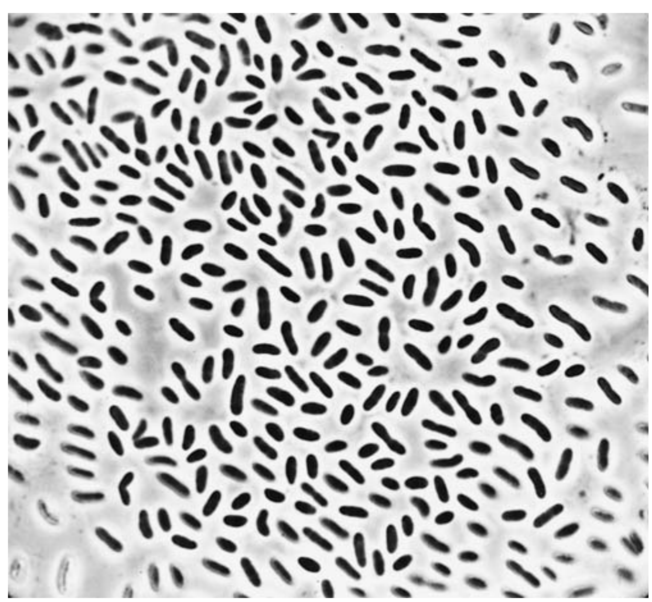

FIGURE BXII.β.22. Seven-day-old cells of *D. gummosa* on nitrogen-free agar containing 2% glucose. Phase-contrast microscopy (× 950).

**Editorial Note: Derxia* was placed in the *Beijerinckiaceae* in the first edition of the *Manual*; because the 16S rDNA sequence of *Derxia gummosa* had not been published. However, now because of the 16S rDNA placement, the genus *Derxia* has been moved to the family *Alcaligenaceae* and is no longer listed in *Beijerinckiaceae*.

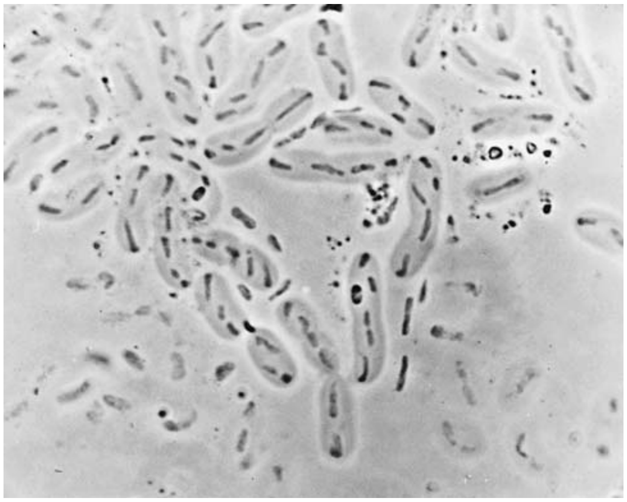

FIGURE BXII.β.23. Three-month-old cells of *D. gummosa* on nitrogen-free glucose agar. The cells show shrinkage and are enclosed by a thick slime envelope. Phase contrast microscopy (× 950).

Colonial and cultural characteristics Growth in liquid media usually starts as a ring at the glass-liquid interface and develops into a thick, wrinkled, tough pellicle. Shallow layers of medium change into a firm gelatinous mass after 2 weeks. The color gradually becomes a dark red-brown.

Growth on nitrogen-deficient agar media begins as thin, whitish or semitransparent scattered colonies. Later, more massive, highly raised or dome-shaped colonies emerge that rapidly assume a diameter of 1 cm or more (giant colonies) (Fig. BXII.β.24). These colonies are very like those of *Beijerinckia* species. For further comparisons of the differential characteristics and carbon compounds of *Beijerinckia* and *Derxia*, see Tables BXII.α.141 and BXII.α.142 in *Beijerinckia*. Colonies are at first whitish or dull yellow with a smooth surface, but the surface soon becomes coarse and wrinkled and the color deepens to a dark mahogany-brown. The slime of these colonies is very tenacious and gumlike, but in the other developmental stages it is more soft and smeary.

FIGURE BXII.β.24. Colony type of *D. gummosa* on nitrogen-free glucose agar with calcium carbonate (× 1.0).

As noted by Jensen et al. (1960) in the original description of *D. gummosa*, aerobic growth on nitrogen-free, mineral glucose agar[1] consists of a mixture of a few "massive" colonies among many "thin," whitish colonies. It is the former that are associated with N_2 fixation; their slime affords some protection to the oxygen-sensitive nitrogenase system by decreasing the penetration of oxygen to the cells (Hill and Postgate, 1969). The occurrence of two kinds of colonies under aerobic conditions is probably due to the occurrence of local areas of decreased oxygen concentration on the plates. It is only in these areas that N_2 fixation and extensive cell multiplication can occur that leads to the formation of the "massive" colonies. Under microaerobic conditions (pO_2 <0.2 atm), all of the colonies on a plate develop into the "massive" type (Hill, 1971).

Metabolism and metabolic pathways As for *Beijerinckia* species, *Derxia* can utilize many sugars, organic acids, and alcohols for growth (see Table BXII.α.142 in Genus *Beijerinckia*). Growth on methane or methanol as sole carbon source has also been reported for *D. gummosa* (Sampaio et al., 1981).

The efficiency of N_2 fixation by *D. gummosa* varies between 9 and 25 mg N/g of glucose consumed, but in most strains it is distinctly lower than in *Azotobacter* or *Beijerinckia*. There is no requirement for amino acids, vitamins, or growth factors, but trace elements, particularly molybdenum, are required. Vanadium cannot replace the molybdenum for N_2 fixation, suggesting that the alternative V nitrogenase (nitrogenase-2) is not present (for further explanation see the genus *Azotobacter*). Nitrite but not nitrate inhibits nitrogenase activity as do ammonia and glutamine (Wang and Nicholas, 1986c).

Growth with combined nitrogen sources is much faster than with N_2 and is completely uniform, in contrast to the uneven growth on nitrogen-free agar. Colonies change from a pale yellow through rust-brown to almost black (darkest if nitrate is present) and sometimes a light brown, water-soluble pigment is produced. Growth with glutamic acid, ammonium acetate, alanine, sodium nitrate, and urea decreases from abundant to good in approximately the same sequence (Becking, 1984b). Aspartic acid, asparagine, and peptone give a much slower growth that is uneven and mostly confined to scattered colonies. Glycine seems to be toxic.

Although Thompson and Skerman (1979) reported four of six strains tested as able to utilize nitrate as N source, these strains gave negative results in tests of nitrite production from nitrate (see also Becking, 1984b). The reason for this discrepancy is not clear, but it is certain that some strains have nitrate reductase. The enzyme was purified from *D. gummosa* (unnamed strain supplied by Y.T. Tchan) and contained two dissimilar subunits, 80 and 88 kDa in size (Wang and Nicholas, 1986a). Induction of

1. Nitrogen-free, glucose mineral medium (g/l distilled water): K_2HPO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 0.25 (or 0.2); NaCl, 0.25; $FeSO_4 \cdot 7H_2O$, 0.1; $CaCl_2$ or $CaCO_3$, 0.1; $Na_2MoO_4 \cdot 2H_2O$, 0.005; and glucose, 10.0 (or 20.0); pH, 6.9. For a solid medium, add 15.0 g agar per liter.

nitrate reductase formation by nitrate was inhibited by ammonium or glutamine. Nitrite reductase was also purified (this enzyme also reduces hydroxylamine) (Wang and Nicholas, 1986d). Thus, at least some isolates of *D. gummosa* have both enzymes needed for conversion of nitrate to ammonia (assimilation).

As with most other *Proteobacteria*, *Derxia gummosa* assimilates ammonia via glutamine synthetase/glutamate synthase. Both enzymes were purified (Wang and Nicholas, 1985) and found to have physical and biochemical properties similar to these enzymes in other microorganisms, including adenylation of glutamine synthetase in response to ammonium.

D. gummosa grows autotrophically in an atmosphere containing $H_2/CO_2/O_2$, with either N_2 or NH_4^+ as the nitrogen source (Pedrosa et al., 1980). Indeed, it appears to grow nearly as well autotrophically as it does heterotrophically. Ribulose-1,5-bisphosphate activity, which mediates the CO_2 fixation, occurs in autotrophically grown cells but not in cells grown heterotrophically. Shankar et al. (1986) found that rapid O_2 depletion in a closed system caused variable, sometimes extremely poor, autotrophic growth; these authors developed a flow-through culturing technique that gave consistent results. Hydrogen recycling also takes place via an electron transport chain consisting of flavoprotein, ubiquinone, cytochrome *b*, and cytochrome *a* (Wang and Nicholas, 1986b).

Indole may or may not be produced from tryptophan. Starch is not hydrolyzed. *D. gummosa* antagonizes the growth of Gram-positive bacteria (Thompson and Skerman, 1979). Growth occurs on 1% peptone.

Ecology *Derxia* occurs mainly in tropical soils. It was isolated originally by Jensen et al. (1960) from a West Bengal soil having a pH of 6.5. It is widely distributed in Brazil (Campêlo and Döbereiner, 1970), Indonesia, China, and southern Africa (Becking, 1981). In Brazil, Campêlo and Döbereiner (1970) found it to be most frequent in flooded soils, less frequent in humid soils, and least frequent in dry soils. In comparing isolations made on a nitrogen-free, mineral starch agar, they found that *Derxia* could be more often isolated from root pieces of plants (mostly Gramineae) than from soil samples obtained from the same locality. In soil, the presence of the organisms seemed to be favored when the soil pH was between 5.1 and 5.5, although isolations were made from soils over a pH range of 4.5–6.5.

Enrichment and Isolation Procedures

The sieved soil method may be used for isolation. Soil particles are regularly distributed over the surface of nitrogen-free mineral media with glucose[2] (Becking, 1984b). Mannitol and starch were previously suggested to be suitable C sources for isolation of *Derxia* (Jensen et al., 1960; Campêlo and Döbereiner, 1970), but Thompson and Skerman (1979) found all six strains tested unable to hydrolyze starch, and three of them were unable to utilize mannitol. Consequently, the use of mannitol or starch for isolation/enrichment of *Derxia* is not recommended. After growth on glucose N-free medium, one looks for the development of yellowish colonies around the soil particles. These colonies eventually become much larger and acquire a rust-brown color. Isolates should be further purified by repeated streaking.

2. Nitrogen-free, mineral glucose agar for sieved-soil method (g/l distilled water): glucose, 20.0; K_2HPO_4, 0.8; KH_2PO_4, 0.2; $MgSO_4 \cdot 7H_2O$, 0.5; $FeCl_3 \cdot 6H_2O$, 0.025 (or 0.05); $Na_2MoO_4 \cdot 2H_2O$, 0.005; $CaCl_2$, 0.05; and agar, 15.0. The pH is adjusted to 6.9.

Derxia strains are acid-tolerant and have been isolated from cultures designed to enrich for *Beijerinckia* strains by use of a liquid acidic nitrogen-free glucose medium[3] (Becking, 1984b). This medium is dispensed into Petri dishes so as to form a thin layer 2–3 mm deep.

Maintenance Procedures

The maintenance procedures are the same as those described for the genus *Beijerinckia*.

Procedures for Testing Special Characters

The ability to grow autotrophically can be tested on a solid or liquid medium[4] in the presence or absence of $(NH_4)_2SO_4$ (1.0 g/l). Cultures are incubated at 30°C in sealed vessels under the following atmospheres: (a) O_2/N_2, 1:99, v/v; (b) $0_2/CO_2/N_2$, 1:5:94; (c) $O_2/H_2/N_2$, 1: 5:94; and (d) $O_2/H_2/CO_2/N_2$, 1:5:5:89. (Under atmospheres containing CO_2 the medium may also need to contain $NaHCO_3$ (1.0 g/l) to prevent acidification.) Significant growth should occur only when both H_2 and CO_2 are provided, even when N_2 is the sole nitrogen source. Under conditions of H_2/CO_2 dependent autotrophic growth under N_2-fixing or non-N_2-fixing conditions, the average doubling time of *D. gummosa* is 34.1 h (Pedrosa et al., 1980). A flow-through system for culturing *D. gummosa* autotrophically was also described (Shankar et al., 1986).

Differentiation of the genus *Derxia* from other genera

Derxia can be distinguished from other genera of N_2-fixing bacteria by its very slimy (gummy) growth, both on agar plates and in liquid media, combined with appearance of the cells (Figs. BXII.β.22 and BXII.β.23) depending on age and type of medium (cells on peptone medium are very pleomorphic). *Azotobacter* and *Azomonas* species never produce such slimy colonies. Confusion with *Beijerinckia* is unlikely since *Beijerinckia* cells usually show very characteristic cells with two polar bodies containing PHB, whereas *Derxia* cells contain numerous PHB-containing bodies. Moreover, in contrast to *Beijerinckia* colonies, the colonies of *Derxia* acquire on aging a typical dark mahogany-brown color. In addition, *Derxia* is catalase negative, whereas *Beijerinckia* is catalase positive.

Distinction of *Derxia* and *Beijerinckia* species is also demonstrated by the differential ability to utilize compounds as carbon sources (see Table BXII.α.142 in the genus *Beijerinckia*). Most useful are possibly malonate, aspartate, glutamate, and ethylamine, carbon sources on which *D. gummosa* can grow but not species of *Beijerinckia* (Thompson and Skerman, 1979). In addition, resistance/sensitivity to antibiotics distinguish these genera. *D. gummosa* is more resistant to chlortetracycline and sulfanilamide than are *Beijerinckia* species (25 versus 1 μg/ml and

3. Liquid acidic nitrogen-free glucose medium (g/l distilled water): glucose, 20.0; KH_2PO_4, 1.0; and $MgSO_4 \cdot 7H_2O$, 0.5. The pH is adjusted to 5.0.

4. Medium for testing autotrophy (per liter of distilled water): KH_2PO_4, 1.2 g; K_2HPO_4, 0.8 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; NaCl, 0.2 g; $CaCl_2 \cdot 2H_2O$, 0.02 g; $FeSO_4 \cdot 7H_2O$, 0.002 g; trace element solution (see below), 2.0 ml; biotin, 10 μg; and agar, 15.0 g. Trace element solution (g/l): $Na_2MoO_4 \cdot 2H_2O$, 1.0; $MnSO_4 \cdot H_2O$, 1.75; H_3BO_3, 1.4; $CuSO_4 \cdot 5H_2O$, 0.04; and $ZnSO_4 \cdot 7H_2O$, 0.12. This medium was employed by Pedrosa et al. (1980) in their studies of *Derxia*. In those studies, a very low concentration of potassium malate (0.1 g/l) was sometimes added to the medium. It should be noted that most strains of *Derxia* (including the type strain) give only scant growth with malate. Thompson and Skerman (1979) reported no growth on DL-malate in all of the six strains that they tested.

125 versus 1–5 μg/ml, respectively). *Beijerinckia* species are more resistant to chloramphenicol and penicillin than is *D. gummosa* (125 versus 5 μg/ml and 25 versus 1 μg/ml, respectively) (Thompson and Skerman, 1979). *D. gummosa* can utilize glutamate as a nitrogen source, whereas species of *Beijerinckia* cannot. Unlike most other aerobic diazotrophic species, *Derxia* can grow as a facultative hydrogen autotroph.

Taxonomic Comments

Derxia, like *Beijerinckia*, was previously classified in the family *Beijerinckiaceae* in the order *Rhizobiales*, class *Alphaproteobacteria*. This placement was based on phenotypic characterization, not 16S rDNA sequence. De Smedt et al. (1980), based on rRNA hybridization, placed *D. gummosa* in the third rRNA superfamily, which also contains *Pseudomonas solanacearum*, *Chromobacterium violaceum*, *Janthinobacterium lividum*, and *Alcaligenes faecalis*. Phenotypically, both *Derxia* and *Beijerinckia* species produce a viscous, tenacious slime and form colonies that are similar in several respects. They utilize similar carbon sources, and they have a molybdenum requirement for N_2 fixation that cannot be replaced by vanadium (Thompson and Skerman, 1979; Becking, 1984a, b) (see also Tables BXII.α.141 and BXII.α.142 in the genus *Beijerinckia*). In addition, both are isolated from similar habitats. It is likely that other species of *Derxia* besides *D. gummosa* exist, but none have been formally named. Roy and Sen (1962) described a new species of *Derxia* from a sample of jute from Uttar Pradesh, India. Wu and Chen (1991) proposed a new species, *"Derxia peritricha"*, for an isolate that shared many cultural characteristics with *D. gummosa*, and DNA hybridization studies also indicated significant similarity.

Further Reading

Becking, J.H. 1992. The Genus *Derxia*. *In* Balows, Trüper, Dworkin and Schleifer (Editors), The Prokaryotes. A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications, Springer-Verlag, New York. pp. 2605–2611.

List of species of the genus Derxia

1. **Derxia gummosa** Jensen, Petersen, De and Bhattacharya 1960, 193[AL]
gum.mo'sa. L. fem. adj. *gummosa* slime (gum) producing.

The characteristics are as described for the genus.

Originally isolated from a soil of West Bengal of pH 6.5, but later also from slightly acidic or neutral soils of South America (Brazil, Surinam), South Africa, and Java (Becking, 1984b).

The mol% G + C of the DNA is: 70.4–71.7 (T_m) (De Ley and Park, 1966); 69.2–72.6 (T_m) (De Smedt et al., 1980).

Type strain: ATCC 15994, DSM 723, NCIB 9064.

Genus V. **Oligella** *Rossau, Kersters, Falsen, Jantzen, Segers, Union, Nehls and De Ley 1987, 205[VP]*

Karel Kersters and Marc Vancanneyt

O.li.gel'la. Gr. adj. *oligos* little, scanty; M.L. dim. ending *-ella*; M.L. fem. n. *Oligella* referring to small bacterium with limited nutritional properties.

Small rods or coccobacilli, usually not exceeding 1 μm in length and often occurring in pairs; cell width is seldom larger than 0.6 μm. Gram negative, noncapsulated, and nonsporeforming. **Motility, if present, is by means of peritrichous flagella. Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Moderately fastidious chemoorganotrophs growing at 30°C and 37°C. Grow on nutrient agar, but growth is enhanced by the addition of yeast autolysate, serum, or blood. No pigments and no odor are produced. Nonhemolytic. **Biochemically they are rather inert**; only a few organic acids and amino acids are oxidized or utilized as the sole carbon source. **Carbohydrates are neither fermented nor oxidized. Oxidase positive and usually catalase positive.** Indole and H_2S are not formed. Gelatin is not hydrolyzed. The urease test is useful to differentiate the two species. The major cellular fatty acids are *cis*-vaccenic acid ($C_{18:1\ \omega7c}$) and palmitic acid ($C_{16:0}$); two 3-hydroxylated acids ($C_{14:0\ 3OH}$ and $C_{16:0\ 3OH}$) are also present, whereas branched-chain acids are absent. Mainly isolated from the genitourinary tract of humans. Pathogenicity is unknown but likely low. Belongs to the *Betaproteobacteria*; the genera *Brackiella*, *Pelistega*, and *Taylorella* are phylogenetic neighbors.

The mol% G + C of the DNA is: 46–48.

Type species: **Oligella urethralis** (Lautrop, Bøvre and Frederiksen 1970) Rossau, Kersters, Falsen, Jantzen, Segers, Union, Nehls and De Ley 1987, 206[VP] (*Moraxella urethralis* Lautrop, Bøvre and Frederiksen 1970, 255.)

Further descriptive information

Oligella urethralis is nonmotile, whereas most strains of *Oligella ureolytica* are motile by peritrichous flagella. However, motility of *Oligella ureolytica* may be difficult to demonstrate. Colonies on blood agar develop rather slowly and are more overtly white than those of all recognized species of *Moraxella*.

The following descriptive information is mainly based on data from Clark et al. (1984), Schreckenberger and von Graevenitz (1999), Schreckenberger et al., (1999), and, in particular, on the properties of 15 *O. urethralis* strains and 11 *O. ureolytica* strains as reported by Rossau et al. (1987). *Oligella* strains can grow in the presence of up to 3% NaCl. *O. ureolytica* and some strains of *O. urethralis* can also grow in the presence of 4.5% NaCl. Nitrite is reduced. The following physiological features are negative: acid production in oxidative-fermentative (O/F) media containing D-glucose, D-fructose, D-xylose, maltose, and *meso*-ribitol; formation of fluorescent pigment on King B medium; growth on cetrimide; hydrolysis of acetamide, DNA, esculin, gelatin, starch, and Tween 80; lysine and ornithine decarboxylase; and arginine dihydrolase. The following organic compounds are utilized as the sole carbon source (as tested with API auxanographic galleries): acetate, D-alanine, benzoate, fumarate, L-glutamate, glutarate, DL-3-hydroxybutyrate, itaconate, 2-ketoglutarate, DL-lactate, L-malate, pyruvate, succinate, and *n*-valerate. The following compounds are not utilized as carbon source (as tested with API auxanographic galleries): acetamide, *N*-acetylglucosamine, aconitate, adipate, β-

alanine, 2-aminobenzoate, 3-aminobenzoate, 4-aminobenzoate, DL-2-aminobutyrate, DL-3-aminobutyrate, DL-4-aminobutyrate, amygdalin, amylamine, D-arabinose, L-arabinose, D-arabitol, L-arabitol, arbutin, L-arginine, L-aspartate, azelate, benzylamine, betaine, butylamine, caprate, caprylate, cellobiose, citraconate, L-citrulline, creatine, L-cysteine, diaminobutane, dulcitol, *meso*-erythritol, esculin, ethanolamine, ethylamine, D-fructose, D-fucose, L-fucose, D-galactose, gentiobiose, D-gluconate, D-glucosamine, D-glucose, DL-glycerate, glycerol, glycine, glycogen, glycolate, heptanoate, histamine, L-histidine, *o*-hydroxybenzoate, *meso*-inositol, inulin, 2-ketogluconate, 5-ketogluconate, DL-kynurenine, lactose, levulinate, L-lysine, D-lyxose, maleate, malonate, maltose, D-mandelate, L-mandelate, D-mannitol, D-mannose, melezitose, melibiose, L-methionine, methyl-α-D-glucoside, methyl-α-D-mannoside, methyl-β-D-xyloside, L-ornithine, oxalate, pelargonate, L-phenylalanine, phthalate, *iso*-phthalate, pimelate, raffinose, L-rhamnose, *meso*-ribitol (adonitol), D-ribose, salicin, sarcosine, sebacate, L-serine, sorbitol, L-sorbose, spermine, starch, suberate, sucrose, D-tagatose, D-tartrate, *meso*-tartrate, terephthalate, L-threonine, trehalose, trigonelline, tryptamine, D-tryptophan, L-tryptophan, turanose, L-tyrosine, urea, *meso*-xylitol, D-xylose, and L-xylose. The following substrates are hydrolyzed (as tested with API-ZYM galleries): L-leucyl-2-naphthylamide, 2-naphthyl butyrate, and 2-naphthyl caprylate. The following substrates are not hydrolyzed (using API-ZYM galleries): *N*-benzoyl-DL-arginine-2-naphthylamide, 6-bromo-2-naphthyl-α-D-galactopyranoside, 6-bromo-2-naphthyl-α-D-mannopyranoside, 6-bromo-2-naphthyl-β-D-glucopyranoside, L-cystyl-2-naphthylamide, *N*-glutarylphenylalanine-2-naphthylamide, naphthol-AS-BI-β-D-glucuronate, 1-naphthyl-*N*-acetyl-β-D-glucosaminide, 2-naphthyl-α-L-fucopyranoside, 2-naphthyl-β-D-galactopyranoside, 2-naphthyl-α-D-glucopyranoside, 2-naphthylmyristate, 2-naphthylphosphate (at pH 5.4), and L-valyl-2-naphthylamide.

According to version 3.5 of the Biolog database, the following substrates of the Biolog GN Microplate yield positive results with *Oligella* strains: acetic acid, alaninamide, D-alanine, L-alanine, bromosuccinic acid, formic acid, L-glutamic acid, 2-hydroxybutyric acid, 3-hydroxybutyric acid, itaconic acid, 2-ketobutyric acid, 2-ketoglutaric acid, 2-ketovaleric acid, DL-lactic acid, L-leucine, methylpyruvate, monomethylsuccinate, L-proline, propionic acid, succinamic acid, and succinic acid.

The major cellular fatty acids of *Oligella* are *cis*-vaccenic acid ($C_{18:1\ \omega7c}$) and palmitic acid ($C_{16:0}$) (comprising respectively approximately 35–45% and 20–25% of the total fatty acid content). Two 3-hydroxylated acids $C_{14:0\ 3OH}$ and $C_{16:0\ 3OH}$ are present (3–5%), whereas branched chain acids are reported to be absent (Rossau et al., 1987; Moss et al., 1988; Schreckenberger and von Graevenitz, 1999). Only *O. ureolytica* strains characteristically possess in addition lactobacillic acid ($C_{19:0\ cyclo\ \omega8c}$) (Rossau et al., 1987). However, when cultivated on tryptic soy medium, no $C_{19:0\ cyclo\ \omega8c}$ was detected for the type strain of *O. ureolytica* (M. Vancanneyt, unpublished data).

O. urethralis contains ubiquinone with eight isoprene units as the major isoprenolog (Moss et al., 1988).

O. urethralis produces 2-hydroxyputrescine and putrescine as predominant polyamine compounds (respectively 22 and 10 μmol/dry weight), and smaller amounts of spermidine (4 μmol/g dry weight) (H.-J. Busse, personal communication).

Oligella urethralis strains are generally susceptible to most antibiotics, including penicillin, whereas *O. ureolytica* is susceptible to a limited number of antibiotics (Welch et al., 1983). Quinolone resistance has been reported in *O. urethralis* (Riley et al., 1996).

The size of *Oligella* genomes is 1.2–1.4 × 10^9 Da (Rossau et al., 1987).

Oligella strains have been mainly isolated from the human genitourinary tract, and both species have been reported to cause urosepsis (Rockhill and Lutwick, 1978; Pugliese et al., 1993). Some strains of *O. urethralis* were also isolated from the ear, blood, and a foot wound. Cases of septic arthritis and chronic ambulatory peritoneal dialysis peritonitis caused by *O. urethralis* have been reported (Mesnard et al., 1992; Riley et al., 1996). *O. urethralis* has also been isolated from the conjunctiva of rabbits (Marini et al., 1996).

Enrichment and Isolation Procedures

The nutritional requirements of *Oligella* have not been studied in detail. Strains grow on ordinary blood media, heart infusion agar, tryptic soy agar, and Drigalski agar. Incubation in the presence of 5% CO_2 will usually enhance growth. Growth on MacConkey agar is variable. The majority of the *O. urethralis* strains will also grow on nutrient agar. No procedures for the selective isolation of *Oligella* have been worked out.

Maintenance Procedures

Oligella strains can be maintained by classical preservation techniques such as lyophilization, storage in liquid nitrogen, and storage in a freezer at −80°C.

Differentiation of the genus *Oligella* from other genera

Table BXII.β.35 summarizes the differential characteristics between *Oligella* and the phylogenetically closely related genera *Pelistega* and *Taylorella*, as well as the phenotypically similar species *Bordetella bronchiseptica*, *Moraxella osloensis*, and *Ralstonia paucula*, a new species encompassing bacteria of the CDC group IVc-2 (Vandamme et al., 1999).

Rossau et al. (1987), Holt et al. (1994), Weyant et al. (1996), Schreckenberger et al. (1999), and Schreckenberger and von Graevenitz (1999) have compiled other useful tables for differentiating *Oligella* from morphologically or biochemically similar bacterial taxa such as *Moraxella*. Gas chromatographic analysis of the cellular fatty acids yields usually a good discrimination between these taxa; e.g., *Oligella* cells possess $C_{18:1\ \omega7c}$ as the major acid, whereas authentic *Moraxella* species lack this compound, and typically contain oleic acid ($C_{18:1\ \omega9c}$) (Moss et al., 1988) (Table BXII.β.35). The biochemical inertness of the *Oligella* strains renders the identification of *Oligella* and phenotypically similar species difficult. Due to its fast and strong urease reaction, *O. ureolytica* can be confused with *B. bronchiseptica* or *Ralstonia paucula* (CDC group IVc-2) (Table BXII.β.35).

Taxonomic Comments

The genus *Oligella* currently contains two species: *Oligella urethralis*, which was previously classified in the genus *Moraxella*, and *Oligella ureolytica*, which was formerly referred to as CDC group IVe bacteria. Based on comparative 16S rDNA-analysis *Oligella* belongs to the *Betaproteobacteria*, its closest phylogenetic neighbors are the genera *Brackiella*, *Pelistega*, and *Taylorella* (see Fig. BXII.β.25 in this chapter and Fig. BXII.β.21 in the chapter on the family *Alcaligenaceae*).

Oligella urethralis was first described as *Moraxella urethralis* by Lautrop et al. (1970), who stated that the allocation of these bacteria in the genus *Moraxella* was only a matter of convenience. Hence in the previous edition of *Bergey's Manual*, *M. urethralis* was considered as a *species incertae sedis* of the genus *Moraxella*

[c]Isolated from human genitourinary tract.

[d]Isolated from respiratory tracts of pigeons.

[e]Isolated from genital tract of mares; caused endometritis and cervicitis.

[f]Isolated from various human clinical and environmental sources.

[g]Isolated from respiratory tract of animals and humans.

[h]Isolated from clinical sources.

[i]The references for the fatty acid data are as follows: *Oligella* (Rossau et al., 1987), *Pelistega* (Vandamme et al., 1998), *Taylorella* (Rossau et al., 1987), *Ralstonia paucula* (P. Vandamme, personal communication), *Bordetella bronchiseptica* (Vancanneyt et al., 1995), and *Moraxella osloensis* (Moss et al., 1988; Vandamme et al., 1993b).

[j]SF 3 (summed feature 3) comprises $C_{14:0\ 3OH}$ or $C_{16:1\ iso\ I}$, or any combination of these fatty acids.

(Bøvre, 1984b), which is phylogenetically quite distinct from *Oligella* (Fig. BXII.β.25); the authentic *Moraxella* species belong to the *Gammaproteobacteria* (Rossau et al., 1991; Pettersson et al., 1998b). Although *O. urethralis* displays several phenotypic features in common with *Moraxella* species (particularly *M. osloensis*), genetic transformation studies with streptomycin resistance as a marker indicated that the species *Oligella urethralis* (previously named *Moraxella urethralis*) displayed no distinct genetic affinities to the authentic *Moraxella* species (Bøvre, 1980). Consequently, Bøvre (1984b) suggested that the species might belong to a separate genus. Moreover, *Oligella* cells are also smaller and lack the typical plumpness of moraxellae, and their cellular fatty acid composition differs significantly (Moss et al., 1988; Table BXII.β.35). *O. urethralis* was formerly also referred to as "CDC group M-4", and includes some of the strains previously called "*Mima polymorpha* biovar oxidans".

O. ureolytica was previously known as CDC group IVe, displaying some phenotypic similarities (e.g., rapid and strong urease test) with *Bordetella bronchiseptica* and *Ralstonia paucula* (formerly CDC group IVc-2) (Clark et al., 1984; Vandamme et al., 1999).

The grouping of *Oligella* in the *Betaproteobacteria* was initially established by Rossau et al. (1987) based on rRNA–DNA hybridization studies. Recently the knowledge of the phylogenetic relationships of the genus has been refined by an analysis of the nearly complete 16S rDNA sequences of the type strains of the species *O. urethralis* and *O. ureolytica* (M. Vancanneyt and B. Hoste, unpublished data) (Fig. BXII.β.25). The type strains of the two *Oligella* species display a significant 16S rDNA similarity (97%). The nearest phylogenetic neighbors of *Oligella* are *Pelistega europaea* (92.1%) and *Taylorella equigenitalis* (91.8%) (Fig. BXII.β.25). At present *Pelistega* encompasses one species, *P. europaea* (Vandamme et al., 1998), which is involved in the path-

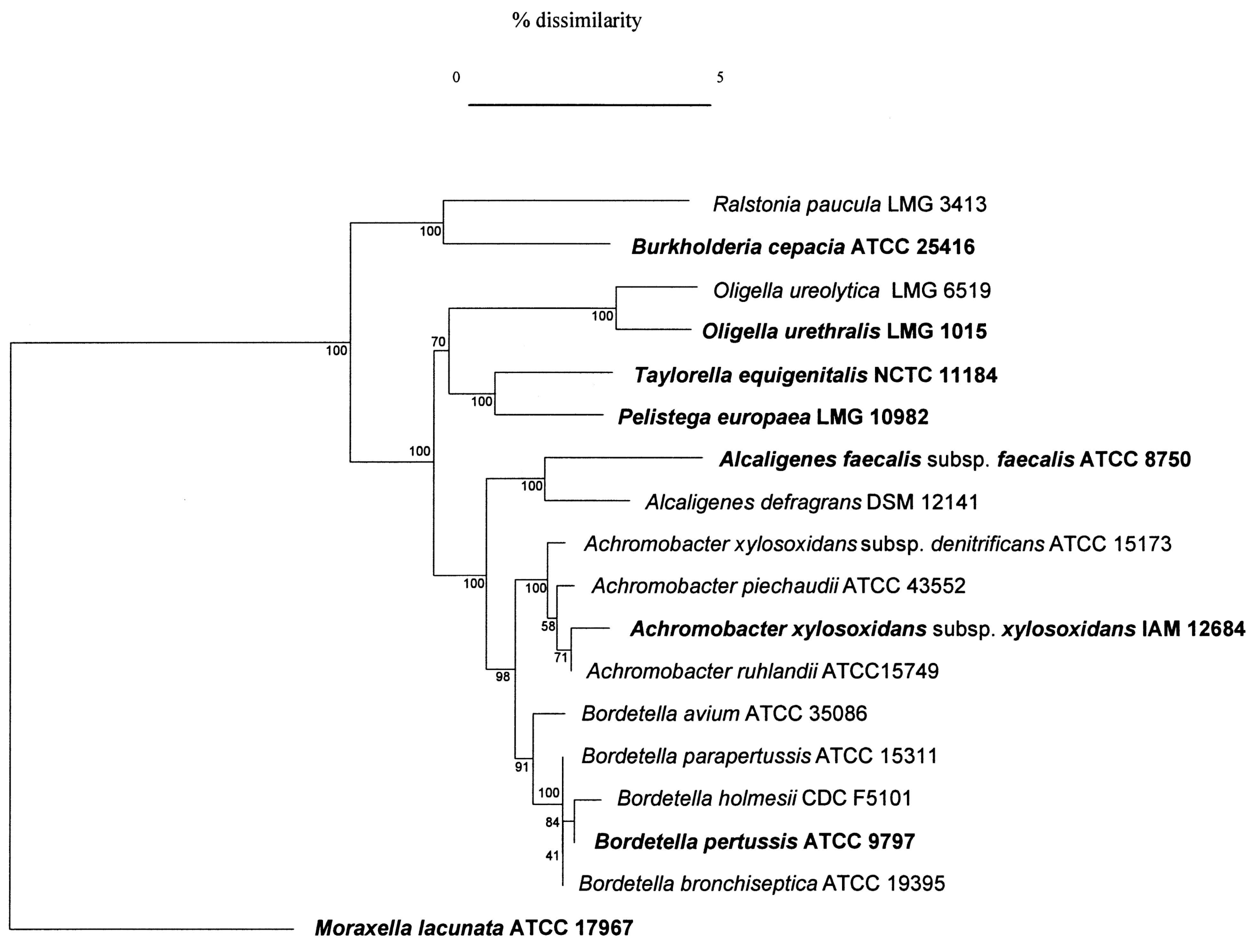

FIGURE BXII.β.25. Phylogenetic tree of members of the genus *Oligella* and related bacteria. The analysis was performed using the software package GeneCompar (Applied Maths, Kortrijk, Belgium) after including the consensus sequence in a multiple alignment of small ribosomal subunit sequences collected from the international nucleotide sequence library EMBL. A resulting tree was constructed using the neighbor-joining method. Unknown bases and gaps were not considered in the numerical analysis. Bootstrap probability values are indicated at the branch-points (100 trees resampled). All strains are type strains and the type species are indicated in bold.

ogenesis of respiratory diseases in pigeons. *Taylorella equigenitalis*, the sole species of the genus *Taylorella* (Sugimoto et al., 1983) is the causative agent of contagious equine metritis, a sexually transmitted bacterial disease of horses. The phylogenetic grouping of *T. equigenitalis* within the *Betaproteobacteria* was reported by Bleumink-Pluym et al. (1993) and Rossau et al. (1987). The 16S rDNA similarity values of *Oligella* versus the investigated type strains of the various species of the family *Alcaligenaceae* vary between 91.3% and 92.6%, whereas similarity values with the type species of the genus *Moraxella* are only 82% (Fig. BXII.β.25). It is surprising that the phylogenetically related taxa *Achromobacter*, *Alcaligenes*, *Bordetella*, *Oligella*, *Pelistega*, and *Taylorella* (Fig. BXII.β.25) cover in their genomic DNA a very broad mol% G + C range (36–70) (Table BXII.β.35).

The majority of the above-mentioned taxa, including *Oligella* but excluding some of the *Bordetella* species, can be circumscribed as oxidase positive, indole-negative, asaccharolytic nonfermenting Gram-negative bacteria. Strains of the genera *Alcaligenes*, *Achromobacter* (Yabuuchi et al., 1998a), and *Bordetella* can be implicated in human and animal diseases.

Acknowledgments

We thank B. Hoste for help in the determination of the sequence of the rRNA gene of *O. urethralis* and *O. ureolytica*.

Differentiation of the species of the genus *Oligella*

Characteristics useful in differentiating the species of *Oligella* are given in Table BXII.β.36.

List of species of the genus Oligella

1. **Oligella urethralis** (Lautrop, Bøvre and Frederiksen 1970) Rossau, Kersters, Falsen, Jantzen, Segers, Union, Nehls and De Ley 1987, 206[VP] (*Moraxella urethralis* Lautrop, Bøvre and Frederiksen 1970, 255.)
u.re.thra′ lis. Gr. *ourethra* urethra; M.L. gen. n. *urethralis* of the urethra.

The description is as given for the genus and as listed in Tables BXII.β.35 and BXII.β.36. Cells are nonmotile. Inclusions of intracellular poly-β-hydroxybutyrate have been reported. Grows at 42°C. Urease negative (Christensen's). No growth on *p*-hydroxybenzoate. Nitrate is not reduced, but denitrification is usually positive. Usually highly sensitive to penicillin. Lactobacillic acid ($C_{19:0\ cyclo\ \omega 8c}$) is not detectable among the cellular fatty acids.

Has been isolated from human urine, the human genitourinary tract, and the ear.

The mol% G + C of the DNA is: 46–47.5 (T_m).

Type strain: ATCC 17960, CCUG 13463, CDC 7603, DSM 7531, LMG 5303.

GenBank accession number (16S rRNA): AF133538, AF227163.

TABLE BXII.β.36. Differential features of the species of the genus *Oligella*[a,b]

Characteristic	*O. urethralis*	*O. ureolytica*
Motility	−	d
Growth at 42°C	+	−
Growth in the presence of 4.5% NaCl	d	+
Urease	−	+[c]

Presence of $C_{19:0\ cyclo}$ fatty acid (>1%)	−	+

[a]Symbols: see standard definitions.

[b]Data from Clark et al. (1984), Rossau et al. (1987), and Schreckenberger and von Graevenitz (1999).

[c]The urease reaction is strongly positive.

[d]Demonstration of gas may be difficult.

2. **Oligella ureolytica** Rossau, Kersters, Falsen, Jantzen, Segers, Union, Nehls and De Ley 1987, 209[VP]
ur′ e.o.ly.ti.ca. M.L. n. *urea* urea; Gr. adj. *lyticus* dissolving; M.L. adj. *ureolytica* dissolving (hydrolyzing) urea.

The description is as given for the genus and as listed in Tables BXII.β.35 and BXII.β.36. The species accommodates the CDC group IVe strains.

Some strains are motile by means of long peritrichous flagella. No growth at 42°C. Grows on *p*-hydroxybenzoate as carbon source. The urease test (Christensen's) is usually strongly positive after 4 h. Most strains reduce nitrate and are resistant to penicillin. Among the cellular fatty acids lactobacillic acid ($C_{19:0\ cyclo\ \omega 8c}$) is present in moderate amounts.

Isolated from human urine, particularly from males.

The mol% G + C of the DNA is: 46–47 (T_m).

Type strain: ATCC 43534, CCUG 1465, CDC C379, LMG 6519.

GenBank accession number (16S rRNA): AJ251912.

Genus VI. **Pelistega** *Vandamme, Segers, Ryll, Hommez, Vancanneyt, Coopman, De Baere, Van De Peer, Kersters, De Wachter and Hinz 1998, 437*[VP]

PETER VANDAMME AND KARL-HEINZ HINZ

Pe.li′ ste.ga. Gr. n. *peleia* pigeon; Gr. fem. n. *stege* house, stay, residence; N.L. fem. n. *Pelistega* refers to the bacteria living in pigeons.

Cells in 16–24-h-old cultures on blood agar are 0.2–0.4 × 1–2 µm, with **variable morphological forms**. Gram negative. **Nonsporeforming.** Capsulated. **Nonmotile. Optimal growth under microaerobic conditions.** Growth is weak under aerobic conditions and absent under anaerobic conditions. Growth at 37°C and 42°C, not at 24°C. Does not require growth factors on conventional media. No growth on MacConkey agar. **Glucose is oxidized with the production of alkali**, no fermentation of, or acid production from, glucose. **Catalase and oxidase activity is present.** No reduction of nitrate, no denitrification, no production of acetylmethylcarbinol, indole, or methyl red, no esculin hydrolysis, β-galactosidase, DNase, chondroitin sulfatase, hyaluronidase, lysine decarboxylase, ornithine decarboxylase, lecithinase, or phenylalanine deaminase activity. **Alkaline and acid phosphatase activity is present.** Thus far only isolated from pigeon samples.

The mol% G + C of the DNA is: 42–43.

Type species: **Pelistega europaea** Vandamme, Segers, Ryll, Hommez, Vancanneyt, Coopman, De Baere, Van De Peer, Kersters, De Wachter and Hinz 1998, 437.

FURTHER DESCRIPTIVE INFORMATION

The genus *Pelistega* belongs to the *Betaproteobacteria* with the genus *Taylorella* as its closest relative (Fig. BXII.β.26). Other genera belonging to the same phylogenetic neighborhood are *Bordetella*, *Alcaligenes*, and *Burkholderia*.

Strains of the genus *Pelistega* have been isolated from samples of lungs, air sac exudate, and trachea mucosa of pigeons; less frequently from other organs such as the liver and spleen. The pathogenicity is unknown.

ENRICHMENT AND ISOLATION PROCEDURES

At present, blood agar is the only medium by which *Pelistega* strains have been successful isolated. MacConkey agar and litmus

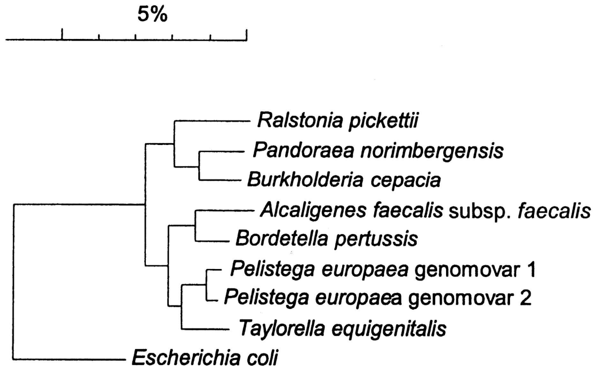

FIGURE BXII.β.26. Phylogeny of *Pelistega europaea.* Bar = 5% difference in 16S rRNA nucleotide sequences. The neighbor-joining method was used for tree construction. Accession numbers for the sequences used are: *Alcaligenes faecalis* subsp. *faecalis* LMG 1229^T, D88008; *Bordetella pertussis* LMG 14455^T, U04950; *Burkholderia cepacia* LMG 1222^T, M22518; *Pandoraea norimbergensis* LMG 18379^T, Y09879; *Pelistega europaea* genomovar 1 LMG 10982^T, Y11890 and *Pelistega europaea* genomovar 2 LMG 15725, AF190911; *Ralstonia pickettii* LMG 5942^T, X67042; *Taylorella equigenitalis* LMG 6222^T, X68645; *Escherichia coli* (J01695) was chosen as an outgroup.

lactose agar are not suitable for primary isolation. Selective procedures have not been developed. Clinical specimens are plated on blood agar plates and incubated at 37°C for 24–48 h in a microaerobic atmosphere with a high humidity (e.g., candle jar conditions). *Pelistega* strains can be identified especially by the characters given in Table BXII.β.37. The numerical analysis of the whole-cell fatty acid patterns by using the MIDI system also allows a rapid and reliable identification.

Maintenance Procedures

Cultures may be stored for many years by lyophilization, freezing at −80°C, or in liquid nitrogen. Cryoprotective agents such as 10% glycerol or DMSO should be added to cultures before freezing. Strains also remain viable for over 10 years when stored as dense suspensions in skimmed milk in a frozen state at −70°C. Twenty-four-hour blood agar cultures will survive refrigeration (4°C) in ambient air for at least 1 week.

Differentiation of the genus *Pelistega* from other genera

Comparative 16S rDNA sequence analysis revealed that *Pelistega europaea* belongs to the *Betaproteobacteria* with *Taylorella equigenitalis* as its nearest neighbor (Fig. BXII.β.26). Like *Pelistega europaea, Taylorella equigenitalis* (the type species of the genus *Taylorella*) is a microaerobic, Gram-negative, nonmotile, rod-shaped organism that does not acidify carbohydrates and exhibits catalase, oxidase, and acid and alkaline phosphatase activity. *Taylorella equigenitalis* differs from *Pelistega europaea* by the absence of urease and arginine dihydrolase activity, and by alkali production from glucose. *Taylorella equigenitalis* strains can also be differentiated from *Pelistega europaea* by means of whole-cell protein and fatty acid analysis and by its mol% G + C content (about 36–37% for the former and 42–43% for the latter). The most salient differences between *Pelistega europaea* and *Taylorella equigenitalis*, however, are the fastidious growth requirements of the latter, while *Pelistega europaea* grows abundantly when incubated under microaerobic conditions. Vandamme et al. (1998) reported a remarkable stimulation of growth of *Taylorella equigenitalis* strains by the addition of growth factors, which was not recorded for *Pelistega europaea* strains. Earlier studies by Sugimoto et al. (1983), however, did not reveal this growth stimulation.

Table BXII.β.37 lists differential diagnostic characteristics that can be used to distinguish *Pelistega europaea* from other species that may be encountered in specimens from pigeons: *Riemerella anatipestifer, Ornithobacterium rhinotracheale, Chryseobacterium meningosepticum,* and *Pasteurella* species.

Taxonomic Comments

Vandamme et al. (1998) described a polyphasic taxonomic study of a collection of 24 pigeon isolates that remained unidentified after preliminary examination by conventional biochemical tests. Additional extensive biochemical characterization by using a considerable number of conventional tests and several API microtest systems further substantiated the high phenotypic similarity among all of the strains examined. Unexpectedly, whole-cell fatty acid analysis demonstrated a marked subdivision of the pigeon isolates into two main clusters. Strains of both clusters had the same major fatty acid components but there were marked quantitative differences. However, the same strains were again further subdivided into four subgroups and several strains with unique patterns by means of one-dimensional whole-organism protein electrophoresis. The DNA base ratio of representative strains of these subgroups was determined, and all values were between 42–43 mol% G + C. Results obtained by whole-cell protein electrophoresis were a good indicator of the level of DNA–DNA hybridization, as only within the protein electrophoretic subgroups high binding levels were detected (>82%); all other values were low or insignificant.

In taxonomic practice, the DNA–DNA hybridization level within a bacterial species is mostly above 50–70%. This level is primarily determined by the phenotypic consistency of the taxon studied, as species should be identifiable by phenotypic characteristics (Wayne et al., 1987; Ursing et al., 1995). The term "genomovar" refers to closely related genomic species that cannot be distinguished by phenotypic characteristics (Ursing et al., 1995). The group of pigeon isolates obviously comprised several subgroups that were genotypically distinct enough to warrant their classification as different species. However, in the absence of differential phenotypic characteristics between these genomovars, all isolates were included in a single nomenspecies, *Pelistega europaea.*

Strain LMG 10982 (representing genomovar 1) was chosen as the type strain for the nomenspecies. Strains LMG 15725, LMG 11609, and LMG 12985 were selected as reference strains for genomovars 2, 3, and 4, respectively. In addition, several strains with unique whole-organism protein patterns were not formally classified into different genomovars until the DNA–DNA hybridization levels between these strains and the four designated genomovars were fully determined.

It therefore should be clear that *Pelistega europaea* presently encompasses multiple genomic species. It is not unlikely that this name may be restricted in the future to only one or a few of these genomovars, upon discovery of differential diagnostic features.

List of species of the genus Pelistega

1. **Pelistega europaea** Vandamme, Segers, Ryll, Hommez, Vancanneyt, Coopman, De Baere, Van De Peer, Kersters, De Wachter and Hinz 1998, 437[VP]
eu.ro.pae′ a. L. adj. *europaea* of Europe, because the first collection of strains was isolated in different European countries.

Cells in 16–24-h-old cultures on blood agar are 0.2–0.4 × 1–2 μm, with variable morphological forms. Gram negative. Nonsporeforming. Capsulated. Nonmotile.

Strains produce convex, circular, and grayish-white to yellowish colonies with entire edge and smooth surface on blood agar.

Optimal growth under microaerobic conditions. Growth is weak under aerobic conditions, and absent under anaerobic conditions. Growth at 37°C and 42°C, not at 24°C. Does not require growth factors on conventional media. In standard II nutrient broth, growth appears as moderate turbidity and pellicle near the surface of the broth after 24–48 h of incubation. In most cases, a small, button-like sediment could be seen. No growth on litmus lactose agar at the primary isolation from the infected tissues. However, after some passages on artificial media some strains showed a poor growth. No growth on MacConkey agar.

All strains produce catalase and oxidase activity; urease and arginine dihydrolase activity is strain dependent. No reduction of nitrate, no denitrification, no production of acetylmethylcarbinol, indole, or methyl red, no esculin hydrolysis, gelatinase (except strain LMG 11609), β-galactosidase, DNase, chondroitin sulfatase, hyaluronidase, lysine decarboxylase, ornithine decarboxylase, lecithinase, or phenylalanine deaminase activity. Glucose is oxidized with the production of alkali, no fermentation of, or acid production from, glucose. Malonate is not used as a carbon source. Strain-dependent utilization of citrate on Simmons' citrate agar.

No acid production from D-glucose, D-fructose, sucrose, lactose, maltose, D-galactose, galacturonate, D-mannose, rhamnose, cellobiose, palatinose, dextrin, *N*-acetyl-D-glucosamine, lactulose, L-sorbose, adonitol, D-mannitol, L-arabinose, D- and L-arabitol, salicin, D-sorbitol, trehalose, D-xylose, dulcitol, inositol, or *myo*-inositol.

There is no assimilation of D-glucose, maltose, D-mannose, *N*-acetyl-D-glucosamine, D-mannitol, L-arabinose, D-gluconate, caprate, adipate, or phenyl acetate; most strains (18 out of 19 examined) assimilate L-malate.

Alkaline and acid phosphatase, esterase C_4, ester lipase C_8, and leucine, arginine, alanine, glycine, and L-aspartic acid arylamidase activity is present. Activity of naphthol-AS-Bl-phosphohydrolase and lipase (as present in the API ID 32E system) is strain dependent. Lipase C_{14}, valine, leucyl glycine, phenylalanine, histidine, glutamyl glutamic acid, serine, and cystine arylamidase, trypsin, chymotrypsin, α-galactosidase, α-maltosidase, β-glucuronidase, α- and β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activity has not been detected. Proline, pyroglutamic acid, and tyrosine arylamidase activity is strain dependent.

Two major clusters of strains are delineated by means of cellular fatty acid analysis. The major fatty acid components of all strains examined were $C_{12:0}$, $C_{14:0}$, $C_{16:0}$, $C_{16:1\ \omega7c}$, $C_{16:1\ \omega5c}$, $C_{16:0\ 3OH}$, and summed features 3 and 7. However, the percentages of these fatty acids vary strongly among the different genomovars (Table BXII.β.38).

Strains have been isolated on common nonselective blood agar media under microaerobic (candle jar) conditions mainly from samples of lungs, air sac exudate, and

TABLE BXII.β.38. Fatty acid composition of *Pelistega europaea* strains[a]

Fatty acid	Genomovars 1, 2, and 3	Genomovar 4
$C_{12:0}$	4.4 ± 0.7	4.4 ± 1.0
$C_{14:0}$	9.7 ± 1.5	10.8 ± 2.5
$C_{16:0}$	15.7 ± 2.9	25.2 ± 2.8
$C_{18:0}$	Tr	Tr
$C_{16:1\ \omega7c}$	21.7 ± 3.5	41.4 ± 2.7
$C_{16:1\ \omega5c}$	5.2 ± 2.6	Tr
$C_{16:0\ 3OH}$	1.2 ± 0.3	1.2 ± 0.2
$C_{19:0\ 10CH_3}$	Tr	nd
Summed feature 1[b]	Tr	2.7 ± 1.6
Summed feature 3[c]	12.7 ± 2.1	12.4 ± 1.1
Summed feature 7[d]	27.8 ± 9.4	1.5 ± 0.9

[a]Those fatty acids for which the average amount for all taxa was less than 1% are not given. Therefore, the percentages for each group do not total 100%. Mean percentages and standard deviations are given; Tr, trace amount (less than 1%); nd, not detected.

[b]Summed feature 1 comprises $C_{14:1\ \omega5c}$, $C_{14:1\ \omega5t}$, or both.

[c]Summed feature 3 comprises $C_{14:0\ 3OH}$, $C_{16:1\ iso\ I}$, an unidentified fatty acid with equivalent chain length value of 10.928, or 12:0 ALDE, or any combination of these fatty acids.

[d]Summed feature 7 comprises $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, or $C_{18:1\ \omega12t}$, or any combination of these fatty acids.

trachea mucosa, and less frequently from other organs such as the liver and spleen. They also can be isolated from swabs taken from the palatine cleft or trachea of living acutely diseased pigeons. At present the knowledge with regard to pathogenicity is incomplete. The present clinical observations suggest that they are pathogenic and involved especially in pathogenesis of respiratory diseases in pigeons. However, the role of cofactors and the interaction with other agents are uncertain. Bacteria associated with similar clinical signs in pigeons were described by Andreasen and Sandhu (1993). All morphological and biochemical characteristics reported by the latter authors corresponded with our findings.

The type strain was isolated from a pigeon in Belgium.

The mol% G + C of the DNA is: 42–43 (43 for the type strain) (T_m).

Type strain: Strain Hommez N57, LMG 10982.

GenBank accession number (16S rRNA): Y11890.

Additional Remarks: GenBank accession number (16S rRNA) for LMG 15725 (reference strain for genomovar 2) is AF190911.

Genus VII. **Pigmentiphaga** *Blümel, Mark, Busse, Kämpfer and Stolz 2001b, 1870*[VP]

Hans-Jürgen Busse

Pig.men.ti.pha.ga. L. n. *pigmentum* dye; Gr. n. *phagos* eater; M.L. fem. adj. *Pigmentiphaga* eating dyes.

Cells are Gram-negative, motile, rod-shaped, nonsporeforming bacteria 1.3–4 × 0.7–1.2 µm. The colonies are opaque, circular, convex with an entire margin. Growth occurs at 30°, 37°, and 42°C, no growth is found at 4°C.

Oxidase and catalase positive. L-Alanine-*p*-nitroanilide is hydrolyzed. The following compounds are not hydrolyzed: *p*-nitrophenyl-β-D-galactopyranoside, *p*-nitrophenyl-β-D-glucuronide, *p*-nitrophenyl-α-D-glucopyranoside, *p*-nitrophenyl-β-D-glucopyranoside, *p*-nitrophenyl-β-D-xylopyranoside, bis-*p*-nitrophenyl-phosphate, bis-*p*-nitrophenyl-phenyl-phosphonate, bis-*p*-nitrophenyl-phosphoryl-choline, L-aniline-*p*-nitroanilide, γ-L-glutamate-*p*-nitroanilide, and L-proline-*p*-nitroanilide. The following compounds are assimilated: acetate, propionate, *cis*-aconitate, *trans*-aconitate, adipate, azelate, citrate, fumarate, glutarate, DL-3-hydroxybutyrate, itaconate, DL-lactate, mesaconate, 2-oxoglutarate, pyruvate, suberate, L-aspartate, 3-hydroxybenzoate, and 4-hydroxybenzoate. The following compounds are not assimilated: *N*-acetylgalactosamine, *N*-acetylglucosamine, L-arabinose, L-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-maltose, D-mannose, α-D-melibiose, L-rhamnose, D-ribose, D-sucrose, salicin, D-trehalose, D-xylose, adonitol, *i*-inositol, maltitol, D-mannitol, D-sorbitol, putrescine, 4-aminobutyrate, L-alanine, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-serine, L-tryptophan, and phenylacetate. No acids are produced from glucose, lactose, sucrose, D-mannitol, dulcitol, salicin, adonitol, inositol, sorbitol, L-arabinose, raffinose, rhamnose, maltose, D-xylose, trehalose, cellobiose, methyl-D-glucoside, erythritol, melibiose, D-arabitol, and D-mannose.

The **major fatty acids** are $\mathbf{C_{16:0}}$, **summed feature 3** ($C_{16:1\ iso\ I}$ and $C_{14:0\ 3OH}$), **summed feature 7** ($C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, and/or $C_{18:1\ \omega12t}$), **and** $\mathbf{C_{10:0\ 3OH}}$, $\mathbf{C_{14:0\ 2OH}}$, $\mathbf{C_{16:0\ 2OH}}$, and $\mathbf{C_{17:0\ cyclo}}$ **and** $\mathbf{C_{19:0\ cyclo\ \omega8c}}$; the major isoprenoid quinone is **ubiquinone Q-8**. The **polyamine pattern** contains two major compounds: **putrescine** and the unusual **2-hydroxyputrescine**. **Phosphatidylethanolamine** is the major **polar lipid** and **phosphatidylglycerol** and **diphosphatidylglycerol** are minor components.

The mol% G + C of the DNA is: 68.5 ± 0.3.

Type species: **Pigmentiphaga kullae** Blümel, Mark, Busse, Kämpfer and Stolz 2001b, 1870.

List of species of the genus Pigmentiphaga

1. **Pigmentiphaga kullae** Blümel, Mark, Busse, Kämpfer and Stolz 2001b, 1870[VP]

kul.lae. in honor of Hans G. Kulla, who initiated the work about the aerobic degradation of azo dyes by bacteria, which resulted in the isolation of strain K24.

The characteristics of the species is identical to that of the genus. Strain K24[T] has been isolated from soil after continuous enrichment with 1-(4′-carboxyphenylazo)-4-naphthol.

The mol% G + C of the DNA is: 68.5 ± 0.3 (HPLC).

Type strain: K24, DSM 13608, NCIMB 13708.

GenBank accession number (16S rRNA): AF282916.

Genus VIII. **Sutterella** *Wexler, Reeves, Summanen, Molitoris, McTeague, Duncan, Wilson and Finegold 1996a, 257*[VP]

HANNAH M. WEXLER

Sut.ter.el' la. M.L. dim. fem. n. *Sutterella* named in memory of Vera Sutter, respected colleague and director of the Wadsworth Anaerobe Laboratory for twenty years.

Straight rod, 0.5–1 × 1–3 μm. Gram negative. Grows in a microaerophilic atmosphere (2% and 6% oxygen) or under anaerobic conditions. Isolated mainly from the intestinal tract and from infections of gastrointestinal origin. Urease negative. Oxidase negative. Indoxyl acetate negative. Reduces nitrate. **Resistant to 20% bile disks.** Asaccharolytic. Cannot reduce tetrazolium tetrachloride under aerobic conditions if formate and fumarate are added to the medium. **May be resistant to metronidazole.**

Type species: **Sutterella wadsworthensis** Wexler, Reeves, Summanen, Molitoris, McTeague, Duncan, Wilson and Finegold 1996a, 257.

FURTHER DESCRIPTIVE INFORMATION

Biochemical characteristics and oxygen tolerance Like *B. ureolyticus*, *C. gracilis*, and other *Campylobacter* species, members of *Sutterella* are asaccharolytic and reduce nitrate to nitrite. Both *Campylobacter* and *Sutterella* were able to grow on solid media at 2% and 6% oxygen. *C. gracilis* grew only in 6% oxygen on plates containing *Brucella* agar with formate/fumarate but no blood added; if blood was added, *C. gracilis* did not grow. *Sutterella* is resistant to both human bile and oxgall (Table BXII.β.39); this may be important in their ability to survive in the biliary tract and bowel.

Dehydrogenase profiles Three general patterns of dehydrogenase activity were seen among the typical *C. gracilis*, *Sutterella wadsworthensis*, and *Campylobacter* strains studied. The group including the type strain of *C. gracilis* (as well as *C. gracilis* type 2 WAL 10733/FDC 20A1) showed no bands or very faintly reactive malate-specific bands (which appeared only when the gels were very heavily loaded), whereas strains of *Sutterella* had strongly reactive single or multiple bands of a nonspecific dehydrogenase enzyme (with anaerobic incubation only). *Campylobacter* strains (including WAL 10732/FDC 286) had different MDH-specific bands of variable migration distances, both under aerobic and anaerobic incubation conditions.

Cellular fatty acid analysis The fatty acid methyl esters (FAME) found in the different groups of organisms are listed in Table BXII.β.40. Cluster analysis of the cellular fatty acid data indicated three major groups: (1) typical *C. gracilis* (including the strain ATCC 33236^T, (2) the *Sutterella* group, and (3) *Campylobacter* species. Among other differences, the absence of $C_{12:0}$ fatty-acid-methyl-ester (FAME) distinguished *Sutterella* from typical *C. gracilis* and other *Campylobacter* species. The typical *C. gracilis*, *Campylobacter*, and *B. ureolyticus* also cluster quite independently of each other. The strain chosen as the type strain of *Sutterella* (WAL 9799) was selected because it resided in the center of the *Sutterella* cluster. *C. gracilis* ATCC strain 33236^T clustered at the edge of the cellular fatty acid cluster analysis of *C. gracilis*.

16S rRNA sequencing Phylogenetic relationships of *Sutterella* are shown in the chapter describing the family *Alcaligenaceae* (Fig. BXII.β.21).

Sequencing of the 16S rRNA gene was performed for two *Sutterella* strains (WAL 9054 [GenBank L37786] and WAL 7877 [GenBank L37785], *Campylobacter gracilis* strain ATCC 33236^T (GenBank Collection L37787), and *C. rectus* WAL 7943. The 16S rRNA sequences of the two *Sutterella* strains (WAL 9054 and WAL 7877 [1454 and 1419 base pairs sequenced, respectively]) were identical to each other but did not cluster with either the *C. gracilis* or *Campylobacter* strains analyzed or those contained in the databases GenBank or RDP. *C. gracilis* strain ATCC 33236^T branches at the same point as *Campylobacter rectus*.

DNA hybridization The *Sutterella wadsworthensis* type strain did not hybridize with DNA from either *C. gracilis* (10 strains) or other *Campylobacter* species (9 strains), but hybridized strongly (>96%) with DNA from 68% of the *Sutterella* (19 strains) and exhibited hybridization values of >67% with all of the strains tested, indicating that these strains are of the same species or very closely related species that cannot be differentiated phenotypically. Ten *Sutterella* strains did not hybridize at all with the *C. gracilis* type strain, and the DNA of three *Sutterella* strains hybridized very slightly (3%, 5%, and 12%); seven strains of *Campylobacter* did not hybridize at all with *C. gracilis* ATCC 33236^T, and two strains of *C. rectus* hybridized slightly (15%). *C. gracilis* strain ATCC 33236^T hybridized moderately with other typical *C. gracilis* strains (2/9 strains hybridized at 70–80%, 3/9 at 40–50%, 3/9 at 30–50%, and 1/9 at 22%). *C. gracilis* strain WAL 8030 hybridized more strongly with other *C. gracilis* strains, did not hybridize at all with *Sutterella*, and hybridized slightly (23%) with the one *C. rectus* strain tested.

Clinical source The strains belonging to the *Sutterella* group were isolated mainly from infections of gastrointestinal origin (Finegold and Jousimies-Somer, 1997; Jousimies-Somer, 1997). Strains belonging to *C. gracilis* were found virtually only in infections above the diaphragm (e.g., brain, pleural fluid, etc.); only one strain of *C. gracilis* was found from an appendiceal specimen. The resistance of *Sutterella* to both human bile (unpublished data from our laboratory) and oxgall is notable; this may account for their ability to survive in the biliary tract and bowel.

Antimicrobial susceptibility Over 95% of *Sutterella* strains are susceptible to amoxicillin/clavulanate, ticarcillin/clavulanate, cefoxitin, ceftriaxone, and clindamycin. 85–95% of strains are susceptible to piperacillin, piperacillin/tazobactam, ceftizoxime, ciprofloxacin, trovafloxacin, azithromycin, clarithromycin, erythromycin, and roxithromycin.

ENRICHMENT AND ISOLATION PROCEDURES

Sutterella wadsworthensis is isolated on *Brucella* blood agar with 5% lysed sheep blood, 1 μg/ml Vitamin K_1, 1 μg/ml hemin, 1% formate/fumarate (used as a growth supplement). Colonies are seen after 48 h at 37°C in an anaerobic chamber. Colonies are circular, entire, convex, yellow to brown, translucent to opaque, 1–1.5 mm in diameter.

MAINTENANCE PROCEDURES

Strains are kept in skim milk (20%) at −70°C.

DIFFERENTIATION OF THE GENUS *SUTTERELLA* FROM OTHER GENERA

Sutterella can be differentiated from *Campylobacter gracilis* and from other *Campylobacter* species as shown in Table BXII.β.39.

Dehydrogenase patterns are distinctive from those of *C. gracilis* and other campylobacters when the gels are incubated anaerobically. Cellular fatty acid analysis indicates that the cluster of *Sutterella* is distinct from the (separate) clusters formed by *C. gracilis*, *Bacteroides ureolyticus*, or other *Campylobacter* species. 16S rRNA sequence and DNA hybridization data indicate that *Sutterella* is distinct from *C. gracilis* and other *Campylobacter* species at the genus and species levels.

Taxonomic Comments

Historical notes During biochemical characterization and susceptibility testing of isolates from clinical specimens in the Wadsworth Anaerobe laboratory, we found heterogeneity among the strains previously identified as *Campylobacter gracilis.* These organisms differed with regard to their bile resistance and ability to reduce triphenyltetrazolium chloride (TTC). Isolates that were bile resistant and unable to reduce TTC aerobically were compared to other strains of *C. gracilis* (including the ATCC type strain) and five species of *Campylobacter* using biochemical characteristics, cellular fatty acid profiles, DNA relatedness, and 16S rRNA sequence homology.

Campylobacter gracilis was originally known as *Bacteroides gracilis*, one of the members of the *B. ureolyticus* group. These are asaccharolytic, nitrate-positive organisms that require formate or hydrogen as an electron donor and may pit the agar. *B. ureolyticus* and *B. gracilis* clearly do not belong in *Bacteroides sensu stricto* (currently limited to the *B. fragilis* group; Shah and Collins, 1989), and 16S rRNA sequence analysis and DNA–rRNA hybridization studies support description of a tight homology group that includes *B. ureolyticus*, *B. gracilis*, and *Campylobacter* (including some previous *Wolinella* species) (Paster and Dewhirst, 1988; Whiley and Beighton, 1991). Both *B. ureolyticus* and *B. gracilis* are microaerophiles and not anaerobes; it has been proposed that both be included in the group of "true campylobacters" (Han et al., 1991). *B. gracilis* was reclassified as *Campylobacter gracilis*; *B. ureolyticus* was not renamed along with *C. gracilis*; its recommended status was a *species incertae sedis* pending further investigation (Vandamme et al., 1995a).

Strains belonging to *C. gracilis* were (with the exception of one strain) isolated from infections above the diaphragm, while the *Sutterella* strains were mostly isolated from infections below the diaphragm; the metronidazole-resistant strains all belonged to *Sutterella* (Molitoris et al., 1997).

List of species of the genus Sutterella

1. **Sutterella wadsworthensis** Wexler, Reeves, Summanen, Molitoris, McTeague, Duncan, Wilson and Finegold 1996a, 257[VP]
wads.worth' en.sis. M.L. adj. *wadsworthensis* from Wadsworth, referring to the Wadsworth Anaerobe Laboratories, VAMC, West Los Angeles, where the strains were identified.

The characteristics are as described for the genus and as shown in Tables BXII.β.39 and BXII.β.40.

TABLE BXII.β.39. Differentiation of *Sutterella wadsworthensis* from related taxa

Characteristic	*S. wadsworthensis*	*B. ureolyticus*	*Campylobacter*	*Campylobacter gracilis*
Oxidase	−	+	+	−

[a] *C. rectus*, 8 strains; *C. curvus*, 3 strains; *C. concisus* 3 strains; *Campylobacter* sp., 2 strains.

[b]Fatty acid methyl ester.

[c]DMA, dimethyl acetal.

[d] *C. curvus*, 2–5%; other *Campylobacter* strains, 0.

[e]18:1 C11/t9/t6 FAME and/or unknown peak at 17.834.

The mol% G + C of the DNA is: unknown.
Type strain: Strain WAL 9799, ATCC 51579.
Additional Remarks: The type strain was selected because it resided in the center of the *Sutterella* cluster in the cellular fatty acid analysis.

Genus IX. **Taylorella** *Sugimoto, Isayama, Sakazaki and Kuramochi 1984, 503^VP (Effective publication: Sugimoto, Isayama, Sakazaki and Kuramochi 1983, 155)*

NANCY M.C. BLEUMINK-PLUYM AND BERNARD A.M. VAN DER ZEIJST

Tay' lor.el.la. M.L. dim. ending *-ella* M.L. fem. n. *Taylorella* named after C.E.D. Taylor, who first studied the organism.

Generic definition: **Short rods**, 0.7 × 0.7–1.8 μm. **Gram negative**. Nonmotile. Requires an atmosphere enriched with **5–10% CO_2**. Growth on rich peptone based chocolate agar medium at 35–37°C. Colonies are circular, smooth, grayish-white and 0.5–3.0 mm in diameter after an incubation period of 3–6 d. **Oxidase positive.** Catalase, phosphatase, and phosphoamidase are produced. Acid is not produced from carbohydrates. The phylogenetic position based on 16S rDNA analysis is in the *Betaproteobacteria*. The 16S rRNA contains the signature sequences of the *Betaproteobacteria* in 63 of 66 positions.

The mol% G + C of the DNA is: 36.5.

Type species: **Taylorella equigenitalis** (Taylor, Rosenthal, Brown, Lapage, Hill and Legros 1978) Sugimoto, Isayama, Sakazaki and Kuramochi 1984, 503 (Effective publication: Sugimoto, Isayama, Sakazaki and Kuramochi 1983, 155) (*Haemophilus equigenitalis* Taylor, Rosenthal, Brown, Lapage, Hill and Legros 1978, 136.)

FURTHER DESCRIPTIVE INFORMATION

The initial name of this bacterium was *Haemophilus equigenitalis* (Taylor et al., 1978). It was classified based on its mol% G + C content in the family *Pasteurellaceae* as a *species incertae sedis* belonging to the genus *Haemophilus*. In 1983, based on DNA hybridization data, Sugimoto proposed the new genus *Taylorella* with *Taylorella equigenitalis* as the only species (Sugimoto et al., 1983). This was validated in the IJSB in 1984. The 16S rDNA sequence of *Taylorella equigenitalis* was determined in 1993 (Bleumink-Pluym et al., 1993) and a phylogenetic analysis of this sequence revealed a position in the *Betaproteobacteria* apart from the position of *Haemophilus influenzae*, which belongs to the *Gammaproteobacteria*.

Cells of *Taylorella equigenitalis* are short rods or usually coccobacilli. The outer membrane can be covered by a layer of capsular-like material (Hitchcock et al., 1985; Bleumink-Pluym, 1995). Fimbriae have only been demonstrated *in vivo* (Kanemaru et al., 1992). The most abundant outer membrane protein has a molecular mass of 39–41 kDa (Sugimoto et al., 1988). The N-terminus of this immunodominant OMP is similar to that of porins from *Bordetella pertussis*, *Neisseria gonorrhoeae*, and *Neisseria meningitidis* (Bleumink-Pluym, 1995).

T. equigenitalis grows well on agar medium containing a rich peptone base with 5% chocolated sheep blood. Horse blood is not recommended because of the possible presence of antibodies directed toward *T. equigenitalis*. The medium should be supplemented with sodium sulfite (200 mg/l) and L-cysteine hydrochloride (100 mg/l). The plates should be incubated in an atmosphere enriched with 5–10% CO_2. Growth is observed over a temperature range of 30–41°C; optimal temperature is 37°C. Visible colony formation requires at least 48 h. Colonies are circular, smooth, raised, and shiny. They vary in size from 0.5–3.0 mm, are grayish-white, and can subsequently turn yellowish-brown. Sometimes the colonies can be moved freely over the surface of the agar.

Acid is not produced from carbohydrates. Oxidase, catalase, phosphatase, and phosphoamidase are produced. Nitrates and nitrites are not reduced. Lysine and ornithine decarboxylase, arginine dihydrolase, gelatinase, lipase, urease, and deoxyribonuclease are not produced. Indole and H_2S not produced (Sugimoto et al., 1983).

The 16S rDNA sequence of *T. equigenitalis* was compared with entries present in the EMBL and GenBank database. Close relationships with 16S rDNA sequences of *Alcaligenes xylosoxidans* (94.2%) and *Bordetella bronchiseptica* (93.5%) were detected. Two variable regions that distinguish the three closest relatives most effectively are located at the 5′ end of the 16S rDNA at positions 65–97 and 412–478 (*E. coli* numbering).

Hybridizations between DNAs from two different *Taylorella* strains and DNAs from strains of *Bordetella*, *Moraxella*, *Kingella*, *Legionella*, *Haemophilus*, and *Brucella* species revealed no significant relatedness. Relatedness of DNAs from five *Taylorella* strains showed reassociation values of about 68% and a thermal stability difference of 2.5% (Sugimoto et al., 1983), essentially fulfilling the genetic definition of a species.

The genome size of *T. equigenitalis* is 1.5×10^6 bp. DNA of different isolates can be cleaved in a few large fragments by the restriction endonuclease *ApaI*, which recognizes the infrequently occurring GGGCCC sequence. Different genomic restriction patterns can be observed by using field inversion gel electrophoresis (FIGE) (Bleumink-Pluym et al., 1990; Engval et al., 1991; Matsuda et al., 1993). *T. equigenitalis* strains from different outbreaks generally have different genomic restriction patterns.

By immunoblotting, Sugimoto et al. demonstrated that mares experimentally infected with *T. equigenitalis* developed antibodies to a 41-kDa major outer membrane protein (Sugimoto et al., 1988). The N-terminus of this immunodominant OMP is similar to that of porins from *Bordetella pertussis*, *Neisseria gonorrhoeae*, and *Neisseria meningitidis* (Bleumink-Pluym, 1995).

T. equigenitalis is moderately resistant to clindamycin, lincomycin, trimethoprim, and sulfamethoxazole (MIC 32 μg/ml); sensitive to penicillin G, ampicillin, carbenicillin, cephaloridine, cephalotin, erythromycin, tetracycline, kanamycin, gentamicin, neomycin, chloramphenicol, and polymyxin B (Sugimoto et al., 1983). The majority of *T. equigenitalis* strains isolated internationally are resistant to streptomycin (MIC >512), but streptomycin-susceptible strains exist.

Clinical signs of *T. equigenitalis* infection in horses have been reported only in the mare and can be vaginal discharge, infertility, or early abortion. In the acute state of infection a widespread endometritis with local erosion of surface epithelium can be observed. The effect of the disease on fertility can be attributed to acute endometrial inflammation. The principal lesions are in the uterus and are characterized by destruction of endometrial epithelial cells and infiltration of neutrophils into the epithelium and lamina propria of the uterus. Histopathological studies have demonstrated that *T. equigenitalis* adheres to the cilia of the epithelial cells and proliferates on the endometrium (Wada et al., 1983). *In vitro*, *T. equigenitalis* adheres to and invades equine dermal cells. These abilities differ between strains and do not correlate with their genomic restriction patterns (Bleumink-Pluym et al., 1996).

The principal sites of colonization in mares are the urogenital membranes of the clitoral sinuses and fossa, urethra, and cervix. In stallions, the principal sites of colonization are the urogenital membranes of the urethra, urethral fossa, and penile sheath. *Taylorella* can be regarded as a commensal or opportunist as the bacterium is mostly isolated from asymptomatic carriers. Likewise, the prevalence of *Taylorella* in the horse population is high as demonstrated by PCR assay (Bleumink-Pluym et al., 1994).

Enrichment and Isolation Procedures

Taylorella requires rather specific growth conditions and is rapidly overgrown by other bacteria resident in the genital tract of horses. Genital swabs are inoculated on Colombia blood agar base (Oxoid Ltd)-chocolated agar supplemented with sodium sulfite (200 mg/l) and L-cysteine hydrochloride (100 mg/l) (Atherton, 1983) with and without the addition of 5 μg of clindamycin, 1 μg trimethoprim, and 5 μg of amphotericin-B per ml. Plates are incubated with 7% CO_2 in air at 37°C for 6 d. Colonies are circular, smooth, grayish-white, and vary in size from 0.5–3.0 mm. Colonies suspected of being *T. equigenitalis* are Gram stained and tested for oxidase. Slide agglutination, indirect immunofluorescence with hyperimmune serum, or PCR detection based on 16S rDNA sequences can be used for confirmation.

Maintenance Procedures

Plate cultures will survive for 3 weeks without subcultivation but should be kept in an atmosphere enriched with 5–10% CO_2. All strains can be maintained for up to 4 yr at −70°C in brain heart infusion broth containing 15% glycerol. Lyophilization, e.g., in skim milk, can also be used for conserving cultures.

Differentiation of the genus *Taylorella* from other genera

The differential characteristics of the genus *Taylorella* are listed in Table BXII.β.41.

Taxonomic Comments

The phylogenetic position of *Taylorella equigenitalis* in the *Betaproteobacteria* differs from that of *Haemophilus influenzae*, which belongs to the *Gammaproteobacteria*, and supports its exclusion from the family *Pasteurellaceae*. *Taylorella* does not seem to fit in one of the known bacterial families. Based on 16S rDNA analysis *Taylorella* is most closely related to *Bordetella* and *Alcaligenes*. Although these species share substantial 16S rDNA sequences (93.5% and 94.2%, respectively), it is not likely that they belong to the same family. No relatedness was detected in a DNA–DNA hybridization between *Taylorella* and *Bordetella*, which is in accord with the variation in the mol% G + C contents of their genomes. *Bordetella* and *Alcaligenes* have a mol% G + C content of ~69, while *Taylorella* has a mol% G + C content of 36.5. Members of the genera *Bordetella*, *Alcaligenes*, and *Taylorella* occur in different ecological niches. The principal habitat of *Taylorella* is the mucosal membrane surface of the genital tract of horses. Certain phenotypic characteristics are shared with other bacteria harboring mucous membranes of the genital tract, like *Neisseria gonorrhoeae*. Both species are transmitted sexually, cause similar clinical signs of infection (*Taylorella* in horses; *N. gonorrhoeae* in humans), have similar culture conditions, are oxidase positive, have variable colony morphology, and have a similarity in the N-terminal amino acid sequences of the 41-kDa and 17-kDa outer membrane protein.

List of species of the genus Taylorella

1. **Taylorella equigenitalis** (Taylor, Rosenthal, Brown, Lapage, Hill and Legros 1978) Sugimoto, Isayama, Sakazaki and Kuramochi 1984, 503[VP] (Effective publication: Sugimoto, Isayama, Sakazaki and Kuramochi 1983, 155) (*Haemophilus equigenitalis* Taylor, Rosenthal, Brown, Lapage, Hill and Legros 1978, 136.)
e.qui.ge.ni.ta′ lis. L. gen. n. *equi* of the horse; L. adj. *genitalis* genital; L. adj. *equigenitalis* genital of the horse.

All characteristics are as described for the genus *Taylorella*.

This strain was isolated in 1977 from a cervical swab of a thoroughbred mare with contagious metritis.

The mol% G + C of the DNA is: 36.5 (T_m).

Type strain: Strain 61717/77, CIP 7909, DSM 10668, NCTC 11184.

GenBank accession number (16S rRNA): X68645.

Family IV. **Comamonadaceae** Willems, De Ley, Gillis and Kersters 1991a, 447[VP]

ANNE WILLEMS AND MONIQUE GILLIS

Co.ma.mo.na.da' ce.ae. M.L. fem. n. *Comamonas* type genus of the family; suff. *-aceae* to denote a family; M.L. fem. pl. n. *Comamonadaceae* the *Comamonas* family.

Cells are **straight** or **slightly curved rods or spirilla**. Gram negative. Most genera are **motile by a single polar flagellum or by bipolar tufts of 1–5 flagella**; one genus (*Variovorax*) is motile by sparse peritrichous flagella, and another (*Brachymonas*) lacks flagella. No endospores are formed. Coccoid bodies are rarely formed, but do occur in some (*Aquaspirillum*) species. (The use of square brackets indicates these species are not true aquaspirilla, which are related to type species *Aquaspirillum serpens.*) **Chemoorganotrophic or facultatively chemolithotrophic with H_2 or CO oxidation.** Possess a strictly respiratory type of metabolism, with oxygen as the terminal electron acceptor. Some species can also use nitrates. **Oxidase positive**, except for the genus *Xylophilus.* **Optimal growth temperature ranges from 24 to 35°C**, except for *Polaromonas* and *[Aquaspirillum] psychrophilum*, which prefer 4 and 18°C, respectively. Yellow, insoluble pigments are produced by the genera *Hydrogenophaga*, *Variovorax*, and *Xylophilus.* Nitrogen fixation has been reported for some *Hydrogenophaga* species. A wide variety of organic acids, including amino acids, is used, but sugars are rarely attacked. **Major fatty acids are palmitoleic acid ($C_{16:1}$), palmitic acid ($C_{16:0}$) and *cis*-vaccenic acid ($C_{18:1\ \omega7c}$),** and the major quinone is **ubiquinone Q-8**.

Members of the *Comamonadaceae* have been **isolated from soil, mud, and water, in natural and industrial environments**. Strains from the genera *Comamonas* and *Acidovorax* have also been isolated from clinical samples, but are not regarded as pathogenic. The genus *Xylophilus* is pathogenic to grapevines and some members of the genus *Acidovorax* are pathogenic to grasses, orchids, and members of the cucumber family.

The *Comamonadaceae* belong to the *Betaproteobacteria.* At present the following genera belong to this family, on phylogenetic grounds: *Comamonas*, *Acidovorax*, *Alicycliphilus*, *Brachymonas*, *Caldimonas*, *Delftia*, *Diaphorobacter*, *Hydrogenophaga*, *Lampropedia*, *Macromonas*, *Polaromonas*, *Ramlibacter*, *Rhodoferax*, *Variovorax*, *Xenophilus*, and *Xylophilus.* In addition, a number of misnamed *Aquaspirillum* species belong to the *Comamonadaceae* on phylogenetic grounds. The genera *Aquabacterium*, *Ideonella*, *Leptothrix*, *Roseateles*, *Rubrivivax*, *Schlegelella*, *Sphaerotilus*, *Tepidimonas*, *Thiomonas*, and *Xylophilus* have been placed in the *Comamonadaceae* as *genera incertae sedis.* The genera *Alicycliphilus*, *Caldimonas*, *Diaphorobacter*, *Ramlibacter*, and *Schlegelella* were described after the cut-off date for inclusion in this volume. Differentiating features for a number of these taxa are presented in Table BXII.β.42.

The mol% G + C of the DNA is: 52–70.

Type genus: **Comamonas** De Vos, Kersters, Falsen, Pot, Gillis, Segers and De Ley 1985b, 450 emend. Tamaoka, Ha and Komagata 1987, 57; emend. Willems, Pot, Falsen, Vandamme, Gillis, Kersters and De Ley 1991c, 438.

TAXONOMIC COMMENTS

The family *Comamonadaceae* has been proposed as a formal taxon for the so-called acidovorans rRNA complex (Willems et al., 1991a). This was described as one of the rRNA groups within the large genus *Pseudomonas* in the previous edition of this *Manual* (Palleroni, 1984). Previously, it had been apparent from extensive phenotypic studies that this genus contained several species groups (Stanier et al., 1966). The genotypic basis for these groupings was revealed when the genus *Pseudomonas* was shown by DNA–rRNA hybridizations to consist of at least five main rRNA groups (Palleroni et al., 1973), and further DNA–rRNA hybridizations have shown these groups to be only remotely related to each other (De Vos and De Ley, 1983). The same groupings also have been supported by serological data (Baumann and Baumann, 1978), regulatory patterns in the biosynthesis of aromatic amino acids (Byng et al., 1983), coliphage QB host factor activity and antigenicity (Dubow and Ryan, 1977), fatty acid composition (Oyaizu and Komagata, 1983), and 16S rRNA oligonucleotide cataloging (Woese et al., 1984a).

In addition to at least 10 different *Pseudomonas* species, the *Pseudomonas acidovorans* rRNA group also contained *Comamonas terrigena*, *Xanthomonas ampelina*, *Alcaligenes paradoxus*, and several *Aquaspirillum* species (De Vos and De Ley, 1983; De Vos et al., 1985a, b; Willems et al., 1991a). It thus included common water and soil inhabitants, clinical isolates, plant pathogens, and hydrogen and CO oxidizers. Except for *Comamonas terrigena*, all of these species were phylogenetically unrelated to the type species of their respective genera, and in a series of polyphasic studies, they were therefore gradually transferred to other new or existing genera. An overview of these changes is presented in Table BXII.β.43. Since the original proposal of the family *Comamonadaceae*, four new genera (*Brachymonas*, *Delftia*, *Polaromonas*, and *Rhodoferax*) have been proposed within this group and these are listed in Table BXII.β.43. Not included is *Xenophilus*, which was described after the completion of this chapter (Blümel et al., 2001a).

This subdivision of the *Comamonadaceae* into different genera has relied heavily on DNA–rRNA hybridization data and has now been confirmed and extended by rRNA gene sequence analysis (Wen et al., 1999). Most members of the *Comamonadaceae* share at least 94–95% rDNA sequence similarity. A dendrogram showing the phylogenetic relationships of the *Comamonadaceae* and their nearest neighbors is shown in Fig. BXII.β.27. It was calculated using 16S rRNA gene sequences available from the EMBL database. From these data, it is clear that the genera *Acidovorax*, *Hydrogenophaga*, *Delftia*, *Polaromonas*, *Brachymonas*, and *Rhodoferax* and the species *[Aquaspirillum] gracile* and *[Aquaspirillum] sinuosum* are well separated. It is also apparent that the relationships between *Xylophilus* and *Variovorax*, and between *[Aquaspirillum] metamorphum* and *[Aquaspirillum] psychrophilum* need further study. The bootstrap value for the grouping of *Comamonas terrigena* and *Comamonas testosteroni* is relatively low (70; Fig. BXII.β.27), indicating that this is not a very robust grouping. It may be rearranged as more sequences are included.

It seems quite likely that additional genera will be included in this family, not only because of reclassification of some of the above listed species and genera, but also because of newly isolated groups. Many of the members of the *Comamonadaceae* are common inhabitants of water, soil, and polluted environments, and are regularly isolated in ecological studies. Some *Comamonadaceae*

[a]For symbols see standard definitions; nd, not determined.

[b]In this table the [*Aquaspirillum*] species are listed grouped in a single column, but they are likely to represent several additional genera (Wen et al., 1999).

[c] *[Aquaspirillum] delicatum* has 1 or 2 flagella at one pole (Krieg, 1984b).

[d]The optimal temperature for *[Aquaspirillum] psychrophilum* is 20°C (Krieg, 1984b).

[e]Only *A. konjaci* does not use glucose (Willems et al., 1992a).

[f]Glucose is used only by *[Aquaspirillum] gracile* (Krieg, 1984b).

[g]M, methionine; N, nictotinamide; aa, amino acids; B, biotin; T, thiamine; G, glutamic acid.

[h]Methionine and nicotinamide are required only by *C. terrigena* and the former *[Aquaspirillum] aquaticum* requires niacin (Pot et al., 1992b).

[i]Denitrification and anaerobic growth with nitrate is positive for *[Aquaspirillum] psychrophilum* (Krieg, 1984b).

[j]R, ubiquinone; RQ, rhodoquinone.

have the capacity to degrade complex organic compounds and are of potential use in degradation applications and bioremediation, topics which are the focus of intense research and which result in many new isolates. Some of these new strains may belong to new groups within the *Comamonadaceae*, as has occurred with *Rhodoferax* (Hiraishi, 1994), *Brachymonas* (Hiraishi et al., 1995b) and *Polaromonas* (Irgens et al., 1996).

As mentioned above, the family *Comamonadaceae* encompasses a remarkable diversity of phenotypic traits. In the past, different properties have often been studied in members of this family belonging to different phenotypic groups. This makes phenotypic comparison between members difficult and often incomplete. The accumulation of more 16S rDNA and other sequence data will become increasingly important for the classification within this group. As was shown previously (Amann et al., 1996), it may be possible to derive oligonucleotide probes for the identification of the various genera. The restriction analysis of amplified rRNA genes of a limited number of *Comamonadaceae* has

ANNE WILLEMS AND MONIQUE GILLIS

Co.ma.mo' nas. L. n. *coma* lock of hair; Gr. n. *monas* a unit, monad; M.L. fem. n. *Comamonas* cell with a polar tuft of flagella.

Straight or slightly curved rods or spirilla, 0.3–0.8 × 1.1–4.4 μm; occasionally longer (5–7 μm), irregularly curved cells or spirilla may occur. Cells occur separately or in pairs and **are motile by means of polar or bipolar tufts of 1–5 flagella** except for *C. koreensis*, which is nonmotile. **Gram negative.** No diffusible pigments are produced on nutrient agar. **Oxidase and catalase positive. Aerobic. Chemoorganotrophic**, oxidative carbohydrate metabolism with oxygen as the terminal electron acceptor. *C. nitrativorans* is also capable of denitrification. Good growth on media containing organic acids, amino acids, or peptone; few carbohydrates are used. Major fatty acids are hexadecanoic acid ($C_{16:0}$), hexadecenoic acid ($C_{16:1}$) and octadecenoic acid ($C_{18:1}$); 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$) is always present. **The major quinone is ubiquinone Q-8.**

The mol% G + C of the DNA is: 60–69.

Type species: **Comamonas terrigena** (ex Hugh 1962) De Vos, Kersters, Falsen, Pot, Gillis, Segers and De Ley 1985b, 450, emend. Willems, Pot, Falsen, Vandamme, Gillis, Kersters and De Ley 1991c, 439.

FURTHER DESCRIPTIVE INFORMATION

Cell morphology Cells are rods that are straight or slightly curved in one plane or spirilla. Polar pili have been reported in *Comamonas testosteroni* (Fuerst and Hayward, 1969b).

Cell wall composition Cell walls have a typical Gram-negative structure consisting of an outer membrane and a cytoplasmic membrane, separated by a dense peptidoglycan layer. Analysis of the lipid A component of the lipopolysaccharides in the outer membrane of *C. testosteroni* has revealed the lipid A backbone to consist of 6-*O*-(2-deoxy-2-amino-β-D-glucopyranosyl)-2-deoxy-2-amino-α-D-glucose, which is phosphorylated in positions 1 and 4′. The hydroxyl groups at positions 4 and 6′ are unsubstituted, and position 6′ of the non-reducing terminal residue is the attachment side for the polysaccharide component. The 2, 2′, 3, and 3′ positions of the sugar backbone are *N*-acylated or *O*-acylated by 3-hydroxydecanoic acid, and the hydroxyl groups of the amide-linked residues at positions 2 and 2′ of the backbone are *O*-acylated by tetradecanoic and dodecanoic acids, respectively (Iida et al., 1996).

Colonial characteristics On nutrient agar, colonies are round and convex with a smooth to wavy margin and a smooth to granular surface. Most strains are unpigmented, but some strains may produce a brown diffusible pigment on nutrient agar. Colony diameters can reach 0.4–3 mm after 3 d at 28°C. Occasionally, two colony types, one mucoid and the other non-mucoid, can be isolated from one strain. Comparison of such types by whole-cell protein electrophoresis shows identical protein profiles, and they are therefore considered morphological variants of the same strain (Willems et al., 1991c). For a *C. testosteroni* strain isolated from activated sludge on the basis of its ability to coaggregate with yeast cells, two colony types have been reported to occur together on solid agar media, resulting in composite colonies with sectors of different morphologies (Bossier and Verstraete, 1996). In liquid medium, in the absence of agitation, and in contact with glass, cultures shift towards and are dominated by mucoid-colony-forming cells. In such media, the addition of stress factors such as hydrogen peroxide, sodium dodecyl sulfate, or starvation results in the rapid formation of non-mucoid cells. Non-mucoid cell types rapidly coaggregate and settle in flocs with yeast cells, whereas mucoid cells do not coaggregate with yeast cells (Bossier and Verstraete, 1996).

Nutrition and growth conditions *Comamonas* strains grow well on most organic acids and amino acids but use very few sugars (De Vos et al., 1985b). They are capable of degrading a wide variety of complex aromatic compounds, steroids, and many man-made complex organic molecules. According to Tamaoka et al. (1987), *C. terrigena* requires methionine and nicotinamide as growth factors in a mineral medium with L-glutamate as the carbon source. Optimal growth temperature is 30°C.

Metabolism *Comamonas* strains have a respiratory metabolism using oxygen as the terminal electron acceptor. Although most *Comamonas* strains are capable of nitrate reduction, most cannot reduce nitrites. Only 3 of 42 *C. terrigena* strains have tested positive for nitrite reduction (Willems et al., 1991c). In a study of the denitrifying biofilms at a water treatment plant, *Comamonas* strains were identified, but they were thought to have washed in from previous stages and to not be true members of the denitrifying biofilms (Lemmer et al., 1997). An isolate named *Comamonas* strain SGLY2, capable of aerobic denitrification and nitrogen production without nitrite build-up, has been studied for application in mixed-culture aerated reactors (Patureau et al., 1997).

C. testosteroni strains capable of degrading polycyclic aromatic hydrocarbons, such as phenanthrene, naphthalene, and anthracene, have been described (Goyal and Zylstra, 1996). Their genes for naphthalene and phenanthrene degradation have been cloned and characterized and found to differ from the classical naphthalene degradation genes (*nah*) of *Pseudomonas putida*. Among different *C. testosteroni* strains, at least two different sets of genes for phenanthrene degradation may be present. In addition, in one of the strains, the arrangement of these genes differs from that in *Pseudomonas* species (Goyal and Zylstra, 1996).

The gene *phtD* for 4,5-dihydroxyphthalate decarboxylase, an enzyme involved in phthalate metabolism, has been identified and sequenced. The deduced amino acid sequence shows more than 77% similarity to the *pht5* gene from *Pseudomonas putida*. The sequence upstream of *phtD* and its deduced amino acid sequence show high similarity to *pht1* and its deduced amino acid sequence, which is thought to be the positive regulator for the other *pht* genes of *Pseudomonas putida*. These data suggest a common origin for the genes involved in phthalate metabolism (Lee et al., 1994c).

C. testosteroni uses the meta cleavage pathway for the degradation of 4-chlorophenol and related compounds, as has been demonstrated by the isolation and identification of several of the key enzymes and intermediary metabolites of this pathway (Hol-

lender et al., 1997). The *bphD* gene from strain B-356, encoding for 2-hydroxy-6-oxo(phenyl/chlorophenyl) hexa-2,4-dienoic acid hydrolase has been sequenced, and the gene product has a mechanism of action similar to that of classical lipases and serine hydrolases (Ahmad et al., 1995).

The first step in the degradation of biphenyl and chlorobiphenyl compounds by *C. testosteroni* is their conversion to 2,3-dihydro-2,3-dihydroxybiphenyl by biphenyl/chlorobiphenyl dioxygenase. This enzyme system consists of three components, the genes of which have been sequenced: a terminal oxygenase, which is an Fe–S protein consisting of 2 subunits (encoded by *bphA* and *bphE*); a ferredoxin, encoded by *bphF*; and a ferredoxin reductase encoded by the *bphG* gene, which is not located near the *bphAEF* genes in strain B-356 (Sylvestre et al., 1996b). Most of these enzymes or recombinant forms of them have been characterized in some detail (Hurtubise et al., 1995, 1996). Further degradation steps involve 2,3-dihydro-2,3-dihydroxybiphenyl dehydrogenase (*bphB*), a recombinant form of which has been characterized (Sylvestre et al., 1996a), and 2,3-dihydroxybiphenyl-1,2-dioxygenase (*bphC*), which catalyzes *meta*-1,2 fission of the aromatic ring (Bergeron et al., 1994).

In *Comamonas* sp. strain JS765, nitrobenzene is broken down by nitrobenzene 1,2-dioxygenase to nitrohydrodiol, which spontaneously decomposes into catechol and nitrite. Catechol is then broken down via the meta cleavage pathway. The catechol 2,3-dioxygenase gene *cdoE*, a ferredoxin gene *cdoT*, and a regulatory gene *cdoR* from strain JS765 have been sequenced and their amino acid sequences deduced (Parales et al., 1997).

Experimental evidence indicates that the mechanism of uptake of 4-toluene sulfonate by *C. testosteroni* strain T-2 involves an inducible secondary proton symport system (Locher et al., 1993). Strain T-2 degrades 4-toluene sulfonate and 4-toluene carboxylate by oxygenation of the side chains to 4-sulfobenzoate and terephthalate, respectively, before further oxidation to protocatechuate. The first three enzymes involved in this pathway are a 4-toluenesulfonate methyl-monooxygenase system, which consists of a reductase B and an oxygenase M (*tsaMB* genes), a 4-sulfobenzyl alcohol dehydrogenase (*tsaC*), and a 4-sulfobenzaldehyde (*tsaD*). Their genes are coexpressed under the regulation of *tsaR*. The components of this system have been purified and partially characterized. The *tsaMB* oxygenase system is a class IA mononuclear iron oxidase, with *tsaM* having a Rieske [2Fe–2S] center. *TsaC* is a short-chain zinc-dependent dehydrogenase (Junker et al., 1997). The conversion of 4-sulfobenzoate to protocatechuate requires a 4-sulfobenzoate-3,4-dioxygenase system encoded by the *psbAC* genes and consisting of a reductase C and an oxygenase A, which again contains a Rieske [2Fe–2S] center (Junker et al., 1996). Both sets of genes (*tsaMBCD*, *tsaR*, and *psbAC*) are located on conjugative plasmids in some *C. testosteroni* strains (Junker and Cook, 1997). The degradation of 4-toluene sulfonate by two different strains is comparable in liquid cultures but varies in biofilms (Khlebnikov et al., 1997). Terephthalate is broken down by a terephthalate dioxygenase system to (1*R*,2 *S*)-dihydroxy-3,5- cyclohexadiene-1,4-dicarboxylic acid, which is further degraded by (1*R*,2 *S*)-dihydroxy-1,4-dicarboxy-3,5-cyclohexadiene dehydrogenase to protocatechuate (Oppenberg et al., 1995). The dioxygenase system is a Rieske [2Fe–2S] protein consisting of two subunits, α and β, which are thought to form an $\alpha_2 \beta_2$ structure (Schläfli et al., 1994). Protocatechuate is further degraded via the meta cleavage pathway. Enzymes involved in these processes are thought to be located on the chromosome (Junker and Cook, 1997).

Metabolism of steroids Möebus et al. (1997) have observed that testosterone, used as a sole carbon source by *Comamonas testosteroni*, induces expression of steroid- and aromatic hydrocarbon-catabolizing enzymes and represses at least one amino acid degrading enzyme. It has been suggested that steroids may play a regulative role in catabolic enzyme synthesis in adaptive growth. Several enzymes involved in the steroid metabolism of *C. testosteroni* have been studied. A 3-α-hydroxysteroid dehydrogenase has been isolated and characterized (Oppermann and Maser, 1996), and its gene has been sequenced, cloned and expressed (Abalain et al., 1995). Similarity to ribosomal proteins L10 and L7/12 has led to the suggestion that this enzyme may be formed by fusion of two ribosomal proteins (Baker, 1996). The gene for 3-ketosteroid-δ^4-5-α-dehydrogenase has been sequenced and is located downstream of a gene for 3-ketosteroid-δ^1-dehydrogenase. The gene product is a flavoprotein. Although both of these dehydrogenases are functionally similar, their genes are probably not derived from a common ancestor (Florin et al., 1996). The 3β/17β hydroxysteroid dehydrogenase of *Comamonas testosteroni* has been studied by mutagenic replacement within the active site to identify important residues (Oppermann et al., 1997). The structure and function of δ^5-3-ketosteroid isomerase and 3-oxo-δ^5-steroid isomerase, which catalyze the conversion of δ^5- to δ^4-3-ketosteroids by an intramolecular proton transfer, have been studied extensively (Brothers et al., 1995; Zhao et al., 1996, 1997). A bile acid 3-α-sulfate sulfohydrolase from *Comamonas testosteroni* has been purified and characterized (Tazuke et al., 1994).

Metabolism of other organic compounds *Comamonas* strains capable of degrading terpenes, such as abietane and pimarane-type resin acids, have been isolated by enrichment from wastewater from an aerated stabilization basin of a bleached kraft pulp mill (Morgan and Wyndham, 1996).

Extracellular poly-β-hydroxybutyrate depolymerase has been purified from a *Comamonas* sp. strain. In addition to poly-β-hydroxybutyrate, it can also hydrolyze poly(β-hydroxybutyrate-co-β-hydroxyvalerate) and poly-β-hydroxyvalerate. It differs from other poly-β-hydroxybutyrate depolymerases in that it is insensitive to phenylmethylsulfonyl fluoride and that it hydrolyzes poly-β-hydroxybutyrate to β-hydroxybutyrate monomers (Jendrossek et al., 1993). Part of the encoding gene has been cloned and sequenced, and the deduced protein structure has been comparatively analyzed (Jendrossek et al., 1995). Shinomiya et al. (1997) have since cloned, sequenced, and analyzed a gene for the same enzyme from *C. testosteroni* YM1004 and obtained a very similar sequence.

An aliphatic nitrilase, active on adiponitrile and cyanovaleric acid, has been isolated and purified from *Comamonas testosteroni*, and its gene has been sequenced and overexpressed. The Cys163 residue is thought to play an essential role in the active site (Levy-Schil et al., 1995).

A quinohemoprotein ethanol dehydrogenase, which catalyzes the NAD-independent oxidation of a broad range of alcohols to the corresponding aldehydes and on to the carboxylic acids, has been isolated and purified from *Comamonas testosteroni* cells grown on ethanol. The active holoenzyme has been found to contain pyrroquinoline–quinone, calcium ions, and heme c (De Jong et al., 1995). The encoding gene (*qhedh*) has been cloned, sequenced, and expressed in *E. coli* (Stoorvogel et al., 1996). The enzyme has been investigated for use in the production of (*S*)-solketal (2,2-dimethyl-1,3-dioxolane-4-methanol) by enantio-

selective oxidation of racemic solketal (Geerlof et al., 1994a) and has been applied in electrodes through immobilization in a redox polymer network (Stigter et al., 1997). Quinoline 2-oxidoreductase and 2-oxo-1,2-dihydroquinoline 5,6-dioxygenase, the enzymes involved in the first two steps of the degradation of quinoline and 3-methyl quinoline, have been isolated from *Comamonas testosteroni* strain 63 and their structure and cofactors studied. Quinoline 2-oxidoreductase is a molybdo-iron/sulfur flavoprotein, and 2-oxo-1,2-dihydroquinoline 5,6-dioxygenase is a single component protein (Schach et al., 1995).

The iron-containing nitrile hydratase from *C. testosteroni* strain Nil, which catalyzes the hydration of 5-cyanovaleric acid to adipamic acid, is inactivated by stoichiometric amounts of NO, and is reactivated by photoirradiation. In these reactions, it is similar to a *Rhodococcus* R312 nitrile hydratase, which has a quite different amino acid sequence (Bonnet et al., 1997).

5-Aminolevulinic acid, a precursor to tetrapyrroles, is formed from aminoacylated tRNA–Glu in a two-step pathway by *C. testosteroni*. This pathway involves glutamyl–tRNA reductase, encoded by *hemA*, and glutamine-1-semialdehyde-2,1-aminomutase, encoded by *hemL* (Hungerer et al., 1995). In a study on the synthesis of new agricultural chemicals, *Comamonas testosteroni* strain CMI 2848 possessed the highest activity for hydroxylating 3-cyanopyridine to 3-cyano-6-hydroxypyridine among 4600 isolates screened (Yasuda et al., 1995).

C. testosteroni is capable of selectively degrading L-lysine from racemized lysine crystals, a characteristic which has been applied in the large-scale production of D-lysine (Takahashi et al., 1997).

The various pathways for the biosynthesis of aromatic amino acids and their regulation have been investigated extensively among pseudomonad bacteria. *C. testosteroni* possesses prephenate dehydrogenase and arogenate dehydrogenase reactive with either NAD or NADP. Arogenate dehydratase activity is absent; prephenate dehydratase is present, and its activity is increased 6–12-fold by L-tyrosine (Byng et al., 1983).

Chemotaxonomic data *Comamonas* strains contain ubiquinone Q-8 as the major quinone (>90%), with smaller amounts of Q-7 and Q-9 (Tamaoka et al., 1987). Major fatty acids (comprising 10–40% of the total amount) are palmitic acid ($C_{16:0}$), palmitoleic acid ($C_{16:1}$), and *cis*-vaccenic acid ($C_{18:1\ \omega7c}$). Small amounts (2–7%) of lauric acid ($C_{12:0}$) are present. Myristic acid ($C_{14:0}$) is present as 3–4% of the total in *C. terrigena* and less than 1% of the total in *C. testosteroni*. 2-Hydroxyhexadecanoic acid ($C_{16:0\ 2OH}$) is present as less then 1% of the total in *C. terrigena* and 2–7% in *C. testosteroni* (Tamaoka et al., 1987; Willems et al., 1989). For some fatty acids, the amounts reported by Tamaoka et al. (1987) and Willems et al. (1989) are quite different: 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$), 3–5% and 7–17%, respectively; *n*-heptadecanoic acid ($C_{17:0}$), <2% and traces to 7%; cyclopropane-substituted methylene-hexadecanoic fatty acid ($C_{17:0\ cyclo}$), <2% and 1–15%. The polyamine content of *C. testosteroni* strain DSM 1622 has been determined. The major polyamines (>50%) are 2-hydroxyputrescine and putrescine; spermidine, spermine, and 1,3-diaminopropane are present in much smaller quantities (<5%). Cadaverine has not been detected (Busse et al., 1992).

Plasmids Plasmids have been isolated from and successfully transferred to *Comamonas* strains and may contribute to the catabolic versatility and flexibility of these organisms. *C. testosteroni* strains T-2, PSB-4, and the type strain have been reported to contain two plasmids (pTSA and pT2T), one plasmid (pPSB), and no plasmids, respectively (Junker and Cook, 1997). Plasmid pTSA (85 kb) is a conjugative plasmid belonging to the IncP1 group. It carries the genes *tsaMBCD*, *tsaR*, and *psbAC*, involved in the degradation of 4-toluene sulfonate to protocatechuate, as well as two copies of insertion element IS 1071. Plasmid pPSB (85 kb) is also a conjugative plasmid and carries the *psbAC* genes, as well as two copies of IS 1071. Results of conjugation experiments with the type strain suggest that the *psb* genes are located in a composite transposon (Junker and Cook, 1997).

Comamonas strains have been used in various experiments as recipients of plasmids carrying catabolic genes. Plasmid RP4::Tn4371, carrying genes for biphenyl and 4-chlorobiphenyl degradation, has been transferred from *Enterobacter agglomerans* to indigenous soil bacteria, including *Comamonas* sp., where these catabolic genes are expressed (De Rore et al., 1994). Plasmid PR4::Mu3A, carrying chromosomal DNA fragments encoding the ability to use biphenyl as the sole carbon source, has been transferred to *C. testosteroni* and the catabolic genes effectively expressed (Springael et al., 1996). The plasmids pACK5 and pACT72, which each include a replicon of the cryptic plasmid pAC1 from *Acetobacter pasteurianus*, have been transferred to and successfully expressed in *Comamonas terrigena*, as well as in several other Gram-negative and Gram-positive taxa (Grones and Turna, 1995).

Antibiotic sensitivity *C. testosteroni* possesses steroid-inducible hydroxysteroid dehydrogenases/carbonyl reductases. This contributes to increased resistance of cells grown on a steroid substrate to the fungal steroid fusidic acid and to faster uptake and alternative metabolism of the anti-insect agent NKI 42255 (2-(1-imidazolyl)-1-(4-methoxyphenyl)-2-methyl-1-propane). These steroid-inducible pathways provide protection against natural and synthetic toxic compounds present in the soil and in the intestinal tracts of mammals (Oppermann et al., 1996).

Ecology *Comamonas* strains have been isolated from sites heavily contaminated with various complex organic compounds and heavy metals. Resistance of *Comamonas* strains to a number of heavy metals has been reported. A cadmium-resistant strain of *C. testosteroni* has been isolated from soil contaminated with heavy metals (Kanazawa and Mori, 1996), and nickel-resistant *Comamonas* strains have been isolated from naturally nickel-percolated soils from New Caledonia (Stoppel and Schlegel, 1995). Among other chromate-reducing bacteria isolated from the cooling water of an electricity generating plant, a strain tentatively identified as *Comamonas testosteroni* has been found to be one of the strongest chromate-reducers and has therefore been implicated in blockage of pipes due to precipitation of chromium (III) oxide (Cooke et al., 1995).

Because of their ability to degrade a wide variety of complex organic compounds, *Comamonas* strains are of potential interest in bioremediation. *C. testosteroni* has been used to degrade 4-toluenesulfonic acid in a continuously operated fixed-bed biofilm reactor (Khlebnikov and Peringer, 1996). *Comamonas* strains are among the rare isolates of the *Betaproteobacteria* that have been identified in activated sludge (Kämpfer et al., 1996). Cells of *C. terrigena* strain N3H are capable of degrading the anion active surfactant dihexyl-sulfosuccinate and have been applied for this purpose immobilized in alginate gel (Huska et al., 1996). Cells starved of a carbon source for 16 h have the highest biotransformation rate of dihexyl-sulfosuccinate (Toth et al., 1996).

Among isolates from a PCB-polluted site, *C. testosteroni* strains comprise the majority and are capable of degrading biphenyl and various polychlorinated biphenyls (Joshi and Walia, 1995).

Comamonas strains that degrade poly-β-hydroxybutyrate (PHB) have frequently been isolated from various environments (Mergaert and Swings, 1996), and the extracellular PHB depolymerase of one strain has been purified and characterized (Jendrossek et al., 1993).

Because of the broad substrate specificity of its 3-α-hydroxysteroid dehydrogenases of *C. testosteroni* and the occurrence of this and related bacterial species in the intestinal tract of vertebrates, it has been suggested that these enzymes may contribute to bioactivation or inactivation of hormones, bile acids, and xenobiotics (Oppermann and Maser, 1996).

Enrichment and Isolation Procedures

Comamonas strains are common inhabitants of soil, mud, and water, in both natural and polluted environments. They have also been isolated from various clinical samples, the hospital environment, and horse and rabbit blood (Willems et al., 1991c). *Comamonas* strains can generally be isolated from water by plating on nutrient agar, but specific selective isolation procedures yielding only *Comamonas* isolates have not been described. The original *C. terrigena* type strain was isolated on a medium of hay infusion filtrate (Mudd and Warren, 1923). Often, selective enrichment can be obtained by targeting the capacity of *Comamonas* strains to degrade particular aromatic compounds, hydrocarbons, and higher dicarboxylic acids by using these compounds as the sole carbon source in a mineral medium. Tamaoka et al. (1987) reported that *C. terrigena* requires methionine and nicotinamide as growth factors and, consequently, these should be added to isolation media.

The following compounds have been used to isolate or enrich for *Comamonas* strains: phenol and *m*-cresol (Gray and Thornton, 1928), abietic and dehydroabietic acid (Morgan and Wyndham, 1996), and poly-β-hydroxybutyrate (Jendrossek et al., 1993). The isolation of *C. testosteroni* strains has been reported with the following compounds: testosterone (Talalay et al., 1952), imidazolylpropionate and imidazolyl-lactate (Coote and Hassal, 1973), *p*-cresol (Dagley and Patel, 1957), fumarate, bromosuccinate, anthranilate, kynurenate, and poly-3-hydroxybutyrate (Stanier et al., 1966), naphthalene (García-Valdés et al., 1988), phenanthrene (Goyal and Zylstra, 1996), chlorophenol and methylphenol (Hollender et al., 1997), and polychlorinated biphenyls (Joshi and Walia, 1995). *C. testosteroni* strains have also been isolated by selecting for cadmium resistance (Kanazawa and Mori, 1996).

Comamonas strains have been isolated increasingly from the clinical environment (Gilardi, 1971, 1985; Ben-Tovim et al., 1974; De Vos et al., 1985b; Willems et al., 1991c) and are regarded as rare opportunistic pathogens (Gilardi, 1985). Sources include blood, pus, urine, pharyngeal mucosae, kidneys, feces, burst appendix, intravenous tubing, and urinary catheters. *Comamonas* strains are isolated from such samples using methods for the isolation of Gram-negative glucose-nonfermenters. This includes the use of a blood agar medium, such as tryptic soy agar plus defibrinated blood, and a selective enteric medium, such as MacConkey agar. The commonly used incubation regime for primary isolation media of 24 h at 35°C should be extended with 24 h at 30°C to permit growth of glucose-nonfermenters that grow slowly at 35°C and may be masked by other bacteria (Rubin et al., 1985).

Maintenance Procedures

Comamonas strains can be maintained on nutrient agar at 4°C for up to 2 months. For long-term preservation, strains can be lyophilized using standard procedures. This can be done routinely by freeze-drying the cells in horse serum (70%) supplemented with glucose (7%) and nutrient broth (0.6%).

Differentiation of the genus *Comamonas* from other genera

Table BXII.β.42 lists features differentiating the genus *Comamonas* from other genera in the family.

Restriction analysis of a 2.4 kb amplified ribosomal DNA fragment containing the 16S rRNA gene, the spacer region between 16S and 23S genes, and part of the 23S rRNA gene with the enzyme *Hin*f1 allows differentiation of *Comamonas* species from members of *Acidovorax*, *Delftia* (formerly *Comamonas acidovorans*), *Hydrogenophaga*, and *Variovorax* (Vaneechoutte et al., 1992).

An oligonucleotide probe targeting 16S rRNA has been used to identify members of the genus *Comamonas*, among other members of the *Comamonadaceae* (Amann et al., 1996). Its sequence is 5′-ACCTACTTCTGGCGAGA-3′, which is homologous to positions 1424–1440 on the rRNA.

Taxonomic Comments

The nomenclatural history of the genus *Comamonas* is complex and was initially quite obscure because of incomplete descriptions and lack of original cultures. *Comamonas* was therefore not included in the Approved Lists of Bacterial Names (Skerman et al., 1980), nor was it listed in the previous edition of this *Manual*, although in the 8th edition of *Bergey's Manual of Determinative Bacteriology*, *Comamonas terrigena*, *"Vibrio cyclosites"*, and "*Vibrio neocistes*" were included as *species incertae sedis* in addendum IV of the genus *Pseudomonas*. The genus became valid only in 1985, when the name was revived (De Vos et al., 1985b).

The name *Comamonas* was originally proposed by Davis and Park (1962) to replace the invalid name *Lophomonas*. This latter genus, with one species (*Lophomonas alcaligenes*), had been proposed for a group of Gram-negative rod-shaped bacteria attacking few carbohydrates and possessing 2–4 lophotrichous flagella (Galarneault and Leifson, 1956). *L. alcaligenes* was considered to be a subjective synonym of the peritrichously flagellated *Vibrio alcaligenes*, which had itself been created (Lehmann and Neumann, 1927) to replace *Bacillus faecalis alcaligenes*, a species which contained Gram-negative, rod-shaped, human fecal isolates that did not attack carbohydrates (Petruschky, 1896). When the genus *Comamonas* was created to replace *Lophomonas*, the former type species (*Lophomonas alcaligenes*) was not maintained because of differences between the original descriptions of *Vibrio alcaligenes* and the new genus *Comamonas*. Instead, *Comamonas percolans*, formerly *Vibrio percolans* (Mudd and Warren, 1923), was proposed as the type species. *Vibrio alcaligenes*, *Vibrio neocistes*, and *Vibrio cyclosites* were also assigned to the new genus *Comamonas*, but were not allocated to a particular species (Davis and Park, 1962). *Comamonas percolans* was eventually shown to be a later subjective synonym of *Vibrio terrigenus*, an organism isolated from soil and motile by means of bipolar tufts of flagella (Günther, 1894), and the organism was therefore renamed *Comamonas terrigena* (Hugh, 1962). Later still, Hugh (1965) reported that the type strains of *Comamonas terrigena* and *Pseudomonas testosteroni* were very similar and suggested both species be united.

The genus *Comamonas* was revived in 1985 (De Vos et al., 1985b) after a polyphasic study that included some of the old preserved isolates. Initially, only four strains, each motile by a polar tuft of flagella, were included in the revived species *Comamonas terrigena*: NCIB 8193^T (formerly *Vibrio percolans*), NCIB

2581 (formerly *Vibrio cyclosites*), NCIB 2582 (formerly *Vibrio neocistes*) and CCUG 12940. Later, *Pseudomonas acidovorans* and *Pseudomonas testosteroni* were transferred to an emended genus *Comamonas* as *Comamonas acidovorans* and *Comamonas testosteroni* (Tamaoka et al., 1987). A polyphasic study that included many unnamed clinical isolates, as well as strains representing related genera, resulted in the inclusion of many more strains in *C. terrigena* and the recognition of three subgroups in this species. These subgroups can be distinguished by DNA–rRNA and DNA–DNA hybridizations, whole cell protein electrophoresis, and immunotyping, but not by morphological, auxanographic, or biochemical characterization; consequently, they have been retained in a single species (Willems et al., 1991c). The first subgroup contains the four strains assigned to *C. terrigena* by De Vos et al. (1985b) and one additional clinical strain. The second subgroup comprises the type strain of *Aquaspirillum aquaticum* and 13 clinical isolates previously designated EF group 10. The third subgroup comprises 13 clinical strains of EF group 10 as well as three misnamed *Pseudomonas* strains from blood. Several new *Comamonas terrigena* strains cannot be assigned to any of the three groups, indicating that this species may contain even more diversity than was previously thought (Willems et al., 1991c). The name *Aquaspirillum aquaticum* was abandoned since it was a later synonym of *Comamonas terrigena*. Since this organism has bipolar tufts of flagella, its inclusion in *Comamonas* brought the genus description, at least for this aspect of morphology, back in line with the original description of *Vibrio terrigenus* (Günther, 1894).

From DNA–rRNA hybridizations it was apparent that the three *C. terrigena* subgroups and *C. testosteroni* were probably more closely related to each other than to *C. acidovorans* (Willems et al., 1991c). This has recently been confirmed by 16S rRNA gene sequence analysis and, consequently, it has been proposed that *C. acidovorans* be transferred to a new genus *Delftia* as *Delftia acidovorans* (Wen et al., 1999). By 16S rDNA analysis, *C. terrigena* and *C. testosteroni* cluster together, but their grouping is not supported by a high bootstrap value. This indicates that the grouping of these branches is not very stable, and their position in the dendrogram may change as sequence data for additional strains are included. It is therefore at present not clear whether both species form a phylogenetically coherent genus, comparable to, for example, *Hydrogenophaga* or *Acidovorax*.

Comamonas spp. are regularly reported in ecological or applied studies involving isolates from soil and water. Although some of these isolates may escape species identification because of inadequacy of the identification methods used, other isolates may represent additional species within the genus. Wen et al. (1999) have described a *Comamonas* strain with an taxonomic position that is intermediate between *C. terrigena* genomic subgroup 1 (*sensu* Willems et al., 1991c) and *C. testosteroni*, but no representatives of the other two genomic subgroups were included in their analysis. It is possible, therefore, that this strain may belong to one of these two *C. terrigena* genomic subgroups.

"Comamonas compransoris", which has been described as a facultatively lithotrophic carbon monoxide or hydrogen oxidizer (Nozhevnikova and Zavarzin, 1974), has been shown to belong to the *Alphaproteobacteria* and has been assigned to the new genus *Zavarzinia* as *Zavarzinia compransoris* (Meyer et al., 1993).

Anne Willems is indebted to the Fund for Scientific Research–Flanders for a position as a postdoctoral research fellow.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *COMAMONAS*

Table BXII.β.44 lists characteristics differentiating *Comamonas terrigena* from *Comamonas testosteroni*.

It is possible to distinguish the three *C. terrigena* groups, as well as *C. testosteroni*, by restriction analysis with the enzyme *Hin*f1 of a 2.4 kb amplified ribosomal DNA fragment containing the 16S rRNA gene, the spacer region between 16S and 23S genes, and part of the 23S rRNA gene (Vaneechoutte et al., 1992).

TABLE BXII.β.44. Characteristics differentiating *Comamonas* species[a,b]

Characteristic	*C. terrigena*	*C. testosteroni*
Occurrence of 2-hydroxy fatty acids	−	+
Growth on:		
L-Histidine	−	+
2-Aminobenzoate (anthranilate)	−	+
Citrate	−	+
Glycolate	−	+
Benzoate	−	+[c]
Testosterone	−	+

[b]Data taken from Palleroni (1984), De Vos et al. (1985b), Tamaoka et al. (1987), and Willems et al. (1991c).

[c]Negative according to Tamaoka et al. (1987); 11–89% of strains are positive (d score) according to Palleroni (1984).

List of species of the genus Comamonas

1. **Comamonas terrigena** (ex Hugh 1962) De Vos, Kersters, Falsen, Pot, Gillis, Segers and De Ley 1985b, 450[VP] emend. Willems, Pot, Falsen, Vandamme, Gillis, Kersters and De Ley 1991c, 439.
ter.ri.ge′na. L. n. *terra* soil; L. v. *gignere* to bear; L. n. *terrigena* borne by the earth (soil), child of the earth.

The characteristics are as described for the genus and as indicated in Tables BXII.β.44 and BXII.β.45.

The type strain was isolated from a hay infusion filtrate.

The mol% G + C of the DNA is: 59.7–63.3 (species); 64 (type strain) (T_m).

Type strain: ATCC 8461, IAM 12409, LMG 1253, NCIB 8193.

GenBank accession number (16S rRNA): AB021418.

2. **Comamonas denitrificans** Gumaelius, Magnusson, Petterson and Dalhammar 2001, 1005[VP]
de.ni.tri′fi.cans. L. prep. *de* away from; L. n. *nitrum* soda; N.L. n. *nitrum* nitrate; M.L. v. *denitrifico* to denitrify; N.L. part.adj. *denitrificans* denitrifying.

The characteristics are the same as those of the genus. This species is not included in Tables BXII.β.44 and BXII.β.45 because it was published after the completion of

[b]Data taken from Palleroni (1984), De Vos et al. (1985b), Tamaoka et al. (1987), and Willems et al. (1991c).

[c]The following characteristics are present in both species: growth at 30 and 37°C, growth on Drigalski-Conradi agar; growth in the presence of 0.5 or 1.5% NaCl; growth on L-proline, L-leucine, L-aspartate, L-glutamate, propionate, butyrate, *n*-valerate, levulinate, isovalerate, *n*-caproate, D-malate, fumarate, glutarate, adipate, pimelate, suberate, azelate, sebacate, DL-lactate, DL-β-hydroxybutyrate, and L-malate; and hydrolysis of 2-naphthylbutyrate, L-leucyl-2-naphthylamide. The following characteristics are absent in both species: growth in the presence of 6.5% NaCl; acid production in 10% lactose, in triple sugar iron medium, and in OF medium with D-glucose, D-fructose, D-xylose, maltose, or adonitol; α-hemolysis; hydrolysis of esculin, gelatin, starch, acetamide, and DNA; lysine and ornithine decarboxylase; arginine dihydrolase; indole production; nitrite reduction; and β-galactosidase. Both species fail to grow on D-arabinose, L-arabinose, D-lyxose, D-ribose, D-xylose, L-xylose, D-fructose, L-fucose, D-fucose, D-tagatose, adonitol, D-arabitol, L-arabitol, *m*-xylitol, *m*-erythritol, *m*-inositol, D-mannitol, D-galactose, D-glucose, D-mannose, L-rhamnose, L-sorbose, dulcitol, sorbitol, D-cellobiose, β-gentiobiose, lactose, maltose, D-melibiose, sucrose, trehalose, D-turanose, D-melezitose, D-raffinose, methyl-β-D-xyloside, methyl-α-D-glucoside, methyl-α-D-mannoside, 2-ketogluconate, 5-ketogluconate, *N*-acetylglucosamine, amygdalin, arbutin, salicin, esculin, glycogen, inulin, starch, L-cysteine, L-ornithine, L-lysine, L-citrulline, β-alanine, L-serine, L-methionine, D-tryptophan, L-arginine, DL-2-aminobutyrate, DL-3-aminobutyrate, DL-5-aminovalerate, 3-aminobenzoate, 4-aminobenzoate, ethanolamine, ethylamine, butylamine, amylamine, benzylamine, acetamide, diaminobutane, urea, betaine, creatine, spermine, sarcosine, histamine, tryptamine, glucosamine, oxalate, maleate, malonate, phenylacetate, *o*-hydroxybenzoate, or D-mandelate. Neither species hydrolyzes 2-naphthylmyristate, 2-naphthylphosphate (pH 8.5), L-cystyl-2-naphthylamide, L-valyl-2-naphthylamide, *N*-benzoyl-DL-arginine-2-naphthylamide, *N*-glutaryl-phenylalanine-2-naphthylamide, 6-bromo-2-naphthyl-α-D-galactopyranoside, 2-naphthyl-β-D-galactopyranoside, naphthol-AS-BI-β-D-glucuronate, 2-naphthyl-α-D-glucopyranoside, 6-bromo-2-naphthyl-β-D-glucopyranoside, 1-naphthyl-*N*-acetyl-β-D-glucosaminide, 6-bromo-2-naphthyl-α-D-mannopyranoside, and 2-naphthyl-α-L-fucopyranoside.

[d]Positive according to Palleroni (1984).

the chapter. The description below is taken from the original description (Gumaelius et al., 2001).

Cells are straight to slightly curved rods, 1–2 × 2–6 μm. On nutrient agar plates, yellow-white colonies are formed, and strain P17 produces a brownish pigment. On this medium cells occur singly or as filaments, motile by means of polar flagella. Growth at 20, 30, and 37°C, but not at 4°C. Reduces nitrate to nitrogen gas and is the only *Comamonas* species to do so. Contains cd_1-type nitrate reductase. All strains utilize fumarate, L-malonate, pyruvate, glycolate, D-β-hydroxybutyrate, α-ketovalerate, L-lactate, L-glutamate, L-lysine, D-saccharate, salicin, L-tartrate, D-glucuronate, succinate, L-alanine, and L-arginine. The following substrates are used by some of the four strains only: citrate, urea, *m*-hydroxybenzoate, *trans*-aconitate, maleinate, D-tartrate, gentisate, *p*-coumarate, hippurate, DL-2-γ-aminobutyrate, L-serine, and esculin. None of the strains use mannoic acid γ-lactone, L-arabinose, D-xylose, D-galactose, maltose, D-cellobiose, D-trehalose, palatinose, sucrose, D-lactose, melibiose, lactulose, β-gentiobiose, D-melezitose, L-raffinose, inosine, adonitol, *meso*-inositol, D-arabitol, glycerol, maltitol, D-sorbitol, dulcitol, L-sorbose, 2-deoxy-D-ribose, L-rhamnose, D-fucose, L-fucose, D-tagatose, D-amygdalin, arbutin, methyl-β-D-galactopyranoside, 5-keto-D-gluconate, D-gluconate, 6-*O*-α-D-galactopyranosyl-D-gluconic acid, D-galactonic acid γ-lactone, D-ribose, L-xylose, D-glucose, D-mannose, L-arabitol, *meso*-erythritol, D-mannitol, xylitol, D-fructose, 6-deoxy-D-galactose, 2′-deoxyinosine, inulin, methyl-α-D-mannopyranoside, methyl-α-D-xylopyranoside, methyl-α-D-galactopyranoside, starch, D-galacturonate, D-arabinose, D-turanose, D-glucuronolactone, glycogen, D-lyxose, *N*-acetyl-D-glucosamine, maltose, D-gluconate, caprate, adipate, maleate, phenylacetate, gelatin, p-nitrophenyl-β-D-galactopyranoside, L-tryptophan, L-histidine, L-ornithine, and arabic acid. Able to grow in 2% saline solution and to survive in 5% NaCl, but not in 9% NaCl. All strains are sensitive to chloramphenicol (30 μg), erythromycin (15 μg), streptomycin (30 μg), tetracycline (30 μg), and ampicillin (10 μg). Sensitivity to rifampicin (5 μg), sulfisoxazole (250 μg), and penicillin G (10 μg) varies among strains.

Isolated from activated sludge with biological nitrogen removal properties.

The mol% G + C of the DNA is: 60.4–60.8 (HPLC).

Type strain: 123, ATCC 700936, CCUG 44425.

GenBank accession number (16S rRNA): AF233877.

3. **Comamonas koreensis** Chang, Han, Chun, Lee, Rhee, Kim and Bae 2002, 380[VP]

ko.re.en′sis. N.L. fem. adj. *koreensis* of Korea, the geographical origin of isolation.

The characteristics are the same as those of the genus. The species is not included in Tables BXII.β.44 and BXII.β.45 because it was published after the completion of the chapter. The description below is taken from the original description (Chang et al., 2002).

Grows at 10, 25, and 37°C, but not at 5 or 42°C. Best growth at pH 7 and 30°C. Grows on nutrient agar with 3% (w/v) NaCl, but not 4.5 or 6.5% NaCl. Aerobic, but also able to grow anaerobically in an atmosphere of $H_2/CO_2/N_2$ (7:5:88) on nutrient agar. Nonmotile, and no flagella are produced. Nitrate is reduced to nitrite; no denitrification. Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and urease are not produced. The following substrates are utilized: cellobiose, malate, maltose, D-psicose, D-raffinose, L-rhamnose, D-glucose, aconitate, D-tagatose, *m*-inositol, and D-mannitol. The following substrates are not used: citrate, caprate, *N*-acetyl-D-galactosamine, *N*-acetylglucosamine, adonitol, esculin, amygdalin, DL-arabinose, DL-arabitol, arbutin, dulcitol, erythritol, DL-fucose, galactose, α-gentiobiose, glycogen, inulin, 2-ketogluconate, 5-ketogluconate, lactose, lactulose, D-lyxose, D-mannose, melibiose, melezitose, methyl-β-D-glucoside, methyl-α-D-glucoside, methyl-α-D-mannoside, methyl-β-D-xyloside, ribose, salicin, sorbitol, sorbose, sucrose, trehalose, D-turanose, DL-xylose, xylitol, adipate, D-gluconate, glycerol, propionate, sebacate, L-threonine, D-alanine, L-alanine, L-aspartate, L-leucine, L-histidine, L-phenylalanine, phenylacetate, D-fructose or starch. Hydrolyzes Tween 80, acetic acid, D-galactonic acid lactone, D-gluconic acid, itaconic acid, methyl pyruvate, monomethyl succinate, quinic acid, D-saccharic acid, succinamic acid, succinic acid, bromosuccinic acid, L-leucyl-2-naphthylamide, 2-naphthylcaprylate, 2-naphthyl phosphate (pH 5.4 and 8.5), and napthol-AS-BI phosphate. Does not hydrolyze gelatin, 2-naphthylbutyrate, 2-naphthyl phosphate (pH 8.5), alaninamide, L-alanylglycine, γ-aminobutyric acid, 2-aminoethanol, arginine, L-asparagine, DL-carnitine, glucuronamide, L-glutamic acid, glycyl-L-aspartic acid, glycyl-L-glutamic acid, hydroxy-L-proline, phenylethylamine, L-proline, putrescine, L-pyroglutamic acid, DL-serine, citric acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, formic acid, D-galacturonic acid, D-glucosaminic acid, D-glucuronic acid, inosine, α-ketobutyric acid, α-ketoglutaric acid, α-ketovaleric acid, DL-lactic acid, malonic acid, thymidine, Tween 40, urocanic acid, uridine, 2,3-butanediol, α-cyclodextrin, dextrin, gelatin, DL-α-glycerol phosphate, glucose-1-phosphate, glucose-6-phosphate, *N*-benzoyl-DL-arginine-2-naphthylamide, 6-bromo-2-naphthyl-α-D-galactopyranoside, 6-bromo-2-naphthyl-β-D-glucopyranoside, 6-bromo-2-naphthyl-α-D-mannospyranoside, L-cystyl-2-naphthylamide, *N*-glutaryl-phenylalanine-2-naphthylamide, 2-naphthylmyristate, 2-naphthyl-β-D-galactopyranoside, naphthol-AS-BI β-D-glucuronate, 2-naphthyl-α-D-glucopyranoside, 1-napthyl-*N*-acetyl β-D-glucosaminide, 2-naphthyl α-L-fucopyranoside, and L-valyl-2-naphthylamide. Acetoin, H_2S, and indole are not produced. No β-galactosidase and tryptophan deaminase.

Major fatty acids are hexadecanoic acid ($C_{16:0}$), *cis*-9-hexadecanoic acid ($C_{16:1\ \omega7c}$), methylene-hexadecanoic acid ($C_{17:0\ cyclo}$), and octadecanoic acid ($C_{18:1}$); 2-hydroxy fatty acids ($C_{15:0\ 2OH}$ and $C_{16:0\ 20H}$) and 3-hydroxy fatty acids ($C_{10:0\ 3OH}$) are present in smaller amounts (<4 %).

Isolated from a wetland sample in Woopo, Republic of Korea.

The mol% G + C of the DNA is: 66 (T_m).

Type strain: YH12, KCTC 12005, IMSNU 11158.

GenBank accession number (16S rRNA): AF275377.

4. **Comamonas nitrativorans** Etchebehere, Errazquin, Dabert, Moletta and Muxí 2001b, 982[VP]

ni.tra.ti.vo′rans. N.L. n. *nitras* nitrate; L. adj. part. *vorans* devouring, digesting; N.L. adj. *nitrativorans* nitrate-consuming.

The characteristics are the same as those of the genus. The species is not included in Tables BXII.β.44 and

BXII.β.45 because it was published after the completion of the chapter. The description below is taken from the original description (Etchebehere et al., 2001b).

Cells are motile with two tufts of polar flagella. On TSA colonies are cream-colored, circular, and 1–2 mm in diameter after 24 h. Growth on acetate, butyrate, *n*-caproate, *i*-butyrate, *i*-valerate, propionate, *n*-valerate, lactate, alanine, benzoate, L-phenylalanine, and ethanol. Weak growth on maleate. No growth on glucose, arabinose, fructose, galactose, xylose, mannitol, malonate, tartrate, *p*-aminobenzoate, gluconate, pyruvate or citrate. Anoxic reduction of nitrate, nitrite, and nitrous oxide to nitrogen. Under anaerobic conditions, the same substrates (except benzoate and phenylalanine) can be used as under aerobic conditions. Optimal pH is 7, and optimal temperature for growth is 30°C.

Isolated from a denitrifying reactor from a landfill leachate treatment system in Montevideo, Uruguay.

The mol% G + C of the DNA is: unknown.

Type strain: 23310, CIP 107121, DSM 13191, NCCB 100007, CCT 7062.

GenBank accession number (16S rRNA): AJ251577.

5. **Comamonas testosteroni** (Marcus and Talalay 1956) Tamaoka, Ha, and Komagata 1987, 58[VP] emend. Willems, Pot, Falsen, Vandamme, Gillis, Kersters and De Ley 1991c, 440 (*Pseudomonas testosteroni* Marcus and Talalay 1956, 661.) *tes.tos.te.ro' ni.* M.L. gen. n. *testosteroni* of testosterone, a chemical compound.

The characteristics are as described for the genus and as indicated in Tables BXII.β.44 and BXII.β.45.

Isolated from soil.

The mol% G + C of the DNA is: 62.5–64.5 (species); 62.5 (type strain) (T_m).

Type strain: ATCC 11996, LMG 1786, NCTC 10698.

GenBank accession number (16S rRNA): M11224.

Genus II. **Acidovorax** *Willems, Falsen, Pot, Jantzen, Hoste, Vandamme, Gillis, Kersters and De Ley 1990, 394[VP] emend. Willems, Goor, Thielemans, Gillis, Kersters and De Ley 1992a, 115*

ANNE WILLEMS AND MONIQUE GILLIS

A.ci.do.vo' rax. L. neut. n. *acidum* acid; L. adj. *vorax* voracious; M.L. masc. n. *Acidovorax* acid-devouring (bacteria).

Straight to slightly curved rods, 0.2–1.2 × 0.8–5.0 μm, occurring singly, in pairs, or in short chains. **Gram negative. Motile by means of one or rarely two or three polar flagella. Aerobic, having a strictly oxidative type of metabolism with O_2 as the terminal electron acceptor**; some strains of two species (*Acidovorax delafieldii* and *Acidovorax temperans*) are capable of **heterotrophic denitrification** of nitrate. Most strains do not produce pigments on nutrient agar, but some phytopathogenic strains may produce a yellow to slightly brown diffusible pigment. **Oxidase positive; urease activity varies among strains. Chemoorganotrophic**, although strains of two species (*A. facilis* and *A. delafieldii*) can grow **lithoautotrophically**, using the oxidation of H_2 as an energy source. Good growth occurs on organic acids, amino acids, and peptone, but organisms show less versatile growth on carbohydrates. Fatty acids present always include 3-hydroxyoctanoic acid ($C_{8:0\ 3OH}$) and 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$); 2-hydroxy-substituted fatty acids are absent. *Acidovorax* strains can be isolated from soil, water, clinical samples, activated sludge, and infected plants.

The mol% G + C of the DNA is: 62–70.

Type species: **Acidovorax facilis** (Schatz and Bovell 1952) Willems, Falsen, Pot, Jantzen, Hoste, Vandamme, Gillis, Kersters and De Ley 1990, 394 (*Pseudomonas facilis* (Schatz and Bovell 1952) Davis, Doudoroff, Stanier and Mandel 1969, 385; *"Hydrogenomonas facilis"* Schatz and Bovell 1952, 88.)

FURTHER DESCRIPTIVE INFORMATION

Flagellation and pili *Acidovorax* cells have one or, rarely, two to three polar flagella (Willems et al., 1992a). In a study of the cell morphology and flagellation of Gram-negative hydrogen bacteria, Aragno et al. (1977) defined three types of flagella on the basis of fine structural details as revealed by electron microscopy. They have reported *A. facilis* to possess a polar monotrichous flagellation, with flagella of 19–20 nm in diameter, a wavelength of 1.4–1.7 mm, and a fine structure of type I. In *A. facilis*, pili may be spread over the total cell surface, but they are observed only rarely (Aragno et al., 1977).

Cell wall composition In a study of the cell envelope of Gram-negative hydrogen bacteria, Walther-Mauruschat et al. (1977) distinguished three types of cell walls, differing mainly in the visibility and location of the peptidoglycan layer. *Acidovorax* possesses type I cell walls, typical of most Gram-negative bacteria and characterized by a multilayered structure, consisting of an outer membrane and a cytoplasmic membrane of similar dimensions and appearance separated by a dense layer of peptidoglycan (Walther-Mauruschat et al., 1977). *A. delafieldii* exhibits a crystalline S layer in close contact with the outer membrane and covering the whole cell surface (Lapchine, 1979; Chalcroft et al., 1986). A second major type of outer membrane protein, Omp34, has been purified and characterized as a typical porin, forming anion-selective channels. The channel conductance depends on ion concentration (Brunen et al., 1991). Functional properties of Omp34 have been studied and are largely determined by positively charged amino acid residues (Brunen and Engelhardt, 1995). The finding of anion-selective porins is compatible with the preference of *Acidovorax* strains for acidic substrates.

Fine structure Intracellular mesosome-like membrane systems with a spiral appearance, often located in the area of cell division or at the cell poles, have been reported in *A. facilis* (Walther-Mauruschat et al., 1977). However, there is a growing consensus that such structures are mostly artifacts resulting from the preparation of cells for electron microscopy. Intracellular inclusions of poly-β-hydroxybutyrate and polyphosphate and translucent glycogen-like inclusions have been detected in *A. facilis* (Walther-Mauruschat et al., 1977). *A. avenae* has been re-

ported to contain inclusion bodies consisting of a proteinaceous ribbon, which is rolled up to form a hollow cylinder (Wells and Horne, 1983). The function of these so-called R-bodies remains uncertain. Similar structures have been described in some kappa-particles, the endosymbionts in killer paramecia, where they are thought to be involved in toxin release (Lalucat et al., 1982).

Colony morphology On nutrient agar, colonies are round with smooth to slightly scalloped or spreading margins. Occasionally, two different but unstable colony margin types may be observed in a culture. A translucent marginal zone may be present. Colonies are convex, smooth to slightly granular, and beige to faintly yellow. At 30°C, colonies can attain diameters of 0.5–3 mm in 3 d and 4 mm in 7 d. Most species do not produce pigments on nutrient agar, but some phytopathogenic strains may produce a yellow to slightly brown diffusible pigment (Willems et al., 1992a; Gardan et al., 2000). Optimal growth temperature is 30–35°C.

Nutrition and metabolism A variety of organic compounds can be used as sole carbon sources (Tables BXII.β.46 and BXII.β.47). *A. facilis* and some strains of *A. delafieldii* are able to grow lithoautotrophically, using the oxidation of hydrogen as an energy source. The hydrogenase is membrane-bound and does not reduce NAD (Schneider and Schlegel, 1977).

Chemotaxonomic characteristics *A. facilis*, *A. delafieldii*, and *A. avenae* have been reported to contain putrescine and 2-hydroxyputrescine as major polyamines and spermidine and spermine in smaller quantities. Some strains contain traces to small amounts of cadaverine and 1,3-diaminopropane (Busse and Auling, 1988; Auling et al., 1991). The fatty acid contents of the four nonphytopathogenic species *A. delafieldii*, *A. facilis*, *A. defluvii* and *A. temperans* have been determined (Willems et al., 1992a; Schulze et al., 1999a). For the phytopathogenic species *A. avenae* and *A. konjaci*, data are limited to five strains of *A. avenae* (Willems et al., 1990) and two strains of *A. anthurii* (Gardan et al., 2000). For all these species major fatty acids (representing at least 11% of total fatty acids) are palmitic acid ($C_{16:0}$), palmitoleic acid ($C_{16:1}$), and *cis*-vaccenic acid ($C_{18:1\ \omega7c}$); small amounts (less than 6%) of lauric acid ($C_{12:0}$), myristic acid ($C_{14:0}$), and 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$), and smaller amounts still (less than 1%) of *n*-pentadecanoic acid ($C_{15:0}$), *n*-heptadecanoic acid ($C_{17:0}$), oleic acid ($C_{18:1\ \omega7c}$), stearic acid ($C_{18:0}$), and cyclopropane-substituted methylene-hexadecanoic acid ($C_{17:0\ cyclo}$) are present. In addition, the nonphytopathogenic species contain 1–2.5% 3-hydroxyoctanoic acid ($C_{8:0\ 3OH}$). No 2-hydroxy substituted fatty acids are present (Willems et al., 1990).

Plasmids Mitomycin treatment of *A. delafieldii* cells results in high numbers of mutants unable to oxidize hydrogen, suggesting that in this species, hydrogenase may be plasmid encoded (Pootjes, 1977); the species has been reported to contain a plasmid (Gerstenberg et al., 1982). However, mutants of *A. facilis* defective in lithoautotrophy, obtained by Tn5 mutagenesis, mitomycin C treatment, and incubation at sublethal temperature, all show wild-type plasmid patterns with the same restriction map. Preliminary hybridization experiments have revealed a transposon location in the chromosomal DNA and not in the plasmid (Warrelmann and Friedrich, 1986).

In a study of the influence of earthworm activity on the transfer of plasmid pJP4 from an inoculated *Pseudomonas fluorescens* strain to indigenous soil bacteria, *Acidovorax* species have been identified among transconjugants (Daane et al., 1996).

A highly efficient transformation system using pBR322-derived plasmid vectors with *A. avenae* as a host bacterium has been developed, following observations of efficient transformation of plasmid pBR322 and derived plasmids in *A. avenae* strain K1 and its proline-auxotrophic mutant Pr47 (Fukumoto et al., 1997).

Phages Phages have been reported in *Acidovorax* only in the original description of *"Hydrogenomonas facilis"*, where the occurrence of plaques in autotrophic cultures was observed approximately two months after isolation (Schatz and Bovell, 1952). Repeated streaking on mineral agar eliminated the plaques, but they reappeared six months later and again a year after purification. Plaques were 3–4 mm in diameter and contained numerous small resistant colonies. It was suggested that the abundance and rapid growth of these resistant strains explained why liquid cultures never cleared. Phages were never observed in heterotrophic cultures (Schatz and Bovell, 1952).

Ecology *A. delafieldii* and *A. facilis* constitute the dominant microorganisms from soils, sludge, old compost, and freshwater sources that are able to degrade poly-3-hydroxybutyrate (PHB) and poly-3-hydroxybutyrate-co-3-hydroxyvalerate (PHBV) *in vitro* (Mergaert and Swings, 1996). *A. avenae* subsp. *avenae* is able to depolymerize synthetic thermoplastic polymers, such as poly-butylene succinate-co-butylene adipate and poly-caprolactone and poly-caprolactone-starch composites, and has been successfully applied in an *in vitro* biodegradation test system (Scandola et al., 1998). Elevated copper concentrations inhibit the degradation of powdered PHB by *A. delafieldii*, as demonstrated using an overlay agar technique (Birch and Brandl, 1996). *A. delafieldii* biofilms have been shown to contribute to copper solvency in laboratory reactors, suggesting that they may contribute to copper dissolution and increased bulk phase copper levels in domestic water systems (Davidson et al., 1996).

Antibacterial and antifungal activities may give pathogenic bacteria an advantage over competitors and, therefore, such activities of phytopathogenic *Acidovorax* species have been investigated. Effects against various Gram-negative and Gram-positive bacteria have been tested, but only *A. avenae* subsp. *cattleyae* shows antibacterial activity, and this is limited to just one of the bacteria tested, *Listeria innocua*. When antifungal activity was tested against *Rhodotorula mucilaginosa*, most strains of *A. avenae* subsp. *avenae* and *A. avenae* subsp. *cattleyae* showed clear antifungal activity, *A. avenae* subsp. *citrulli* strains showed weak or variable antifungal activity, and *A. konjaci* showed no antifungal activity (Hu and Young, 1998).

Pathogenicity Three *Acidovorax* species are the causal agents of diseases on various plants. *A. avenae* subsp. *avenae* causes symptoms of leaf blight in many members of the Poaceae family, including corn (*Zea mays*), sugar cane (*Saccharum officinarum*), and rice (*Oryza sativa*) (Claflin et al., 1989). Small round to oval-shaped, grayish white spots, with a red margin occur and may merge to form red longitudinal stripes. Sometimes, water-soaked lesions occur, which may develop into large necrotic zones. Stalk rot and bud rot have also been reported (Manns, 1909; Rosen, 1922; Lee et al., 1925; Okabe, 1934; Hayward, 1962; Baraoidan, 1981). *A. avenae* subsp. *cattleyae* causes brown spot disease on *Cattleya* and *Phalaenopsis* orchids. Large water-soaked lesions occur on leaves and quickly turn brown, with the surrounding tissue showing yellow-green halos. Large necrotic spots result, and the plant may die if the growth tip is affected (Ark and Thomas, 1946). *A. avenae* subsp. *citrulli* is pathogenic for watermelon (*Ci-*

trullus lanatus) and other members of the family Cucurbitaceae, in which it causes bacterial fruit blotch. The disease appears first on the upper side of the fruit, where dark olive green stains rapidly increase in size. The rind ruptures, allowing access to organisms causing secondary rotting and ultimately leading to the collapse of the fruit. Leaf lesions are inconspicuous, small, dark brown spots with margins that, when viewed from the bottom of the leaf, appear water-soaked (Latin and Hopkins, 1995).

A. konjaci causes leaf blight on *Amorphophallus rivieri* cv. Konjac, a food crop in Japan. It is characterized by small water-soaked spots, which soon extend to become larger lesions with yellowish halos. The whole leaf may ultimately rot away and drop, leaving just bare stalks (Goto, 1983). *A. anthurii* causes leaf spot on *Anthurium*; first symptoms consist of necrotic lesions close to veins and leaf margins, which blacken and turn gray (Gardan et al., 2000). From these lesions the bacteria enter the leaf and spathe

[a]For symbols see standard definitions. Data taken from Haynes and Burkholder (1957) (for *A. avenae* subsp. *cattleyae*), Schaad et al. (1978), Goto (1983), Ramundo and Claflin (1990), Willems et al. (1990, 1992a), and Hu et al. (1991).

[b]Positive according to Schaad et al. (1978).

[c]Positive according to Goto (1983).

[d]Negative according to Goto (1983).

[e]Negative according to Schaad et al. (1978).

[f]Growth on the following substrates was positive for all *Acidovorax* species: D-fructose, glycerol, D-malate, L-malate, fumarate, suberate, azelate, DL-lactate, DL-3-hydroxybutyrate, L-glutamate, and L-proline. Growth on the following substrates was negative for all *Acidovorax* species: D-arabinose, L-xylose, adonitol, D-lyxose, L-arabitol, methyl-xyloside, L-sorbose, D-tagatose, dulcitol, inositol, methyl-D-mannoside, methyl-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, salicin, β-gentiobiose, D-turanose, starch, glycogen, xylitol, 5-ketogluconate, L-mandelate, caprylate, pelargonate, glycolate, itaconate, phenylacetate, benzoate, *o*-hydroxybenzoate, D-mandelate, isophthalate, terephthalate, glycine, D-tryptophan, trigonelline, L-lysine, betaine, creatine, 3-aminobenzoate, 4-aminobenzoate, urea, sarcosine, ethylamine, butylamine, amylamine, benzylamine, diaminobutane, spermine, histamine, tryptamine, and glucosamine. In addition, *A. facilis*, *A. delafieldii*, and *A. temperans* do not hydrolyze the following substrates: L-valyl-2-naphthylamide, *N*-benzoyl-DL-arginine-2-naphthylamide, *N*-glutaryl-phenylalanine-2-naphthylamide, 6-bromo-2-phosphodiamide-3-naphthoic acid-2-methoxyanilide (= napthol-AS-BI-phosphodiamide), 6-bromo-2-naphthyl-α-D-galactopyranoside, 2-naphthyl-β-D-galactopyranoside, 6-bromo-2-hydroxy-3-naphthoic acid-2-methoxyanilide-β-D-glucuronate (=naphthol-AS-BI-β-D-glucuronate), 2-naphthyl-α-D-glucopyranoside, 6-bromo-2-naphthyl-β-D-glucopyranoside, 1-naphthyl-*N*-acetyl-β-d-glucosaminide, 6-bromo-2-naphthyl-α-D-mannopyranoside, and 2-naphthyl-α-L-fucopyranoside.

[g]11–89% of strains are positive (d score) according to Hu et al. (1991).

[h]Positive according to Hu et al. (1991).

[i]Late positive reaction (5 days).

[j]Negative according to Hu et al. (1991).

parenchymas and become systemic, resulting in tissue discoloration and plant death.

Pathogenicity tests with *A. avenae* subsp. *avenae* on watermelon, cantaloupe, squash, cucumber, tomato, and cowpea are negative (Schaad et al., 1978). Similar tests with *A. avenae* subsp. *citrulli* on tomato, cowpea, corn, and Konjac are also negative (Schaad et al., 1978; Goto, 1983). Tests with *A. konjaci* on cantaloupe, squash, and cucumber are negative and on watermelon results in a hypersensitive reaction (Goto, 1983). Phytopathogenicity of the other *Acidovorax* species has not been reported.

Enrichment and Isolation Procedures

For most *Acidovorax* species, no special isolation procedures have been described, and most strains have been isolated using standard techniques from soil, water, sludge, or infected plant material. These normally result in the isolation of strains of various taxa, except for phytopathogenic species, which are isolated from infected tissue that often contains only the causal bacterium. *A. facilis* was originally isolated from lawn soil in a mineral medium[1] supplemented with 0.05% $NaHCO_3$ and incubated at 25°C under an atmosphere of CO_2/air/H_2 (10:30:60) (Schatz and Bovell, 1952). *A. delafieldii* was originally isolated from soil, using poly-3-hydroxybutyrate as the sole carbon source in a mineral liquid enrichment culture (Delafield et al., 1965). This procedure yielded strains belonging to various species of Gram-negative, polarly flagellated, straight to slightly curved, nonsporeforming rods, one of which was later named *Pseudomonas delafieldii* (Davis et al., 1970). A phenanthrene-degrading *A. delafieldii* strain has been isolated from creosote-contaminated soil by enrichment cultures on phenanthrene (Shuttleworth and Cerniglia, 1996).

1. The mineral medium contains (g/l distilled water) KH_2PO_4, 1.0; NH_4NO_3, 1.0; $MgSO_4 \cdot 7H_2O$, 0.2; $FeSO_4 \cdot 7H_2O$, 0.01; and $CaCl_2 \cdot 2H_2O$, 0.01; pH 6.8–7.2 (Schatz and Bovell, 1952).

Aznar et al. (1992) have isolated *A. delafieldii* from a hypertrophic freshwater lagoon on casein peptone starch agar and have studied *A. delafieldii* strains isolated from healthy and diseased eels from eel farms. Some isolates of *A. delafieldii* and *A. temperans* have originated from various clinical sources, where they were isolated using routine clinical techniques (Willems et al., 1990). *A. defluvii* was isolated from activated sludge form a wastewater treatment plant in Munich (Schulze et al., 1999a).

The phytopathogenic species can be isolated from infected plant material. Small pieces (about 1 cm^2) of diseased tissue are cut from lesions in leaf blades, surface-sterilized (for example, with 70% ethanol (Goto, 1983), 0.5% sodium hypochlorate (Schaad et al., 1978), or 70% ethanol followed by 0.001% mercuric chloride and again 70% ethanol (Hayward, 1962) and rinsed with sterile distilled water. The tissue may be further mashed mechanically. The suspension can then be plated out immediately or left to diffuse at room temperature for several hours before plating out on a suitable medium, such as yeast extract–peptone agar. Plates are incubated at 28–30°C, and colonies usually appear within 2 days (Hayward, 1962; Schaad et al., 1978; Goto, 1983).

Maintenance Procedures

Acidovorax strains can be maintained on nutrient agar at 4°C for up to 2 months. Unlike some autotrophic species, *A. facilis* does not readily lose its H_2-oxidizing capacity when grown heterotrophically over long periods of time or in the presence of 100% O_2 (Schatz and Bovell, 1952).

For long-term preservation, strains can be lyophilized using standard procedures. For example, at the BCCM-LMG (Ghent, Belgium) culture collection this is routinely done in horse serum.

Differentiation of the genus *Acidovorax* from other genera

See Table BXII.β.42 for the family *Comamonadaceae* for features differentiating *Acidovorax* from the other genera of this family.

An oligonucleotide probe for the genus *Acidovorax*, which hybridizes to variable region II of the 16S rRNA gene, has been designed to allow differentiation from species of *Comamonas* and *Hydrogenophaga*, but hybridization conditions are crucial. In the presence of 0–10% formamide, *Acidovorax* strains, and *Variovorax paradoxus*, hybridize with the probe. In the presence of 20% formamide, *Variovorax paradoxus* no longer hybridizes with the probe, but *A. delafieldii* is also negative (Amann et al., 1996).

Taxonomic Comments

Pseudomonas facilis was originally described as *"Hydrogenomonas facilis"*, a hydrogen oxidizing isolate from lawn soil (Schatz and Bovell, 1952). When the genus *"Hydrogenomonas"* was later abandoned, *"Hydrogenomonas facilis"* was transferred to the genus *Pseudomonas* (Davis et al., 1969). *Pseudomonas delafieldii* was proposed for a number of strains phenotypically similar to *Pseudomonas facilis* but unable to oxidize hydrogen (Davis et al., 1970). By DNA–rRNA hybridization, it was later shown that the genus *Pseudomonas* was polyphyletic and consisted of five distinct and remotely related groups that could not be maintained in a single genus (De Vos and De Ley, 1983). *Pseudomonas facilis* and *Pseudomonas delafieldii* belong to the acidovorans rRNA complex in the *Betaproteobacteria*. In a polyphasic study of the relationships within this group, it was shown that both species, together with a number of clinical isolates that had been provisionally grouped in the so-called EF groups 13 and 16, form a separate rRNA subbranch, for which the genus *Acidovorax* was proposed. Initially, three species were proposed: *Acidovorax facilis* for *Pseudomonas facilis*, *Acidovorax delafieldii* for *Pseudomonas delafieldii* and most of the strains of EF group 13, and *Acidovorax temperans* for most of the strains from EF group 16 and several misnamed *Pseudomonas* and *Alcaligenes* strains (Willems et al., 1990).

In an extension of this polyphasic study, several phytopathogenic *Pseudomonas* species were also transferred to the genus *Acidovorax* (Willems et al., 1992a). Several species causing disease on Poaceae have been united in *Acidovorax avenae* subsp. *avenae*. The causal agent of leaf blight on oats in Ohio was first described by Manns (1909) as *Pseudomonas avenae*. A similar disease of foxtail in Arkansas was attributed to a new species *"Pseudomonas alboprecipitans"* (Rosen, 1922). Later, isolates from diseased corn from Georgia and Florida were compared with the descriptions of both species, and Schaad et al. (1975) concluded that *"Pseudomonas alboprecipitans"* was a later synonym of *Pseudomonas avenae*. *Pseudomonas rubrilineans*, the causal agent of red stripe disease on sugarcane, was originally described as *Phytomonas rubrilineans* (Lee et al., 1925), but was later transferred to *Xanthomonas* (Starr and Burkholder, 1942) and then to *Pseudomonas* (Hayward, 1962). Later Ramundo and Claflin (1990) demonstrated the synonymy between *Pseudomonas rubrilineans* and *Pseudomonas avenae* by comparing physiological, biochemical, and serological data. *"Pseudomonas setariae"*, the causal agent of brown stripe disease on *Setaria italica*, was first described as *"Bacterium setariae"* (Okabe, 1934), but was later transferred to *Pseudomonas* (Săvulescu, 1947). It was not included on the Approved Lists (Skerman et al., 1980) because the only extant strain was considered a member of *Pseudomonas avenae*.

A second subspecies, *Acidovorax avenae* subsp. *cattleyae*, has been proposed for a pathogen of *Cattleya* orchids (Willems et al., 1992a). This organism was first described as *"Bacterium cattleyae"* by Pavarino (1911); later, brown spot disease on *Cattleya* and *Phalaenopsis* species was attributed to *Phytomonas cattleyae* (Ark and Thomas, 1946). This species was later transferred to *Pseudomonas* (Săvulescu, 1947). Based on a phenotypic analysis and DNA–DNA hybridizations, Hu et al. (1991) considered *Pseudomonas cattleyae* to be a synonym of *Pseudomonas avenae*.

A third subspecies, *Acidovorax avenae* subsp. *citrulli*, has been proposed as the causal agent of leaf blight on watermelon. It had been described as *Pseudomonas pseudoalcaligenes* subsp. *citrulli*, mainly because of its phenotypic similarity to the *Pseudomonas alcaligenes* group (Schaad et al., 1978). Hu et al. (1991) transferred this subspecies to *Pseudomonas avenae* as *Pseudomonas avenae* subsp. *citrulli*.

Acidovorax konjaci has been proposed as a separate species (Willems et al., 1992a) comprising *Pseudomonas pseudoalcaligenes* subsp. *konjaci*, a pathogen isolated from the leaves of the Konjac plant (*Amorphophallus konjac*) (Goto, 1983). In addition, this subspecies was first transferred as a separate subspecies to *Pseudomonas avenae* by Hu et al. (1991).

Thus, the genus *Acidovorax* now contains seven species, which can be separated in two groups: the soil and water inhabitants *A. facilis*, *A. delafieldii*, *A. defluvii*, and *A. temperans*, which also include some opportunistic clinical isolates, and the phytopathogenic species *A. avenae* with its three subspecies, *A. konjaci* (Willems et al., 1992a), and *A. anthurii* (Gardan et al., 2000). This separation into two groups is reflected in the 16S rDNA phylogeny of these organisms (Willems et al., 1992a), but they have been maintained in a single genus because of phenotypic similarities (Willems et al., 1992a). More recently, the 16S rRNA gene

sequence analysis of the type strains of the all *Acidovorax* species has confirmed that *Acidovorax* does form a separate phylogenetic cluster within the *Comamonadaceae*, with all species showing at least 95.5% sequence similarity, thus supporting the grouping of the previously described rRNA subbranches into a single genus. DNA–DNA hybridizations do not show any significant DNA-binding among any of the *Acidovorax* species. They demonstrate that *A. avenae* consists of at least three subgroups for which separate subspecies have been proposed (Willems et al., 1992a). DNA-binding values of 54–67% have been obtained among the subspecies, whereas within the subspecies, values of at least 75% are obtained. These three subspecies can also be distinguished by 16S rDNA sequence comparison (Wen et al., 1999).

Acknowledgments

Anne Willems is indebted to the Fund for Scientific Research, Flanders for a position as a postdoctoral research fellow.

List of species of the genus Acidovorax

1. **Acidovorax facilis** (Schatz and Bovell 1952) Willems, Falsen, Pot, Jantzen, Hoste, Vandamme, Gillis, Kersters and De Ley 1990, 394[VP] (*Pseudomonas facilis* (Schatz and Bovell 1952) Davis, Doudoroff, Stanier and Mandel 1969, 385; *"Hydrogenomonas facilis"* Schatz and Bovell 1952, 88.)
fa' ci.lis. L. adj. *facilis* ready, quick.

Wilde and Schlegel (1982) have reported strains to be tolerant to 60% O_2 when grown autotrophically and 100% O_2 when grown heterotrophically. Characteristics differentiating *A. facilis* from the other *Acidovorax* species are presented in Table BXII.β.46. Further descriptive information is provided in Table BXII.β.47. Isolated from lawn soil in the United States.

The mol% G + C of the DNA is: 64–65 (T_m); type strain, 65 (T_m).

Type strain: ATCC 11228, CCUG 2113, DSM 649, LMG 2193.

GenBank accession number (16S rRNA): AF078765.

2. **Acidovorax anthurii** Gardan, Dauga, Prior, Gillis and Saddler 2000, 245[VP]
an.thu' ri.i. L. fem. n. *Anthurium* anthurium; L. gen. n. *anthurii* of anthurium, referring to the plant from which the phytopathogenic bacterium was first isolated.

The characteristics are the same as those of the genus. This species is not included in Tables BXII.β.46 and BXII.β.47 because it was published after the completion of the chapter. The description below is taken from the original description (Gardan et al., 2000).

On YBGA, colonies are circular, raised with an entire margin. A white-creamy, and a brown diffusible pigment is produced.

Catalase and urease are positive. Poly-β-hydroxybutyrate is accumulated in the cell; arginine is used as the sole source of carbon. H_2S is produced from cysteine and cellulose is hydrolysed. Indole, levane, and acetoin are not produced. Casein and esculin are not hydrolyzed. Acid is produced from galactose, arabinose, and glycerol. Acetate, formate, glycerol, DL-5-aminobutyrate, D(−)tartrate, and azelate are utilized. Trehalose, caprylate, D-ribose, D-glucose, *N*-acetylglucosamine, L-arginine, saccharose, inositol, sarcosine, itaconate, D-xylose, L-tryptophan, esculin, and mannitol are not utilized. The sole hydroxylated fatty acid present is 3-hydroxy-decanoic acid.

All strains elicit a hypersensitive reaction on tobacco leaves (HR) and are pathogenic on anthurium, producing typical leaf-spot symptoms.

The mol% G + C of the DNA is: 63.5 (T_m).

Type strain: CFBP 3232, CIP 107058.

GenBank accession number (16S rRNA): AJ007013.

3. **Acidovorax avenae** (Manns 1909) Willems, Goor, Thielemans, Gillis, Kersters and De Ley 1992a, 115[VP] (*Pseudomonas avenae* Manns 1909, 1933; *"Pseudomonas alboprecipitans"* Rosen 1922, 383.)
a' ve.nae. M.L. n. *avena* genus of plants; M.L. gen. n. *avenae* of *Avena*.

This species contains only phytopathogenic strains, which are divided into three subspecies.

The mol% G + C of the DNA is: 67–70 (T_m).

a. **Acidovorax avenae** *subsp.* **avenae** (Manns 1909) Willems, Goor, Thielemans, Gillis, Kersters and De Ley 1992a, 117[VP] (*Pseudomonas avenae* Manns 1909, 1933; *Pseudomonas avenae* subsp. *avenae* Manns 1909, 1933; *"Pseudomonas alboprecipitans"* Rosen 1922, 383.)

Characteristics differentiating *A. avenae* subsp. *avenae* from the other *Acidovorax* species are presented in Table BXII.β.46. Further descriptive information is provided in Table BXII.β.47. This subspecies is pathogenic for various species of Poaceae, including oats, corn, wheat, barley, sorghum, rye, sugarcane, rice seedlings, Italian millet, pearl millet, barnyard millet, foxtail millet, finger millet, Proso millet, and Vasey grass. There are phytopathological indications that strains pathogenic to rice are different from strains pathogenic to other plants, supported also by the detection of a protein specific to the rice-pathogenic strains (Kadota et al., 1996).

The mol% G + C of the DNA is: 68–70 (T_m); type strain, 70 (T_m).

Type strain: ATCC 19860, LMG 2117, NCPPB 1011.

GenBank accession number (16S rRNA): AF078759.

Additional Remarks: The type strain was isolated from *Zea mays* in the United States in 1958.

b. **Acidovorax avenae** *subsp.* **cattleyae** (Pavarino 1911) Willems, Goor, Thielemans, Gillis, Kersters and De Ley 1992a, 118[VP] (*Pseudomonas avenae* subsp. *cattleyae* (Pavarino 1911) Hu, Young and Triggs 1991, 524; *Pseudomonas cattleyae* (Pavarino 1911) Săvulescu 1947, 11; *"Bacterium cattleyae"* Pavarino 1911, 234.)
catt' ley.ae. M.L. fem. n. *Cattleya* a genus of orchids; M.L. gen. n. *cattleyae* of *Cattleya*.

Characteristics differentiating *A. avenae* subsp. *cattleyae* from the other *Acidovorax* species are presented in Table BXII.β.46. Further descriptive information is provided in Table BXII.β.47. Causes leaf spot and bud rot on *Cattleya* and *Phalaenopsis* orchids.

The mol% G + C of the DNA is: 69 (T_m).

Type strain: ATCC 33619, LMG 2364, NCPPB 961.
GenBank accession number (16S rRNA): AF078762.

c. **Acidovorax avenae** *subsp.* **citrulli** (Schaad, Sowell, Goth, Colwell and Webb 1978) Willems, Goor, Thielemans, Gillis, Kersters and De Ley 1992a, 118[VP] (*Pseudomonas avenae* subsp. *citrulli* (Schaad, Sowell, Goth, Colwell and Webb 1978) Hu, Young and Triggs 1991, 524; *Pseudomonas pseudoalcaligenes* subsp. *citrulli* Schaad, Sowell, Goth, Colwell and Webb 1978, 123.)
ci' trul.li. M.L. masc. n. *Citrullus* a genus in the cucumber family; M.L. gen. n. *citrulli* of *Citrullus*.

Characteristics differentiating *A. avenae* subsp. *citrulli* from the other *Acidovorax* species are presented in Table BXII.β.46. Further descriptive information is provided in Table BXII.β.47. Pathogenic for several species of Cucurbitaceae, including watermelon, cantaloupe, cucumber, and squash.

The mol% G + C of the DNA is: 67–68 (T_m); type strain, 68 (T_m).
Type strain: ATCC 29625, ICMP 7500, LMG 5376.
GenBank accession number (16S rRNA): AF078761.
Additional Remarks: The type strain was isolated from a water-soaked lesion on a cotyledon of *Citrullus lanatus* in the United States in 1977.

4. **Acidovorax delafieldii** (Davis *in* Davis, Stanier, Doudoroff and Mandel 1970) Willems, Falsen, Pot, Jantzen, Hoste, Vandamme, Gillis, Kersters and De Ley 1990, 396[VP] (*Pseudomonas delafieldii* Davis *in* Davis, Stanier, Doudoroff and Mandel 1970, 12.)
de.la.fiel' di.i. M.L. gen. n. *delafieldii* of Delafield, named after F.P. Delafield, who first isolated this organism.

Characteristics differentiating *A. delafieldii* from the other *Acidovorax* species are presented in Table BXII.β.46. Further descriptive information is provided in Table BXII.β.47. Isolated from soil, water, and various samples from clinical origin.

The mol% G + C of the DNA is: 65–66 (T_m); type strain, 66 (T_m).
Type strain: ATCC 17505, DSM 64, LMG 5943.
GenBank accession number (16S rRNA): AF078764.
Additional Remarks: This strain was isolated from soil with PHB as the sole carbon source. Since it is not the most representative of the redefined species, strain CCUG 23830B (LMG 8909) has been proposed as an alternative reference strain for this species (Willems et al., 1990).

5. **Acidovorax defluvii** Schulze, Spring, Amann, Huber, Ludwig, Schleifer and Kämpfer 1999b, 1325[VP] (Effective publication: Schulze, Spring, Amann, Huber, Ludwig, Schleifer and Kämpfer 1999a, 205.)
de.flu' vi.i. L. n. *defluvium* sewage; L. gen. n. *defluvii* of sewage.

The characteristics are the same as those of the genus. This species is not included in Tables BXII.β.46 and BXII.β.47 because it was published after the completion of the chapter. The description below is taken from the original description (Schulze et al., 1999a).

The following characteristics are positive for all strains: growth at 28°C, storage of polyhydroxybutyrate, and hydrolysis of L-alanine-pNA. The following characteristics are negative for all strains: growth at 37°C or in the presence of 1.5% NaCl. Utilization of the following substrates for growth: *N*-acetyl-glucosamine, L-arabinose, *p*-arbutin, D-cellulose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, D-maltose, α-D-melibiose, L-rhamnose, D-ribose, sucrose, salicin, D-trehalose, D-xylose, adonitol, *i*-inositol, D-mannitol, D-sorbitol, propionate, azelate, citrate, itaconate, mesaconate, β-alanine, L-aspartate, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-serine, L-tryptophan, *m*-hydroxybenzoate, *p*-hydroxybenzoate, and phenylacetate. Hydrolysis of esculin, pNP-β-D-galactopyranoside, pNP-α-D-glucopyranoside, and pNP-β-glucopyranoside.

The hydroxylated fatty acids 3-hydroxyoctanoic ($C_{8:0\ 3OH}$) and 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$) are present. Isolated from activated sludge of a municipal wastewater treatment plant. The type strain is nonmotile under laboratory conditions, is catalase positive, and reduces nitrate.

The mol% G + C of the DNA is: 62–64 (T_m); value for the type strain, 62.
Type strain: BSB411, DSM12644, CIP 106824.
GenBank accession number (16S rRNA): Y18616.

6. **Acidovorax konjaci** (Goto 1983) Willems, Goor, Thielemans, Gillis, Kersters and De Ley 1992a, 118[VP] *Pseudomonas avenae* subsp. *konjaci* (Goto 1983) Hu, Young and Triggs 1991, 524; *Pseudomonas pseudoalcaligenes* subsp. *konjaci* Goto 1983, 544.)
kon.ja' ci. M.L. gen. n. *konjaci* of the konjac plant, *Amorphophallus rivieri* cv. Konjac.

Characteristics differentiating *A. konjaci* from the other *Acidovorax* species are presented in Table BXII.β.46. Further descriptive information is provided in Table BXII.β.47. Causal agent of leaf blight of *Amorphophallus rivieri* cv. Konjac, a Japanese food crop.

The mol% G + C of the DNA is: 68 (T_m).
Type strain: ATCC 33996, ICMP 7733, LMG 5691.
GenBank accession number (16S rRNA): AF078760, AF137507.
Additional Remarks: The type strain was isolated from *Amorphophallus rivieri* cv. Konjac.

7. **Acidovorax temperans** Willems, Falsen, Pot, Jantzen, Hoste, Vandamme, Gillis, Kersters, and De Ley 1990, 396[VP]
tem' pe.rans. L. v. *temperare* to moderate; M.L. pres. part. *temperans* moderate, referring to the moderate metabolic versatility of the species.

Characteristics differentiating *A. delafieldii* from the other *Acidovorax* species are presented in Table BXII.β.46. Further descriptive information is provided in Table BXII.β.47. Isolated from various samples from clinical environments; one strain was isolated from active sludge from a waste water purification plant in Sweden.

The mol% G + C of the DNA is: 62–66 (T_m); type strain 62 (T_m).
Type strain: CCUG 11779, DSM 7270, LMG 7169.
GenBank accession number (16S rRNA): AF078766.
Additional Remarks: The type strain was isolated from a urine sample of a 68-year-old male patient in Göteborg, Sweden.

Genus III. **Brachymonas** *Hiraishi, Shin and Sugiyama 1995b, 879[VP] (Effective publication: Hiraishi, Shin and Sugiyama 1995c, 110)*

AKIRA HIRAISHI

Bra.chy.mo'nas. Gr. adj. *brachy* short; Gr. n. *monas* a unit; M.L. fem. n. *Brachymonas* a small short unit.

Cells are coccobacilli or short rods, 0.6–1.0 × 0.8–1.5 µm, with rounded ends, occurring singly, in pairs, and in chains. Nonsporeforming, nonencapsulated, and nonmotile. Gram negative.

Aerobic chemoorganotrophs having a strictly respiratory type of metabolism, with oxygen as the terminal electron acceptor. **Growth occurs anaerobically with nitrate** as the terminal electron acceptor. Denitrification positive. Liquid cultures and colonies are cream to pale yellow. Grow well in ordinary nutrient media containing peptone or in mineral media supplemented with simple organic compounds as electron donors and carbon sources. **Do not utilize sugars as carbon or energy sources.** Mesophilic, neutrophilic, and nonhalophilic. Catalase and oxidase positive. No hydrolysis of polysaccharides, protein, or lipids.

Straight-chain hexadecanoic acids ($C_{16:0}$ and $C_{16:1}$) are the major components of cellular fatty acids. 3-Hydroxydecanoic acid ($C_{10:0\ 3OH}$) is present. Ubiquinones and rhodoquinones with eight isoprene units (Q-8 and RQ-8) are the major respiratory quinones. Isolated from activated sludge systems, such as soybean-curd wastewater sludge and municipal sewage sludge.

The mol% G + C of the DNA is: 63–65.

Type species: **Brachymonas denitrificans** Hiraishi, Shin and Sugiyama 1995b, 879 (Effective publication: Hiraishi, Shin and Sugiyama 1995c, 110.)

FURTHER DESCRIPTIVE INFORMATION

The description of the genus *Brachymonas* is based on only one species, *B. denitrificans*. Morphological features are as shown in Fig. BXII.β.28. Electron microscopy of negatively stained cells shows that the cells have no flagella. Colonies on agar media are of intermediate size (3–5 mm after 3 d), smooth, circular, convex, and cream to pale yellow. Some strains produce mucoid colonies upon subculture, and it is hard to harvest cells from such colonies by ordinary centrifugation. In liquid cultures with shaking, growth occurs as a uniform cell suspension. No flocculent growth is found at any growth stage.

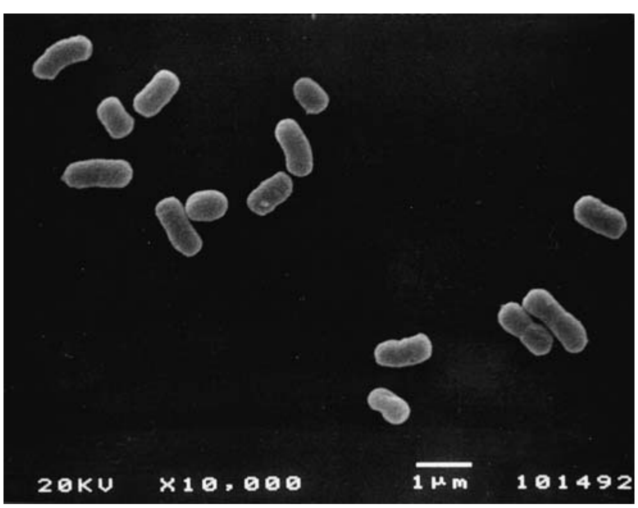

FIGURE BXII.β.28. Scanning electron micrograph showing general cell morphology of *Brachymonas denitrificans* (strain AS-P1[T]).

Cells exhibit a doubling time of 1.5–2.0 h under optimal aerobic growth conditions (in peptone–yeast extract medium or lactate–mineral salt medium). Anaerobic growth with nitrate is somewhat slower (doubling time 2–3 h) and is accompanied with nitrogen gas production. Some strains are also capable of growing anaerobically with trimethylamine-*N*-oxide (TMAO) as the terminal electron acceptor, but growth is much slower (doubling time 9–10 h). No strains grow anaerobically with fumarate as the terminal oxidant, but cell-free extracts from these strains exhibit fumarate-reducing activity with reduced FMN as an electron donor. It is unknown whether this activity is related to the occurrence of the low-potential quinone rhodoquinone or if it has some biological significance. A wide variety of simple organic compounds are used as electron donors and carbon sources for both aerobic and denitrifying growth. Good growth occurs with the salts of organic acids (e.g., acetate, lactate, pyruvate, fumarate, and succinate) and amino acids (e.g., alanine, glutamate, leucine, phenylalanine, and proline). Carbohydrates are never utilized.

The optimal temperature for growth is 30–35°C and the optimal pH is 7.0–7.5. NaCl is not required for optimal growth, but multiplication occurs at NaCl concentrations of up to 3%. Growth factors are not required. Ammonium salts are used as nitrogen sources. Sulfate is assimilated as the sulfur source. The following characteristics are negative: indole production; Voges–Proskauer reaction; urease; phenylalanine deaminase; decarboxylation of arginine, lysine, and ornithine; and hydrolysis of aliginic acid, chitin, starch, gelatin, casein, tributyrin, and Tween 80.

Palmitoleic acid ($C_{16:1}$) and palmitic acid ($C_{16:0}$) are the major components of whole-cell fatty acids, constituting 33–43% and 21–28% of the total content, respectively. In addition, a considerable amount (10–17%) of $C_{18:1}$ acid is present. 3-Hydroxydecanoic acid ($C_{10:0\ 3OH}$) is the main fatty acid component of the outer membranes. The major respiratory quinones are Q-8 and RQ-8. The RQ/Q molar ratio is higher in cells growing in complex media (0.09–0.10) than in those in a chemically defined medium with lactate as the sole carbon source (<0.05). In addition, the RQ/Q ratio is higher in aerobically grown cells than in anaerobically grown cells using nitrate or TMAO as the terminal electron acceptor.

Strains of *B. denitrificans* have hitherto been isolated from activated sludge systems, such as soybean-curd wastewater sludge and municipal sewage sludge (Hiraishi and Komagata, 1989b). In addition, rhodoquinone-producing denitrifying strains that are phenotypically similar to *Brachymonas* have been isolated from photosynthetic wastewater treatment sludge (Hiraishi et al., 1991b). As suggested by their capacity for denitrification, *Brachymonas* strains may play important roles in nitrogen removal and organic matter removal in biological wastewater treatment systems.

ENRICHMENT AND ISOLATION PROCEDURES

Selective isolation and enrichment of *Brachymonas* from the environment are difficult, but the following mineral medium sup-

plemented with 20 mM acetate and 20 mM potassium nitrate is recommended (per liter distilled water): $(NH_4)_2SO_4$, 1 g; KH_2PO_4, 1 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; $CaCl_2 \cdot 2H_2O$, 0.05 g; trace element solution SL8, 1 ml (Biebl and Pfennig, 1978) (pH 6.8). The medium is incubated anaerobically (under denitrifying conditions).

Brachymonas strains grow well in ordinary complex nutrient media, such as PBY medium (0.5% peptone, 0.2% beef extract, and 0.1% yeast extract) (Hiraishi and Komagata, 1989a). Good growth also occurs in the mineral medium described previously with 20 mM lactate or acetate as the sole carbon source.

Maintenance Procedures

Cultures are well preserved in liquid nitrogen or by lyophilization. Preservation can also be done in a mechanical freezer at −80°C.

Procedures for Testing Special Characters

The presence of both respiratory quinones Q-8 and RQ-8 is a characteristic feature of *Brachymonas* and can be determined by TLC and reverse-phase HPLC (Hiraishi and Hoshino, 1984). In silica-gel TLC, rhodoquinones migrate just behind ubiquinones and are detectable as a pink to purple band under visible light. The type of rhodoquinone homologs, as well as ubiquinones, can be determined by reverse-phase HPLC with an ODS column and methanol–isopropyl ether (3:1, v/v) as the mobile phase.

Differentiation of the genus *Brachymonas* from other genera

The genus *Brachymonas* can be differentiated from phenotypically and phylogenetically related genera by the features listed in Table BXII.β.48.

Taxonomic Comments

Brachymonas strains were isolated from activated sludge and first designated unidentified rhodoquinone-containing chemoorganotrophic bacteria (Hiraishi and Komagata, 1989b). This was the first demonstration of the existence of rhodoquinone-containing chemoorganotrophic bacteria, as, before this study, rhodoquinones had been known to be distributed only in phototrophic purple bacteria among the procaryotes (Hiraishi and Hoshino, 1984; Hiraishi, 1988b). A phylogenetic analysis based on 16S rDNA sequences has shown that *B. denitrificans* strains form a major cluster in the *Betaproteobacteria*, together with members of the genera *Comamonas*, *Variovorax*, and *Rhodoferax* (Hiraishi et al., 1995b). The nearest phylogenetic neighbor is *Comamonas testosteroni* (95% similarity). Also genomic DNA–DNA hybridization studies have shown that *B. denitrificans* forms a genetically coherent group, in that the levels of hybridization among strains of the species are 74–100%. Based on this phylogenetic evidence, together with the chemotaxonomic information, creation of a new genus and species with the name *Brachymonas denitrificans* was proposed for these strains (Hiraishi et al., 1995b). *Brachymonas* may belong to the family *Comamonadaceae*.

Differentiation of the species of the genus *Brachymonas*

The genus *Brachymonas* includes only one species, *B. denitrificans*, at this time. The general characteristics of *B. denitrificans* are indicated in Table BXII.β.49.

List of species of the genus Brachymonas

1. **Brachymonas denitrificans** Hiraishi, Shin and Sugiyama 1995b, 879[VP] (Effective publication: Hiraishi, Shin and Sugiyama 1995c, 111.)
de.ni.tri′ fi.cans. M.L. adj. *denitrificans* denitrifying.

The characteristics are as described for the genus and indicated in Tables BXII.β.48 and BXII.β.49. The habitat is activated sludge.

The mol% G + C of the DNA is: 63–65 (HPLC).
Type strain: AS-P1, JCM 9216.
GenBank accession number (16S rRNA): D14320.

TABLE BXII.β.48. Differential characteristics of *Brachymonas* and phenotypically and phylogenetically related genera[a]

Characteristic	*Brachymonas*	*Acidovorax*	*Comamonas*	*Hydrogenophaga*	*Variovorax*
Cell shape	Short rods, coccobacilli	Rods	Rods	Rods	Rods

TABLE BXII.β.49. Other characteristics of *Brachymonas denitrificans*[a]

Characteristic	Result or reaction
Cell size (μm)	0.6–1.0 × 0.8–1.5
Yellow pigment	d
Temperature range for growth (°C)	10–40
pH Range for growth	5–9
Growth with 3% NaCl	+
Growth with 5% NaCl	−
Anaerobic growth with:	
Fumarate, dimethylsulfoxide, HCO_3^-/pyruvate	−
Nitrate	+
TMAO	d
N_2 gas production from nitrate	+
Growth factor requirement	−
Catalase, oxidase	+
Hydrolysis of starch, alginate, chitin, casein, gelatin, tributyrin, Tween 80	−
Electron donors and carbon sources:	
Ethanol, propylene glycol, acetate, butyrate, lactate, pyruvate, succinate, fumarate, malate, glutarate, alanine, asparagine, glutamate, leucine, phenylalanine, proline	+
Propionate, benzoate	d
L-Arabinose, D-xylose, D-ribose, L-rhamnose, D-glucose, D-mannose, D-fructose, cellobiose, lactose, sucrose, adonitol, mannitol, sorbitol, glycerol, methanol, formate, caproate, caprylate, pelargonate, citrate, malonate, tartrate, glycolate, gluconate, aminobutyrate, arginine, glycine, histidine, lysine, ornithine, tryptophan	−
Major fatty acids	$C_{16:0}$, $C_{16:1}$
3-OH fatty acid	$C_{10:0}$
Major quinones	Q-8, RQ-8
Mol% G + C of DNA	63–65

[a]For symbols see standard definitions; Q-8, ubiquinone-8; RQ-8, rhodoquinone-8.

Genus IV. **Delftia** *Wen, Fegan, Hayward, Chakraborty and Sly 1999, 573*[VP]

LINDSAY I. SLY, AIMIN WEN AND MARK FEGAN

Delf′ tia. M.L. fem. n. *Delftia* referring to the city of Delft, the site of isolation of the type species, and in recognition of the role of Delft research groups in the development of bacteriology.

Cells are **straight to slightly curved rods**, 0.4–0.8 × 2.5–4.1 μm (occasionally up to 7 μm), occurring **singly or in pairs**. **Motile by means of polar or bipolar tufts of one to five flagella.** Do not produce endospores. Gram negative. **Oxidase and catalase positive.** No fluorescent pigment produced. Poly-β-hydroxybutyrate is accumulated. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nonfermentative. Reduce nitrate to nitrite. Do not denitrify. **Chemoorganotrophic**. Good growth occurs on media containing organic acids, amino acids, peptone, and carbohydrates. Utilize mannitol and fructose as the sole carbon source, but not glucose. No autotrophic growth with H_2. Hydrolyze acetamide. No levan formation from sucrose. Arginine dihydrolase absent. *Meta* cleavage of protocatechuate. Lipase (Tween 80 hydrolysis) positive. **Main polyamines are putrescine and 2-hydroxyputrescine.** The **major quinone is ubiquinone Q-8**; minor quinones are Q-7 and Q-9. Major fatty acids are hexadecanoic acid ($C_{16:0}$), hexadecenoic acid ($C_{16:1}$), and octadecenoic acid ($C_{18:1}$). 3-hydroxy fatty acids ($C_{10:0\ 3OH}$ and $C_{8:0\ 3OH}$) but not 2-hydroxy fatty acids are present. DNA–rRNA hybridization and 16S rRNA sequence analysis places the genus in the family *Comamonadaceae*. Isolated from soil, sediment, activated sludge, crude oil, oil brine, water, and various clinical samples.

The mol% G + C of the DNA is: 67–69.

Type species: **Delftia acidovorans** (den Dooren de Jong 1926) Wen, Fegan, Hayward, Chakraborty and Sly 1999, 573 (*Pseudomonas acidovorans* den Dooren de Jong 1926, 106; *Comamonas acidovorans* (den Dooren de Jong 1926) Tamaoka, Ha and Komagata 1987, 58.)

FURTHER DESCRIPTIVE INFORMATION

The description of *Delftia* is based on data from a number of studies (Ikemoto et al., 1978b; Palleroni, 1984; De Vos et al., 1985b; Tamaoka et al., 1987; Busse and Auling, 1988; Willems et al., 1989, 1991c, 1992a; Wen et al., 1999).

Growth occurs at 30°C, but not at 4°C and 41°C. Growth occurs in the presence of 0.5 or 1.5% NaCl. No pigments are produced on nutrient agar.

The following organic compounds can be utilized as carbon and energy sources: acetate, acetamide (reported as a variable reaction by Tamaoka et al., 1987 and Willems et al., 1991c), aconitate, adipate, D-alanine (reported as a variable reaction by Willems et al., 1991c), L-alanine (reported as a variable reaction by Willems et al., 1991c), 2-aminobutyrate (reported as a variable reaction by Willems et al., 1991c), δ-aminovalerate, L-aspartate, azelate, butanol, 2,3-butylene glycol, butyrate, caproate (reported as a variable reaction by Willems et al., 1991c), citraconate, citrate (reported as a variable reaction by Willems et al., 1991c), ethanol, D-fructose, fumarate, gluconate, L-glutamate, glutarate, glycerate, glycine (reported as a variable reaction by Willems et al., 1991c), glycolate, hippurate, L-histidine, *m*-hydroxybenzoate, *p*-hydroxybenzoate, β-hydroxybutyrate, hydroxymethylglutarate, isobutyrate, L-isoleucine (reported as a variable reaction by Willems et al., 1991c), isovalerate, itaconate, α-ketoglutarate, kynurenate, L-kynurenine, lactate, levulinate, L-leucine, D-malate (reported as a variable reaction by Willems et al., 1991c), L-malate, maleate (reported as a variable reaction by Willems et al., 1991c), malonate (reported as a variable reaction by Willems et al., 1991c), mannitol, mesaconate, mucate, nicotinate, DL-norleucine (re-

ported as a variable reaction by Willems et al., 1991c), L-norleucine (reported as a variable reaction by Willems et al., 1991c), DL-norvaline, phenylacetate (reported as a variable reaction by Willems et al., 1991c), L-phenylalanine (reported as a variable reaction by Willems et al., 1991c), pimelate, L-proline, *n*-propanol, propionate, pyruvate, quinate, saccharate, sebacate, suberate, succinate, L(+)-tartrate (reported as a variable reaction by Willems et al., 1991c), *m*-tartrate, trigonelline (reported as a negative reaction by Willems et al., 1991c), L-tryptophan (reported as a variable reaction by Willems et al., 1991c and Tamaoka et al., 1987), D-tryptophan (reported as a variable reaction by Willems et al., 1991c), L-tyrosine, and valerate.

The following compounds are not utilized: *N*-acetylglucosamine, adonitol, 3-aminobenzoate, amylamine, anthranilate, D-arabinose, L-arabinose, D-arabitol, L-arabitol, arbutin, L-arginine, benzoate (reported as a variable reaction by Willems et al., 1991c), benzoylformate, benzylamine, betaine, butylamine, caprylate, cellobiose, L-citrulline, creatine, L-cysteine, diaminobutane, dodecane, dulcitol, erythritol, esculin, ethanolamine, ethylamine, ethylene glycol (reported as a positive reaction by Tamaoka et al., 1987), D-fucose (reported as a variable reaction by Willems et al., 1991c), D-galactose, β-gentiobiose, geraniol, glucosamine, D-glucose, methyl-α-D-glucoside, glycogen, heptanoate, hexadecane, histamine, *o*-hydroxybenzoate, poly-β-hydroxybutyrate, DL-β-hydroxybutyrate, inulin, isophthalate, 2-ketogluconate, 5-ketogluconate, lactose, L-lysine, D-lyxose, maltose, D-mandelate, L-mandelate (reported as a variable reaction by Willems et al., 1991c), D-mannose, methyl-α-D-mannoside, D-melezitose, D-melibiose, naphthalene, L-ornithine, oxalate, pantothenate, pelargonate (reported as a variable reaction by Willems et al., 1991c), phenol, phenylethanediol, phthalate (reported as a variable reaction by Willems et al., 1991c), propylene glycol (reported as a positive reaction by Tamaoka et al., 1987), putrescine, D-raffinose, L-rhamnose, D-ribose, salicin, sarcosine (reported as a variable reaction by Willems et al., 1991c), L-serine, sorbitol, L-sorbose, spermine, sucrose, starch, D(−)-tartrate, terephthalate, testosterone, L-threonine (reported as a variable reaction by Willems et al., 1991c and a positive reaction by Tamaoka et al., 1987), trehalose, tryptamine, D-turanose, urea, L-valine (reported as a variable reaction by Willems et al., 1991c), *m*-xylitol, D-xylose, L-xylose, and methyl-β-D-xyloside.

Variable utilization among different strains occurs with β-alanine, 2-aminobenzoate, 4-aminobenzoate, 3-aminobutyrate, 4-aminobutyrate, 5-aminobutyrate, α-aminovalerate, amygdalin, 2,3-butylene glycol, caprate, *m*-erythritol, glycerol, heptanoate, *m*-inositol, isobutanol, DL-kynurenine, L-methionine, and tagatose.

The following characteristics are absent: growth in the presence of 6.5% NaCl, acid production in 10% lactose, in triple sugar iron medium, and in oxidative-fermentative medium containing D-glucose, D-fructose, D-xylose, maltose, or adonitol; production of H_2S in triple sugar iron medium; hydrolysis of esculin, gelatin, and DNA; indole production, and β-galactosidase activity; hydrolysis of 2-naphthylmyristate, L-valyl-2-naphthylamide, *N*-benzoyl-DL-arginine-2-naphthylamide, *N*-glutaryl-phenylalanine-2-naphthylamide, 6-bromo-2-naphthyl-α-D-galactopyranoside, 2-naphthyl-β-D-galactopyranoside, naphthol-AS-BI-β-D-glucuronate, 2-naphthyl-α-D-glucopyranoside, 6-bromo-2-naphthyl-β-D-glucopyranoside, 1-naphthyl-*N*-acetyl-β-D-glucosaminide, 6-bromo-2-naphthyl-α-D-mannopyranoside, and 2-naphthyl-α-L-fucopyranoside.

Enrichment and Isolation Procedures

The type strain was isolated from soil enriched with acetamide in Delft in the Netherlands in 1926. Since then the bacterium has been shown to be ubiquitous. Strains have been isolated from soil, soil enriched with indole, soil enriched with *p*-hydroxybenzoate, sediment, activated sludge, sludge enriched with testosterone, crude oil, oil brine, water, and various clinical samples such as urine, pus, and pharyngeal swabs (Willems et al., 1991c). There is increasing evidence of the diverse metabolic capability of *Delftia* in the environment, particularly with respect to the degradation and mineralization of xenobiotic pollutants such as aniline, 2-chloroaniline, and 3-chloroaniline (Ferschl et al., 1991, Hinteregger et al., 1994; Boon et al., 2001), and the enantiomers of 2-(4-sulfophenyl)butyrate (Schulz et al., 2000).

Maintenance Procedures

Cultures are easily maintained on nutrient agar in the laboratory. Cryogenic storage in liquid nitrogen in nutrient broth containing 10% glycerol, and by freeze drying in glucose peptone broth containing horse serum are successful for long-term preservation of *Delftia* cultures.

Differentiation of the genus *Delftia* from other genera

The characteristics for differentiating *Delftia* from other members of the *Comamonadaceae* are given in Table BXII.β.50.

Taxonomic Comments

Phylogenetically, *Delftia* belongs to the family *Comamonadaceae* in the class *Betaproteobacteria* according to DNA–rRNA hybridization (Willems et al., 1991a) and rDNA sequence analysis (Wen et al., 1999) (Fig. BXII.β.29). The type species *Delftia acidovorans* belongs to a deep distinct branch. Although the position of the *Delftia acidovorans* branch is not well supported by bootstrap analysis, *D. acidovorans* is consistently the only member of the branch that does not cluster with species of *Comamonas*—where it had been assigned until its transfer to *Delftia* by Wen et al. (1999). The separation of *D. acidovorans* from *Comamonas* is supported by results from DNA–rRNA hybridization (Willems et al., 1991c), 16S rRNA cataloging (Woese et al., 1984a, c), 16S rDNA sequences (Wen et al., 1999), and conventional and chemotaxonomic methods (Tamaoka et al., 1987).

List of species of the genus Delftia

1. **Delftia acidovorans** (den Dooren de Jong 1926) Wen, Fegan, Hayward, Chakraborty and Sly 1999, 573[VP] (*Pseudomonas acidovorans* den Dooren de Jong 1926, 106; *Comamonas acidovorans* (den Dooren de Jong 1926) Tamaoka, Ha and Komagata 1987, 58.)
a.ci.do' vo.rans. L. neut. n. *acidum* acid; L. v. *voro* to devour; M.L. part. adj. *acidovorans* acid devouring.

The characteristics are the same as for the genus and as given in Table BXII.β.50. Strains have been isolated from soil, sediment, activated sludge, crude oil, oil brine, water, and various clinical samples.

The mol% G + C of the DNA is: 67 (T_m).

Type strain: Stanier 14, ACM 489, ATCC 15668, DSM 39, IAM 12409, IMET 10620, JCM 5833, KS 0057, LMG 1226, NCIB 9681.

GenBank accession number (16S rRNA): AF078774, AB021417.

Genus V. **Hydrogenophaga** *Willems, Busse, Goor, Pot, Falsen, Jantzen, Hoste, Gillis, Kersters, Auling and De Ley 1989, 329*[VP]

ANNE WILLEMS AND MONIQUE GILLIS

Hy.dro.ge.no'pha.ga. Gr. n. *hydro* water; Gr. n. *gennao* to create; M.L. *hydrogenum* hydrogen, that which produces water; Gr. v. *phagein* to eat; M.L. fem. n. *Hydrogenophaga* eater of hydrogen.

Straight to slightly curved rods, 0.3–0.6 × 0.6–5.5 µm, occurring singly or in pairs. **Gram negative. Motile by means of one or, rarely, two polar to subpolar flagella.** Colonies are yellow due to the presence of **carotenoid pigments**. **Aerobic. Oxidase positive** and **catalase positive**, except for *H. pseudoflava*, which is catalase variable. **Chemoorganotrophic or chemolithoautotrophic**, using the oxidation of H_2 as an energy source and CO_2 as a carbon source. Oxidative carbohydrate metabolism occurs, with oxygen as the terminal electron acceptor; alternatively, two species (*H. pseudoflava* and *H. taeniospiralis*) are capable of **heterotrophic denitrification** of nitrate. Good growth occurs on media containing organic acids, amino acids, or peptone; there is less versatility in the use of carbohydrates. Cellular lipids contain 3-hydroxyoctanoic acid ($C_{8:0\ 3OH}$) either alone or together with 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$); 2-hydroxy-substituted fatty acids are absent. **Ubiquinone Q-8** is the main quinone. Putrescine and 2-hydroxyputrescine are present in approximately equimolar concentrations, either exclusively or as the dominant polyamines.

The mol% G + C of the DNA is: 65–69.

Type species: **Hydrogenophaga flava** (Niklewski 1910) Willems, Busse, Goor, Pot, Falsen, Jantzen, Hoste, Gillis, Kersters, Auling, and De Ley 1989, 329 (*Pseudomonas flava* (Niklewski 1910) Davis, Doudoroff, Stanier, and Mandel 1969, 385; *Hydrogenomonas flava* Niklewski 1910, 123.)

FURTHER DESCRIPTIVE INFORMATION

Flagellation *Hydrogenophaga* cells have one or, rarely, two flagella with polar or subpolar insertion. Aragno et al. (1977) have defined three types of flagella in Gram-negative bacteria based on fine structural details as revealed by electron microscopy. They have reported the flagellar fine structure of *Hydrogenophaga flava* and *Hydrogenophaga palleronii* to be of type I, with flagella having diameters of 13.5–14.0 nm and 14–16 nm, respectively, and wavelengths of 1.2–1.3 µm and 1.2–2.0 µm, respectively. For *Hydrogenophaga pseudoflava*, the flagellar diameter is 13.5–14.0 nm and the wavelength is 1.4–1.9 µm, but the interpretation of flagellar fine structure is uncertain. Pili occur over the total cell surface in *H. flava* and *H. pseudoflava* and are inserted at the polar caps in *H. palleronii* (Aragno et al., 1977) and *Hydrogenophaga taeniospiralis* (Lalucat et al., 1982).

Cell wall composition Walther-Mauruschat et al. (1977) have distinguished three types of cell walls in Gram-negative bacteria, differing mainly in the visibility and location of the peptidoglycan layer. *Hydrogenophaga* possesses type I cell walls, typical of most Gram-negative bacteria, in which the outer membrane and the cytoplasmic membrane are of similar dimensions and appearance and are separated by a dense peptidoglycan layer (Walther-Mauruschat et al., 1977). Cytochromes of the *a*, *b*, and *c* types are present in the membrane fraction, and cytochrome *c* is found in the soluble fraction of autotrophically or heterotrophically grown cells of *H. pseudoflava*, autotrophically grown cells of *H. taeniospiralis*, and heterotrophically grown cells of *H. palleronii* and *H. pseudoflava* (Auling et al., 1978; Lalucat et al., 1982). In addition, *Hydrogenophaga taeniospiralis* contains cytochrome *a* in the soluble fraction (Lalucat et al., 1982), and *H. pseudoflava* contains small amounts of cytochrome *d* when grown autotrophically (Auling et al., 1978).

Fine structure Intracellular mesosome-like membrane systems with a spiral appearance, often located in the area of cell division or at the cell poles, have been reported in *H. flava*, *H. pseudoflava*, and *H. palleronii* (Walther-Mauruschat et al., 1977). The significance of these structures is unclear, and there are indications they may be artifacts resulting from preparation of cells for electron microscopy. Intracellular inclusions of poly-β-hydroxybutyrate and polyphosphate are present, and translucent glycogen-like inclusions may also be detected (Walther-Mauruschat et al., 1977; Lalucat et al., 1982). *H. taeniospiralis* has been reported to contain R-bodies, which are inclusion bodies consisting of a proteinaceous ribbon that is rolled up to form a hollow cylinder. The function of these structures remains uncertain. Similar structures have been described in some kappa-particles, the endosymbionts in killer paramecia, where they are thought to be involved in toxin release (Lalucat et al., 1982).

Pigments Colonies on nutrient agar are yellow due to the presence of carotenoid pigments. Their absorption maxima in acetone have been reported to be approximately 405, 425, and 446 nm for *H. pseudoflava* (Auling et al., 1978) and *H. palleronii* (Davis et al., 1970; Auling et al., 1978) and approximately 440 and 465 nm for *H. flava* (Davis et al., 1970). More recently, Urakami et al. (1995a) have reported an absorption maximum of 450 nm for the carotenoid pigments of all *Hydrogenophaga* species except *H. taeniospiralis*, for which no absorption spectrum has been determined.

Nutrition and metabolism A variety of organic compounds can be used as sole carbon sources (Tables BXII.β.51 and BXII.β.52). In general, *H. palleronii* is less versatile in its carbohydrate usage than are the other *Hydrogenophaga* species (Willems et al., 1989). The carbohydrate metabolism of *H. pseudoflava* has been studied, and doubling times in various growth conditions have been determined. Glucose and fructose are degraded via the Entner–Doudoroff pathway and 6-phosphogluconate dehydrogenases are not detected in this species (Lee and Schlegel, 1981). Protocatechuate is cleaved via the *meta* mechanism by *H. palleronii* and *H. flava* (Davis et al., 1970); no data are available for the other two species. No organic growth factors are required. All *Hydrogenophaga* species are facultatively chemolithoautotrophic, using the oxidation of hydrogen as an energy source. Hydrogenase is membrane-bound and does not reduce NAD (Aragno and Schlegel, 1992). Some strains of *H. pseudoflava* are capable of nitrogen fixation and carry genes homologous to *Klebsiella pneumoniae nifHDK* genes. It is therefore assumed that the *nif* genes are located on the chromosome (Jenni et al., 1989). Such nitrogen-fixing strains are isolated under heterotrophic selection conditions with combined nitrogen (Jenni et al., 1989). The strains of *H. pseudoflava* that were previously named *"Pseudomonas carboxydoflava"* are capable of autotrophic growth using CO or hydrogen oxidation as an energy source. These organisms can also grow mixotrophically, using the oxidation of CO or hydrogen as an additional energy source while growing hetero-

[b]Data from Lalucat et al. (1982), Palleroni (1984), Jenni et al. (1989), and Willems et al. (1989).

trophically (Kiessling and Meyer, 1982). The CO dehydrogenase from *H. pseudoflava* is a molybdenum-containing iron–sulfur flavoprotein with molybdopterin cytosine dinucleotide as the molybdenum cofactor (Tachil and Meyer, 1997). Urothine, which is excreted by *H. pseudoflava*, is produced through the degradation of this cofactor (Volk et al., 1994). *H. pseudoflava* produces poly(3-hydroxybutyrate) when grown on glucose, xylose, or arabinose as the sole carbon source. With propionic acid as a cosubstrate, co-polymers of 3-hydroxybutyric and 3-hydroxyvaleric acids are produced (Bertrand et al., 1990). When grown on combined substrates of glucose and lactones, *H. pseudoflava* strains also accumulate large amounts of copolyesters. The copolyester produced depends on the lactone cosubstrate provided: γ-butyrolactone yields poly(3-hydroxybutyrate-co-4-hydroxybutyrate), while γ-valerolactone yields poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (Choi et al., 1995b). *H. palleronii* strain S1 has been reported to break down 4-aminobenzenesulfonate (sulfanilate) in coculture with *Agrobacterium radiobacter* strain S2. Strain S1 fails to grow as an axenic culture in a mineral medium with the same carbon source, but does grow on this substrate after addition of either a sterile supernatant from strain S2 or a combination of 4-aminobenzoate, biotin, and vitamin B_{12} (Dangmann et al., 1996).

Other biochemical characteristics *Hydrogenophaga* species possess a Q-8 ubiquinone system (Willems et al., 1989; Urakami et al., 1995a). Putrescine and hydroxyputrescine are the main polyamines and are present in approximately equimolar amounts; in addition, *H. pseudoflava* contains small amounts of spermidine and spermine (Willems et al., 1989). Major fatty acids (representing at least 7% of total fatty acids) are palmitic acid ($C_{16:0}$), palmitoleic acid ($C_{16:1}$), and *cis*-vaccenic acid ($C_{18:1\ \omega 7c}$). No 2-hydroxy substituted fatty acids are present, but all species contain small amounts (1–5%) of 3-hydroxyoctanoic acid ($C_{8:0\ 3OH}$), and *H. flava* and *H. pseudoflava* contain small amounts (1–6%) of 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$) (Willems et al., 1989; Urakami et al., 1995a). In addition, *H. pseudoflava*, *H. taeniospiralis*, and *H. palleronii* contain about 2%, 5%, and 10–20 %, respectively, of a cyclopropane substituted fatty acid ($C_{17:0\ cyclo}$) (Willems et al., 1989).

Plasmids Two plasmids have been found in *"Pseudomonas carboxydoflava"* (Gerstenberg et al., 1982; Kraut and Meyer, 1988), now incorporated into *H. pseudoflava*. Plasmids have not been detected in *H. pseudoflava* strains previously classified as *Pseudomonas pseudoflava* (Gerstenberg et al., 1982; Jenni et al., 1989) or in *H. palleronii* (Gerstenberg et al., 1982).

Phages Auling et al. (1978) have tested susceptibility of *H. pseudoflava*, *H. palleronii*, and *H. flava* strains to a number of temperate phages that were isolated originally from autotrophically grown *Pseudomonas pseudoflava* strains. The bacteriophages have a very restricted host range, showing no effects on *H. flava*, *H. palleronii*, *Variovorax paradoxus*, or *Ralstonia eutropha*. Lalucat et al. (1982) have reported that old heterotrophically-grown cultures of *H. taeniospiralis*, when treated with mitomycin C, occasionally contain phage tails and empty phage-head-like particles, and even complete phages with contracted tails in one instance. Suspensions of these structures do not have a lytic effect on any of the four *Hydrogenophaga* species, nor on *V. paradoxus*. The use of ultraviolet light or a temperature shift does not induce the formation of similar phage-like structures. The presence of defective phages in *H. taeniospiralis* may be seen as an argument in favor of the hypothesis that the characteristic R-bodies present in this species may be coded by defective phages, in analogy to a hypothesis put forward to explain the presence of R-bodies in *Caedibacter*, obligate endosymbionts of certain species of paramecia (Lalucat et al., 1982).

Antibiotic sensitivity Most *Hydrogenophaga* species are susceptible to a wide range of antibiotics and bacteriostatic agents (Auling et al., 1978). Table BXII.β.52 contains a detailed listing of antibiotic sensitivities for all species, except *Hydrogenophaga taeniospiralis*, for which few such data are available.

Ecology *Hydrogenophaga* species occur in water, mud, and soil, from which they are usually isolated using enrichment procedures for autotrophic hydrogen oxidizers. All strains isolated are initially capable of autotrophic growth, but some species, such as the type species *Hydrogenophaga flava*, may lose this ability. Nitrogen fixation has been reported in some strains of *H. pseudoflava*, but not in the type strain. *Hydrogenophaga* strains are among the bacteria detected in biofilms in a sand filter used for denitrification of treated waste water and occur in both aerobic and anoxic conditions (Lemmer et al., 1997). *Hydrogenophaga* strains are present in the culturable microbial flora isolated from a waste-oil contaminated site during the course of a 2-year bio-

[b]Data taken from Auling et al. (1978), Aragno and Schlegel (1992), Davis et al. (1969, 1970), Palleroni (1984), and Willems et al. (1989). All strains can grow at 30°C and use nitrate as sole nitrogen source and grow on the following substrates: D-malate, DL-β-hydroxybutyrate, fumarate, pyruvate, succinate, gluconate, lactate, glucose, glycerol, *m*-inositol, L-aspartate, L-glutamate, L-malate, and L-proline. None of the strains hydrolyzes starch or poly-β-hydroxybutyrate, possesses arginine dihydrolase or produces acid from ribose. All strains fail to grow on caprate, caprylate, heptanoate, maleate, malonate, mesaconate, *o*-hydroxybenzoate, pelargonate, D-mandelate, isophthalate, adonitol, erythritol, inulin, starch, D-tryptophan, creatine, betaine, histamine, acetamide, sarcosine, and tryptamine.

remediation program (Kämpfer et al., 1993). The mineralization and colonization of palmitic acid by *H. pseudoflava* has been studied to investigate the role of bacterial colonization in the degradation of water-insoluble organic compounds (Thomas and Alexander, 1987). In a study on the influence of temperature on the growth rate of and competition among psychrotolerant Antarctic bacteria, *H. pseudoflava* was used as a model organism in a coculture with a *Brevibacterium* strain (Nedwell and Rutter, 1994). Studies of the biphenyl and polychlorinated biphenyl (PCB)-degrading bacteria isolated from a PCB-contaminated site have identified *H. pseudoflava* as a minor component of the microflora dominated by *Comamonas testosteroni* (Joshi and Walia, 1995). A root-growth promoting effect is attributed to *H. pseudoflava* strains occurring in the rhizosphere of hybrid spruce seedlings (Chanway and Holl., 1993).

Enrichment and Isolation Procedures

Facultatively chemolithotrophic H_2-oxidizing strains of *Hydrogenophaga* can be isolated from soil, mud, or water by enrichment in a mineral medium, when incubated under an atmosphere composed of H_2, O_2, and CO_2. Many of the earlier isolates were obtained using the liquid basal mineral medium[1] described by Palleroni and Doudoroff (1972). After inoculation, cultures are incubated at 30°C under an atmosphere of $H_2/O_2/CO_2/N_2$ (50:4–20:5:25–41) (Davis et al., 1970). A varying proportion of *H. pseudoflava* strains isolated under these conditions may be capable of N_2 fixation, despite the presence of organic nitrogen in the medium (Jenni et al., 1989). Nitrogen-fixing *H. pseudoflava* strains have also been isolated from nitrogen-limited soils that were flushed with a gas mixture composed of $H_2/O_2/CO_2/N_2$ (10:5:55:30) (Aragno and Schlegel, 1992). Heterotrophic strains can be isolated from soil by enrichment with pantothenate (Davis et al., 1970) or poly-β-hydroxybutyrate (Delafield et al., 1965). Other strains have been isolated from soil and water samples using various complex chemicals for enrichment (Komagata et al., 1997; Suyama et al., 1998a; Thomas et al., 1998).

Maintenance Procedures

Hydrogenophaga strains can be maintained under autotrophic or heterotrophic conditions, but autotrophic properties may be lost under a prolonged heterotrophic regime, and it may therefore be advisable to maintain cultures under autotrophic conditions. In particular, *H. flava* has been reported to have lost its capacity for autotrophic hydrogen oxidation (Kluyver and Manten, 1942). In general, autotrophic cultures of hydrogen-oxidizing bacteria remain viable for up to 6 months at 4°C, the exception being *H. pseudoflava*, which requires transferring about every 2 months (Aragno and Schlegel, 1992). For heterotrophic growth, convenient media, such as nutrient agar, can be used; for the maintenance of specific metabolic properties, special selective media may be required.

Hydrogenophaga strains can be lyophilized in skim milk in the presence of a suitable cryoprotectant, such as 5% glutamate, 5% *meso*-inositol, or 10% honey (Aragno and Schlegel, 1992). For preservation of the autotrophic properties, autotrophically grown cells should be used for lyophilization. The use of activated charcoal (5%, w/v) in the suspension medium, together with skim milk (20%, w/v) and raffinose or *meso*-inositol (5% w/v), is also reported to result in good recovery of *Hydrogenophaga* strains after lyophilization (Malik, 1990b).

Differentiation of the genus *Hydrogenophaga* from other genera

See Table BXII.β.42 for the family *Comamonadaceae* for features differentiating *Hydrogenophaga* from other genera.

An oligonucleotide probe for the genus *Hydrogenophaga*, located in variable region II of the 16S rRNA gene, has been designed and shown to allow differentiation from the species of *Comamonas* and *Acidovorax* when hybridized in the presence of 30% formamide (Amann et al., 1996).

Taxonomic Comments

The genus *Hydrogenophaga* consists of four species previously classified in the genus *Pseudomonas*. Earlier still, one of those species, *Pseudomonas flava*, was classified in *Hydrogenomonas*, a large genus containing Gram-negative, facultatively autotrophic, hydrogen bacteria. Davis et al. (1969) proposed that this genus should be abandoned and transferred the various species to other genera. The yellow-pigmented *Hydrogenomonas flava* was transferred to the genus *Pseudomonas*. Several other species of yellow-pigmented hydrogen oxidizers have subsequently been described in the genus *Pseudomonas*. Davis et al. (1970) created *Pseudomonas palleronii*, which differed from *Pseudomonas flava* in its carotenoid pigments and its inability to grow on a number of carbohydrates. Auling et al. (1978) described *Pseudomonas pseudoflava*, a species highly related to *Pseudomonas flava*, and Lalucat et al. (1982) described *Pseudomonas taeniospiralis*, a species containing characteristic R-bodies. By DNA–rRNA hybridizations, the genus *Pseudomonas* was later shown to consist of five distinct groups, which were only remotely related and could not be maintained in a single genus (Palleroni et al., 1973; De Vos and De Ley, 1983). This initiated a gradual removal of species from this genus as new data became available, leading to a classification reflecting phylogenetic relationships. The yellow hydrogen-oxidizing *Pseudomonas* species belonged to the acidovorans rRNA complex, together with a number of other taxa. Based on genotypic, phenotypic, and chemotaxonomic data, it was shown that they were more closely related to each other than to the other members of the acidovorans rRNA complex, and, therefore, a new genus *Hydrogenophaga* was proposed to accommodate them (Willems et al., 1989). More recently, analysis of the 16S rRNA genes of members of the *Comamonadaceae* has confirmed that the genus *Hydrogenophaga* forms a separate cluster in this family (Wen et al., 1999).

Several strains or groups of strains very similar to, but different from, *H. pseudoflava* have been described. They may represent additional separate species, but so far have not been formally named. For instance, Davis et al. (1969) have described *Pseudomonas* strain 450, isolated from soil in Berkeley, California, as being similar to, but phenotypically distinct from, *Pseudomonas flava*. The main differences are its ability to grow autotrophically in the presence of 20% O_2 and its use of a wider variety of carbohydrates for growth. These characteristics also distinguish *H. flava* from *H. pseudoflava* (Auling et al., 1978). A comparison of the metabolic properties of strain 450 and *H. pseudoflava* shows that they are quite similar, the main differences being the absence of denitrification in strain 450 and its inability to use *p*-hydroxybenzoate, phenol, quinate, D-alanine, or L-tryptophan. Auling et al. (1978) did not include this strain in their study when they described *Pseudomonas pseudoflava*, so the precise classification of strain 450 remains uncertain.

1. Basal mineral medium consists of 0.033 M Na-K phosphate buffer, pH 6.8; 0.1% NH_4Cl; 0.05% $MgSO_4 \cdot 7H_2O$; 0.005% ferric ammonium citrate; and 0.0005% $CaCl_2$ (Palleroni and Doudoroff, 1972).

DNA–DNA hybridizations have confirmed that *H. flava* and *H. pseudoflava* are highly related species, with levels of DNA-binding of 48–62%, whereas *H. palleronii* and *H. taeniospiralis* are clearly separate species, each showing no significant DNA-binding with the other *Hydrogenophaga* species (Willems et al., 1989). No significant DNA binding has been detected between representative strains of *Hydrogenophaga* species and *Variovorax paradoxus*, another yellow-pigmented, hydrogen-oxidizing genus of the *Comamonadaceae* (Willems et al., 1991a). In line with these data, comparison of the 16S rRNA gene sequences of the type strains of the *Hydrogenophaga* species demonstrates that *H. flava* and *H. pseudoflava* are highly related (sequence similarity 99.1%; Wen et al., 1999).

Several strains similar to *Pseudomonas pseudoflava* have been isolated from water of a freshwater eutrophic lake by membrane filtration and incubation on mineral medium containing NH_4Cl and pyruvate under an atmosphere of H_2 and O_2. Most of these strains are capable of N_2 fixation, and by phenotypic comparison and DNA–DNA hybridization, they are similar to, but distinct from, *Pseudomonas pseudoflava* (Jenni et al., 1989). Comparison of published phenotypic data for these strains (Aragno and Schlegel, 1992) with those for strain 450, *H. flava*, and *H. pseudoflava* shows this group to be distinguishable. More genotypic data are required to assess whether it represents a separate species.

Differentiation of the species of the genus *Hydrogenophaga*

Characteristics useful in differentiating the various species of *Hydrogenophaga* are listed in Table BXII.β.52.

List of species of the genus Hydrogenophaga

1. **Hydrogenophaga flava** (Niklewski 1910) Willems, Busse, Goor, Falsen, Jantzen, Hoste, Gillis, Kersters, Auling and De Ley 1989, 329[VP] (*Pseudomonas flava* (Niklewski 1910) Davis, Doudoroff, Stanier and Mandel 1969, 385; *Hydrogenomonas flava* Niklewski 1910, 123.)
fla′ va. L. fem. adj. *flava* yellow.

The characteristics are as described for the genus and as listed in Tables BXII.β.51 and BXII.β.52. Optimal temperature, 30°C.

The only available strain was isolated from mud from a ditch.

The mol% G + C of the DNA is: 66.7 (T_m).and 67.3 (Bd).

Type strain: ATCC 33667, CCUG 1658, DSM 619, LMG 2185.

GenBank accession number (16S rRNA): AF078771.

Additional Remarks: This strain has been reported to have lost its ability to grow autotrophically soon after isolation (Kluyver and Manten, 1942) and to grow rather slowly and unreliably (Auling et al., 1978). Therefore, *Hydrogenophaga pseudoflava*, a genotypically and protein electrophoretically very similar species, has been suggested as an alternative reference species for the genus (Willems et al., 1989). However, in later experiments the *H. flava* LMG 2185[T] did grow well autotrophically using H_2 as its energy source (A. Willems, unpublished observation).

2. **Hydrogenophaga intermedia** Contzen, Moore, Blümel, Stolz and Kämpfer 2001, 793[VP] (Effective publication: Contzen, Moore, Blümel, Stolz and Kämpfer 2000, 492.)
in.ter.me′ di.a. L. neut. adj. *intermedium* intermediate, referring to the phylogenetic position of this organism within the genus *Hydrogenophaga*.

The characteristics are the same as those of the genus. This species is not included in Tables BXII.β.51 and BXII.β.52 because it was published after the completion of the chapter. The description below is taken from the original description (Contzen et al., 2000).

H. intermedia is not able to grow chemolithoautotrophically with H_2. The overall polar lipid pattern is characterized by nearly equal amounts of phosphatidylglycerol, phosphatidylethanolamine, and diphosphatidylglycerol. The fatty acid pattern is typical of the genus *Hydrogenophaga* and includes 3-hydroxyoctanoic acid ($C_{8:0\ 3OH}$). The presence of $C_{19:0\ cyclo\ \omega 8\text{-}9}$ differentiates *H. intermedia* from other *Hydrogenophaga* species.

Colonies are circular, entire, slightly convex, smooth, and pale yellow on YPG agar at 25°C. Growth at 40°C, but not at 10°C. The following compounds can be used as sole carbon sources: gluconate, D-mannitol, adipate, lactate, 3-hydroxybutyrate, 2-oxoglutarate, suberate, L-leucine, phenylalanine, L-proline, 3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate. Hydrolysis of L-alanine-pNA positive. The type strain does not utilize: *N*-acetyl-D-glucosamine, L-arabinose, arbutin, D-cellobiose, D-fructose, D-galactose, D-glucose, maltose, D-mannose, D-melibiose, L-rhamnose, ribose, sucrose, salicin, trehalose, D-xylose, adonitol, inositol, sorbitol, putrescine, acetate, propionate, *cis*-aconitate, *trans*-aconitate, 4-aminobutyrate, azelate, citrate, fumarate, glutarate, itaconate, D-malate, mesaconate, pyruvate, L-alanine, β-alanine, L-aspartate, L-histidine, L-leucine, L-ornithine, L-serine, and L-tryptophan as sole carbon sources. Hydrolysis of the following substrates is negative: pNP-α-D-glucopyranoside, pNP-β-D-glucopyranoside, pNP-β-D-galactopyranoside, pNP-β-D-glucuronide, pNP-phenylphosphonate, pNP-phosphorylcholine, 2-deoxythymidine-5′-pNP-phosphate, glutamate-γ-3-carboxy-pNP-ester, and L-proline-pNP.

Features for the differentiation from other *Hydrogenophaga* species include the use of mannitol (negative in *H. palleroni*) and the inability to use the following substrates: L-arabinose, sucrose, D-galactose, D-fructose, D-mannose, sorbitol, and D-cellobiose (positive for *H. flava*, *H. pseudoflava* and *H. palleroni*), maltose and L-histidine (positive for *H. flava* and *H. pseudoflava*), azelate (positive for *H. pseudoflava*, *H. taeniospiralis* and *H. palleroni*) and D-xylose (positive for *H. pseudoflava* and *H. taeniospiralis*).

The mol% G + C of the DNA is: 68.6 ± 0.1 (HPLC).

Type strain: S1, DSM 5680.

GenBank accession number (16S rRNA): AF019037.

3. **Hydrogenophaga palleronii** (Davis, Stanier, Doudoroff and Mandel 1970) Willems, Busse, Goor, Falsen, Jantzen, Hoste, Gillis, Kersters, Auling and De Ley 1989, 330[VP] (*Pseudomonas palleronii* Davis, Stanier, Doudoroff and Mandel 1970, 11.)
pal.le.ro' ni.i. M.L. gen. n. *palleronii* of Palleroni, named after N.J. Palleroni, who first isolated this organism.

The characteristics are as described for the genus and as listed in Tables BXII.β.51 and BXII.β.52. In addition, some strains have been reported to grow on DL-norleucine (Willems et al., 1989). Optimal temperature is 30°C.

Isolated from soil and water by enrichment for hydrogen autotrophs in minimal media with an atmosphere of $H_2/O_2/CO_2$.

The mol% G + C of the DNA is: 67.3–68.5 (T_m).

Type strain: Stanier 362, ATCC 17724, DSM 63, LMG 2366.

GenBank accession number (16S rRNA): AF019073.

Additional Remarks: This strain contains two stable colony types, which have identical gel electrophoretic protein profiles.

4. **Hydrogenophaga pseudoflava** (Auling, Reh, Lee and Schlegel 1978) Willems, Busse, Goor, Falsen, Jantzen, Hoste, Gillis, Kersters, Auling and De Ley 1989, 330[VP] (*Pseudomonas pseudoflava* Auling, Reh, Lee and Schlegel 1978, 93.)
pseu.do.fla' va. Gr. adj. *pseudes* false; L. fem. adj. *flava* yellow; M.L. fem. adj. *pseudoflava* not the true (*Hydrogenophaga*) *flava*, referring to the close relationship to *Hydrogenophaga flava*.

The characteristics are as described for the genus and as listed in Tables BXII.β.51 and BXII.β.52. In addition, none of the strains tested produce indole, H_2S in triple sugar iron medium, or acid from 10% lactose and triple sugar iron medium. All strains fail to grow on allantoin, DL-threonine, salicylate, 2-methyl-2-propanol, and uric acid, but do grow on L-glutamine and shikimic acid.

Some *H. pseudoflava* strains, but not the type strain, are capable of N_2 fixation (Jenni et al., 1989). The strains previously classified as *"Pseudomonas carboxydoflava"* are capable of mixotrophic growth on organic substrates and CO or H_2 and CO_2. For CO-autotrophic growth, the presence of molybdopterin cytosine dinucleotide is required as a cofactor (Meyer and Schlegel, 1983; Volk et al., 1994).

H. pseudoflava is highly related to *H. flava* (DNA homology values 48–62%; Willems et al., 1989), but can be distinguished by its ability to grow at higher temperatures (up to 41°C) and at oxygen concentrations of 20% and by its ability to use a wider variety of substrates for growth (Auling et al., 1978).

Optimal temperature is 35–38°C.

Isolated from soil, mud, or water by liquid enrichment for hydrogen bacteria in an atmosphere consisting of $O_2/CO_2/H_2$ (10:10:80).

The mol% G + C of the DNA is: 66.2–68.6 (T_m).

Type strain: GA3, ATCC 33668, CCUG 13799, DSM 1034, LMG 5945.

GenBank accession number (16S rRNA): AF078770.

5. **Hydrogenophaga taeniospiralis** (Lalucat, Parés and Schlegel 1982) Willems, Busse, Goor, Falsen, Jantzen, Hoste, Gillis, Kersters, Auling and De Ley 1989, 330[VP] (*Pseudomonas taeniospiralis* Lalucat, Parés and Schlegel 1982, 337.)
tae.ni.o.spi.ra' lis. Gr. n. *taenia* ribbon; L. adj. *spiralis* coiled; M.L. adj. *taeniospiralis* ribbon coiled, after *Caedibacter taeniospiralis*, an organism with which it shares characteristics.

The characteristics are as described for the genus and as listed in Tables BXII.β.51 and BXII.β.52. In addition, this species does not produce indole or acetoin, or H_2S from cysteine, and it does not grow on D-sorbose. No strains able to fix N_2 have been reported. A variable portion of cells in stationary growth phase may contain inclusions, referred to as R-bodies, which are coiled proteinaceous ribbons with an average diameter of 0.25 μm and an average height of 0.21 μm. Similar structures have been described in *Caedibacter taeniospiralis*, a bacterial endosymbiont of *Paramecium*. These R-bodies are thought to originate from defective prophages and extrachromosomal DNA elements and to be involved in conferring the killer trait upon the host paramecium (Lalucat et al., 1982). The R-bodies of *Caedibacter* species have been shown to be quite different from those of *H. taeniospiralis* (Kanabrocki et al., 1986), but the fact that a defective prophage has been detected in *H. taeniospiralis* indicates a possible similar origin in this species (Lalucat et al., 1982).

Optimal temperature is 37°C.

Isolated from soil in Spain.

The mol% G + C of the DNA is: 65.0 (T_m).

Type strain: 2K1, ATCC 49743, CCUG 15921, DSM 2082, LMG 7170.

GenBank accession number (16S rRNA): AF078768.

Genus VI. **Lampropedia** *Schroeter 1886, 151[VP]*

R.G.E. Murray

Lam.pro.pe' di.a. Gr. adj. *lampros* bright, radiant; Gr. n. *pedia* a plain, flat country; M.L. fem. n. *Lampropedia* a shining flat sheet (of cells).

Sheets of rounded, almost cubical cells, arranged in square tablets of 16–64 cells, occasionally separated into pairs or tetrads. **Divide synchronously in a sheet and alternately in two planes.** The cells of a tablet are enclosed within a **complex, structured envelope**. Each cell is enclosed in a **Gram-negative type of cell wall**. Intracellular granules of **poly-β-hydroxybutyrate** are prominent. No flagella occur. **Twitching movements** of small groups of cells occur during active growth. **Obligately aerobic**, having a strictly respiratory type of metabolism with oxygen serving as the terminal electron acceptor. **Growth occurs as a thin, hydrophobic, extending pellicle** on the surface of both liquid and solid media. Nonpigmented. Optimal temperature, 30°C. Optimal pH, 7.0. Oxidase and catalase positive. Chemoorganotrophic. **Energy sources are limited to intermediates of the tricarboxylic acid cycle.** Carbohydrates, alcohols, glucosides, and fatty acids are not utilized. Ammonium salts or certain amino acids can serve as sole nitrogen sources. **Vitamins may be required for growth.** The ecological niche is unknown but observations and isolations indicate an environment rich in organic matter.

The mol% G + C of the DNA is: 61 (Bd).

Type species: **Lampropedia hyalina** (Ehrenberg 1832) Schroeter 1886, 151 (*Gonium hyalinum* Ehrenberg 1832, 63.)

Further descriptive information

This is a genus based mainly on morphological characteristics, and it consists of a single species, *L. hyalina*. The organism is cultivable and strains are available for study. Three other species have been named in the distant past (de Toni and Trevisan, 1889), including pigmented species, but they have not been reisolated in the intervening years and have no validity today.

The characteristic appearance of growth is a hydrophobic pellicle consisting of square tablets of Gram-negative cells, apparently dividing synchronously in two planes (Fig. BXII.β.30), forming continuous but rumpled sheets on the surface of media (Kuhn and Starr, 1965; Puttlitz and Seeley, 1968; Seeley, 1974).

The distinctive morphology (Fig. BXII.β.30) allows recognition in its natural surroundings. In rich organic environments, and especially in laboratory media loaded with sodium acetate, the cells are full of poly-β-hydroxybutyrate (PHB) (see Fig. BXII.β.31) as several small granules or one large granule (Kuhn and Starr, 1965).

L. hyalina exhibits a peculiar form of motility involving sudden, irregular shifts in the position of small groups of cells. Pringsheim (1955) and Puttlitz and Seeley (1968) describe this phenomenon, and it has been compared (Pringsheim, 1966) to movements seen in the *Chroococcales* as an argument for relationship to cyanobacteria. However, such a "twitching" motility is also seen in other nonflagellated bacteria and most of them have fimbriae (Henrichsen, 1972). *Lampropedia* strains have not been shown to have either flagella or fimbriae. Twitching, generally (Henrichsen, 1972) and in this case (Puttlitz and Seeley, 1968), is a function of living, metabolizing cultures.

The cell wall is of the Gram-negative type with an outer membrane and a thin, underlying peptidoglycan layer. It has not been isolated and characterized in chemical terms. All layers of this wall intrude at once to separate the sister cells (Fig. BXII.β.32).

The structure of the cells is not remarkable, but the envelope that encloses each tablet of cells has unusual features (Chapman et al., 1963; Murray, 1963; Pangborn and Starr, 1966). The separate tablets of 16, 32, or 64 cells are surrounded by a hexagonal array of complex spindle-shaped units (spacing is 23–26 nm) on a thin continuous but perforated layer (7.5 nm holes; spacing is 13.5–14.5 nm). This highly structured integument bridges over the spaces between the cells in the tablet (Fig. BXII.β.31). The space between cells, between the walls and the structured envelope, and within the intruding septa (Figs. BXII.β.31 and BXII.β.32) contains fibrous materials and is called the intercalated layer. Two layers form the enveloping structure and each have p6 symmetry: an outer complex of three polypeptides joined

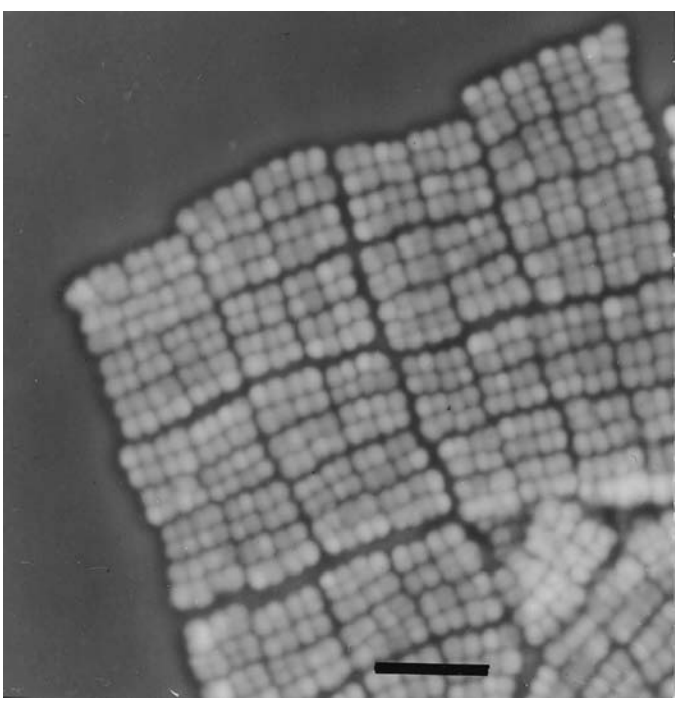

FIGURE BXII.β.30. Light micrograph of a nigrosin preparation of *L. hyalina* showing a corner of a sheet of actively growing tablets of cells. Adjacent tablets are almost synchronized in division. Bar = 5 μm.

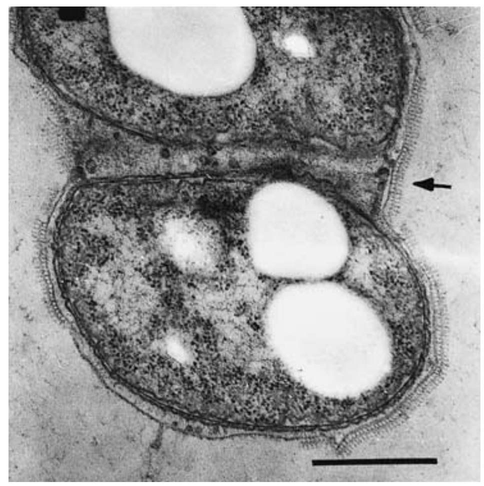

FIGURE BXII.β.31. Section transverse to the edge of a tablet of cells showing a bipartite external structured envelope. The inner layer is obvious in an area exposed by stripping. The envelope encloses the tablet and bridges over the matrix separating adjacent cells (*arrow*). The low density vesicles represent poly-β-hydroxybutyrate granules. Bar = 0.5 μm.

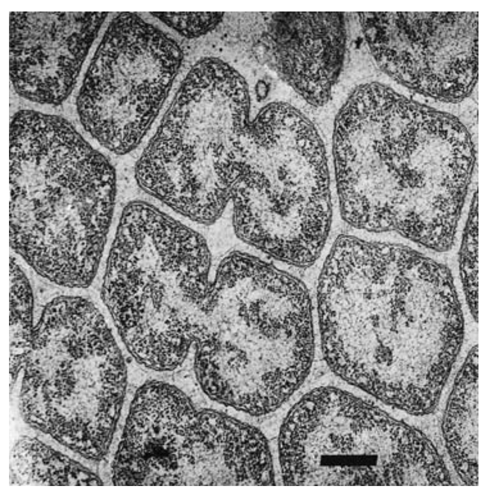

FIGURE BXII.β.32. Electron micrograph of a section in the plane of a tablet to show division and the relatively large volume of nucleoplasm. A matrix substance separates the cell walls (of usual Gram-negative character; see Fig. BXII.β.36) of adjacent cells. Divisions always show a "constrictive" form. Bar = 0.5 μm.

to an inner layer formed by one polypeptide (Austin and Murray, 1987, 1990). The nature of the intercalated materials is unknown. The enveloping layers together accomplish the division and separation of tablets of cells.

Colonial characteristics are determined by the growth habit and the physical nature of the surface of the enveloping layer. The sheets of cells, one cell thick, extend as they grow over the surface of liquid or solid media and tend to wrinkle as they grow to a large size and meet some obstacle to spreading. Many microcolonies are square. An irregularly shaped piece transferred to a liquid medium floats on the surface and maintains that odd shape as it grows; old cultures provide a rain of cells and debris that sink to the bottom. The capacity to float and grow as a pellicle suggests a hydrophobic surface, which is believed to be mediated by fine fibrous material (possibly proteinaceous) external to the envelope array (Lanys, 1972). There is no life cycle.

The description of the genus and its growth characteristics assumes morphological stability. However, mutants are easily derived by isolation of natural variants or stimulated by a mutagen such as nitrosoguanidine (Lanys, 1972, and unpublished results) producing different smooth or rough colonies rather than sheets. Many of these have lost the ability to form tablets or even tetrads, and most have lost the envelope layers (Figs. BXII.β.33 and BXII.β.34). Rough variants usually have retained the envelope arrays (Fig. BXII.β.35), and these most commonly have been derived with the help of nitrosoguanidine. Therefore, it is possible—even probable—that clones exist in nature that are phylogenetically related to *Lampropedia* but show none of the unique morphological characteristics that we use to identify *L. hyalina* in the absence of clear metabolic distinctions. The cultural, physiological, and biochemical characteristics of the available strains have been studied by Puttlitz and Seeley (1968). It is evident that this respiratory, catalase-positive chemoorganotroph requires Krebs cycle intermediates as energy sources and utilizes ammonium salts and a limited palette of amino acids as nitrogen sources. It is slightly fastidious in that it requires biotin and thiamine for growth, but can be cultured in a simple defined medium[1] if these vitamins are supplied. It is a mesophile that grows best at neutral pH and does not tolerate either 0.5% bile or 1.5% salt. It does not produce exoenzymes that degrade proteins, lipids, or the major carbohydrate polymers. So that without its peculiar morphology it is not a distinguished aerobe and would be hard to recognize (see Figs. BXII.β.33, BXII.β.34, and BXII.β.35).

FIGURE BXII.β.33. Light micrograph of a nigrosin preparation of a nonsheeting strain derived from the original isolation of *L. hyalina* ATCC strain 11041 (Murray, 1963). Bar = 5.0 μm.

Nothing is known about the genetics, antigenic structure or antibiotic sensitivity of this organism. The mol% G + C of the DNA (M. Mandel, personal communication) ranges from 60.7–61.2 for all available strains.

The ecological niche is unknown. The microbe is sufficiently distinctive (Starr and Skerman, 1965) to be recognized in its tablet or sheeting form by simple microscopy of natural specimens, and undoubtedly it has been seen many times (Starr, 1981), even if there have been no more than three isolations (Pringsheim, 1955; Frank Kovács' strain "Mac 583", described by Schad et al., 1964; Julius Kirchner, noted by Hungate, 1966). The isolations and sightings (sometimes called "window-pane sarcinas") involved waters infused with quantities of organic material, probably well digested and populated with many other microbes. A partial listing includes waters polluted with sugar refinery wastes, swamp water (Schroeter, 1886), stagnant water including aquatic plants (de Toni and Trevisan, 1889), liquid manure from a barnyard (Pringsheim, 1955), rumen fluid (see Smiles and Dobson, 1956; Eadie, 1962; Hungate, 1966; Clarke, 1979), intestinal content of herbivorous reptiles and their nematodes (Schad et al., 1964), and sewage-polluted, muddy water (R. Kolkwitz, 1909, cited by Starr, 1981). Considering the need for organic acids (Krebs cycle intermediates) and for vitamins, as well as the lack of exoenzymes and growth as a pellicle at the air/water interface, it is not surprising that it thrives in many of these situations. Its real habitat remains to be discovered and could be many other places accessible to these sources, perhaps associated with plants or the soil around them. It is hard to believe that this strict aerobe can be even an irregular inhabitant of cattle or sheep rumen unless the lampropedias found in this site can use some hydrogen acceptor other than oxygen (R.E. Hungate, personal communication). However, there is no doubt of the occasional presence of enough window-pane sarcinas to be detected by microscopy.

Enrichment and Isolation Procedures

L. hyalina will grow on many rich media (both liquid and solidified with agar), but isolation is made difficult by enormous numbers of other bacteria in the source material. Pringsheim (1955) used a capillary to transfer individual tablets of cells to dishes with water over a layer of soil in which starch particles or a grain of wheat was embedded; the lampropedias multiplied as a pellicle in the surface film, and, after 1–2 d at room temperature, could be streaked on an agar medium (0.1% sodium acetate, 0.2% yeast extract, and 0.1% peptone) to give a few isolated microcolonies. Microcolonies can be identified readily by low-power microscopy and subcultured. Kirschner (cited by Hungate, 1966) left rumen fluid standing for several days in an open flask and isolated *Lampropedia* by streaking the pellicle that formed onto rumen fluid

1. The chemically defined medium for growth of *L. hyalina* (Puttlitz and Seeley, 1968) consists of the following (per l distilled water): basal salts solution ($CaCl_2 \cdot 2H_2O$, 0.1 g; $FeSO_4 \cdot 7H_2O$, 0.2 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; $MnCl_2 \cdot 4H_2O$, 0.25 g; distilled water, 1000 ml), 100 ml; sodium pyruvate, 3.0 g; NH_4Cl, 3.0 g; phosphate buffer solution (KH_2PO_4, 7.0 g; K_2HPO_4, 13.0 g; distilled water, 1000 ml), 50 ml; thiamine-HCl, 1.0 mg; biotin, 1.0 mg; and NaOH, 70 mg. The vitamins are added aseptically to the sterile basal medium from stock solutions sterilized by filtration.

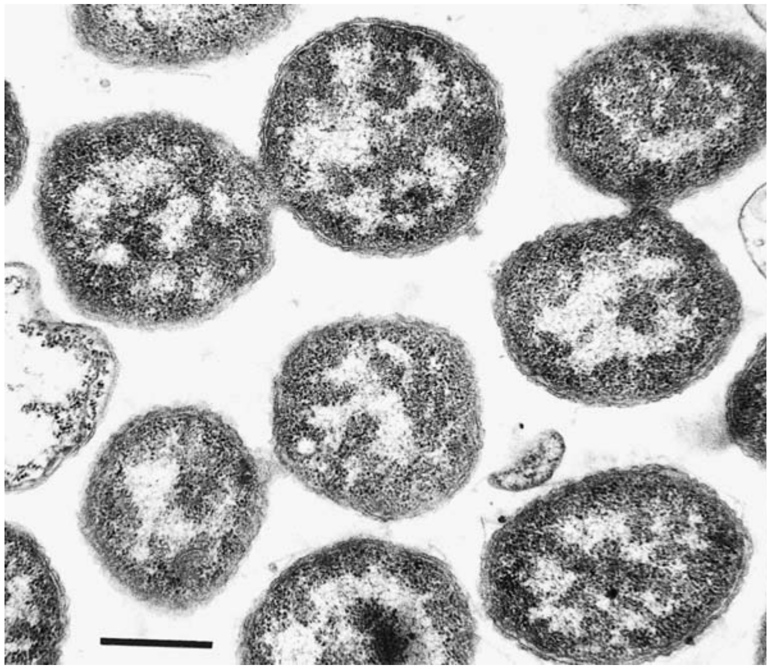

FIGURE BXII.β.34. A derivative of *L. hyalina* ATCC 11041 in section showing that it is almost, if not completely, devoid of the enveloping layers. Bar = 0.5 μm.

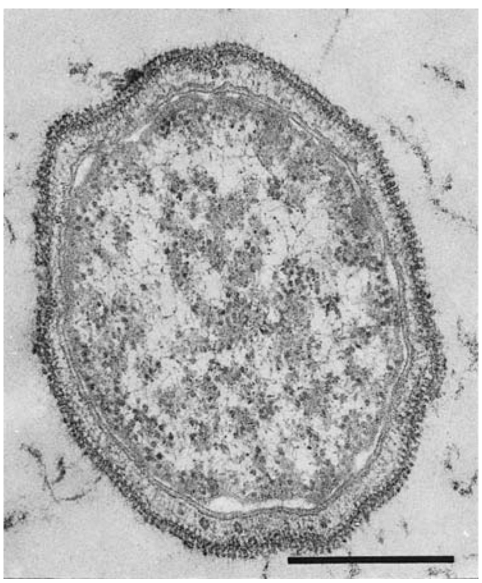

FIGURE BXII.β.35. Electron micrograph of a section of a nonsheeting derivative of *L. hyalina* ATCC 13691, which possesses both the structured and the intercalated enveloping layers outside the cell wall. Bar = 5 μm.

agar, which was then incubated aerobically at room temperature. There are a number of remarks on pellicle formation in the literature, so it seems likely that simple retention at room temperature is the preliminary approach to enrichment.

Maintenance Procedures

The common laboratory practice is maintenance by monthly subculture at room temperature on a neutral pH yeast extract-acetate-peptone agar (0.1–0.5% of each). The organisms survive lyophilization to a fair degree. Undoubtedly, constant subculture can lead to selection of mutants. Murray (1963) observed that ATCC strain 11041, derived from Pringsheim's isolation, had lost its ability to form sheets (Figs. BXII.β.33 and BXII.β.34). Nowadays, safe stocks can be kept in liquid N_2 suspended in the above fluid medium with 20% glycerol added.

Differentiation of the genus *Lampropedia* from other genera

The ability of *Lampropedia* to grow as sheets of cells on liquid or solid media distinguishes it from other genera of nonphotosynthetic bacteria. An organism known as *Thiopedia rosea* has a morphological resemblance to *Lampropedia*, but is photosynthetic (see Taxonomic Comments, below).

Taxonomic Comments

Sequence analysis of rDNA shows that *L. hyalina* belongs among the *Betaproteobacteria* (T.M. Schmidt, personal communication) in a grouping that includes *Comamonas*, *Brachymonas*, and more distantly *Leptothrix* and *Variovorax*. However, some aspects of its unique tablet-forming morphology are repeated in *Thiopedia rosea*, a nonsulfur purple, photosynthetic bacterium (Hirsch, 1977b). A similar type of photosynthetic organism was studied in the electron microscope (Lauritis, 1967) and identified as *"Rhodothece"* (now *Amoebobacter*), which did not get beyond the diplococcal form. The extraordinary feature of this organism was the possession of a superficial wall array virtually identical in fine structure to the complex envelope array of *L. hyalina*. In fact, apart from the chromatophore membranes it was similar to some of the enveloped but nonsheeting variants of *L. hyalina* (Fig. BXII.β.35; S.G. Lanys and R.G.E. Murray, unpublished observations). Natural variants isolated from cultures often lose the enveloping structures and the ability to form tablets (Murray, 1963). Associations dependent upon such similarities are fraught with danger because we have no understanding of the genetics of such structures and whether or not the determinants are ge-

netically transferable to any receptive organisms. It is probable that at least one of the old named species, *"L. violacea"* (see Seeley, 1974), may have been one of the *Chromatiaceae* (such as *Lamprocystis roseopersicina*) because the color of cell suspensions is purple to purple-violet (Pfennig and Trüper, 1974).

No less a problem is presented by Pringsheim's (1966) proposal that *L. hyalina* should be regarded as an apochlorotic species of *Merismopedia*, a large coccoid cyanobacterium that forms squared sheets of cells embedded in a glutinous matrix but without evidence of an enveloping structured array. Somewhat similar associations are evident in *Thiocapsa* and *Lamprocystis* among the *Chromatiaceae*.

Few, if any, of these taxonomic hypotheses can be given any credence without strong supportive evidence based, in all probability, on several accepted molecular markers for phylogenetic relationship. Furthermore, comparative studies of fine structure of a wider range of genera, as well as studies, if possible, of heterotrophically grown *Thiopedia* have yet to be undertaken. Uncertainty about taxonomic associations is exemplified by association with sulfur bacteria in the sixth edition of *Bergey's Manual of Determinative Bacteriology*, complete omission from the seventh edition, and relegation to a genus of uncertain affiliation among Gram-negative cocci in the eighth edition. Obviously, we are no further ahead now, but the tools to solve these problems may be available.

Further Reading

Starr, M.P. 1981. The Genus *Lampropedia*. *In* Starr, Stolp, Trüper, Balows and Schlegel (Editors), The Prokaryotes: a Handbook of Habitats, Isolation and Identification of Bacteria, Springer-Verlag, Berlin. pp. 1530–1536.

List of species of the genus Lampropedia

1. **Lampropedia hyalina** (Ehrenberg 1832) Schroeter 1886, 161[AL] (*Gonium hyalinum* Ehrenberg 1832, 63.)
hya'li' na. Gr. adj. *hyalinos* glassy, shiny; M.L. fem. adj. *hyalina* hyaline.

Cells are 1.0–1.5 × 1.0–2.5 μm. Morphological characteristics are as described for the genus and as depicted in Figs. BXII.β.30, BXII.β.31, BXII.β.32, and BXII.β.36.

Physiological and histochemical characteristics are as described for the genus and as listed in Table BXII.β.53. Utilizes pyruvate, lactate, butyrate, fumarate, malate, succinate (and acetate in the presence of catalytic levels of pyruvate) as sole energy sources. Utilizes NH_2Cl, alanine, arginine, and tyrosine as sole nitrogen sources. Biotin and thiamine are required for growth.

Temperature range for growth, 10–35°C; optimum, 30°C. pH range for growth, 6.0–8.6, optimum, 7.0.

The mol% G + C of the DNA is: 60.7–61.2 (Bd; M. Mandel, personal communication).

Type strain: ATCC 11041.

Additional Remarks: The type strain is inappropriate because it has lost the characteristic of forming tablets and sheets of cells, and has lost the ability to cover its surface with a structured envelope (Murray, 1963). A possible candidate for a neotype is reference strain ATCC 13871.

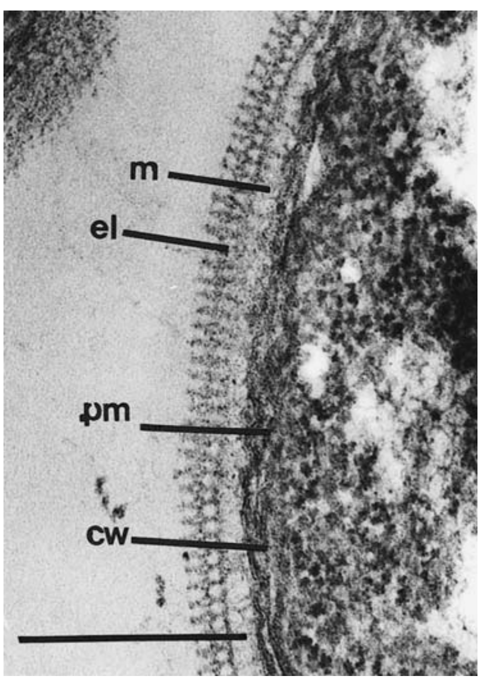

FIGURE BXII.β.36. A high magnification of a section showing the complex structured envelope (*el*), the envelope matrix (*m*), the cell wall (*cw*), and plasma membrane (*pm*). Bar = 0.5 μm.

TABLE BXII.β.53. Physiological and biochemical characteristics of *Lampropedia hyalina*[a,b]

Characteristic	Reaction or result
Growth under anaerobic conditions	−
Intracellular poly-β-hydroxybutyrate formed	+
Oxidase test	+
Catalase test	+
Indole production	−
Acetyl methyl carbinol production (Voges–Proskauer test)	−
Litmus milk	No change
Benzidine test for heme groups	+
Hemolysis on blood agar	−

Hydrolysis of gelatin, casein, fats and fatty acids, starch, hippurate, DNA and urea	−
Growth in the presence of:	
1.0% NaCl	+
1.5% NaCl	−
2.0% sucrose	+
4.0% sucrose	−
0.5% bile	−
Final pH in culture media	8.4–8.6

[a]For symbols see standard definitions.

[b]Data from Puttlitz and Seeley (1968).

Other Organisms

It is possible that the "window-pane sarcina" seen in rumen contents (which usually do not show poly-β-hydroxybutyrate granules; R.E. Hungate, personal communication) is separable from *L. hyalina*, but recognition would require cultivation and meta-

bolic studies. An early sighting gave rise to the name *"Bacterium merismopedioides"* (Zopf, 1883), which might be an appropriate name if a rumen strain is ever differentiated from *L. hyalina*.

Many other synonyms probably have been created. Among them the generic name *"Pedioplana"* (Wolff 1907, 10) was considered to be synonymous with *Lampropedia* by Seeley (1974) but, as Starr (1981) points out, it was described as motile and as possessing flagella.

The *species incertae sedis* included by Seeley (1974) are no longer valid, but memory of them should not be erased because they may represent other physiological variations for rediscovery: *"Lampropedia reitenbachii"* (Caspary) de Toni and Trevisan 1889, 1048; *"Lampropedia violacea"* (Brébisson) de Toni and Trevisan 1889, 1048; and *"Lampropedia ochracea"* (Mattenheimer) de Toni and Trevisan 1889, 1049.

Genus VII. **Macromonas** *Utermöhl and Koppe in Koppe 1924, 632*[AL]

Galina A. Dubinina, Fred A. Rainey and J. Gijs Kuenen

Ma' cro.mo' nas. Gr. adj. *macrus* large; Gr. n. *monas* a unit, monad; M.L. fem. n. *Macromonas* a large monad.

Large cells are colorless, cylindrical, bean-shaped, or slightly bent. Gram negative. Sluggish or rapidly motile by means of a polar tuft of flagella. Strictly aerobic or microaerophilic. A typical characteristic is the presence of several large inclusions of calcium oxalate, previously believed to be calcium carbonate. Sulfur globules may also be present. Multiplication by constriction followed by fission. No resting stages are known. The genus is composed of two species; the type species has not been grown in pure culture. Several strains of the second species have been studied in pure culture.

Phylogenetic analyses based on 16S DNA sequence comparisons place **Macromonas bipunctata** within the *Betaproteobacteria*. Closest related validly described taxa are the species of the genus *Hydrogenophaga*.

Type species: **Macromonas mobilis** (Lauterborn 1915) Utermöhl and Koppe *in* Koppe 1924, 632 (*"Achromatium mobile"* Lauterborn 1915)

Further descriptive information

Cells of the two species are morphologically similar, but differ markedly in size (Table BXII.β.54). *Macromonas bipunctata* cells that lack large inclusions move rapidly. However, as the number of inclusions increases, the motility rate slows down to 600–800 μm/min, which is probably a result of the increased specific gravity of the cells. Between one and four large, or numerous smaller, optically dense inclusions may almost fill the cell (Fig. BXII.β.37). The nature of the refractile intracellular inclusions can be determined by infrared spectroscopy. Absorption spectra of *M. bipunctata* cells grown on medium with succinate have maxima at 1600 and 1300 cm^{-1}, which are typical of the carboxyl groups of oxalate. The polar tuft of flagella ranges in length from 10–40 μm and can sometimes be seen under the light microscope.

Aerobic, aerotactic. Strains of *M. bipunctata* studied thus far are heterotrophs, but can partially oxidize sulfide and thiosulfate by means of hydrogen peroxide.

Both species are found in freshwater environments with low oxygen and hydrogen sulfide concentrations, including hypolimnia, chemoclines, the upper layers of the mud in lakes and ponds, and the surface of sediment in sewage treatment plants. *Macromonas mobilis* has also been reported in acid bog waters (Schultz and Hirsch, 1973).

TABLE BXII.β.54. Differentiation between *M. mobilis* and *M. bipunctata*

Characteristic	*M. mobilis*	*M. bipunctata*
Cell size	6–14 × 10–30 μm	2.2–4 × 3.3–6.5 μm

Enrichment and Isolation Procedures

No methods are known for the isolation and maintenance of cultures of the type species *M. mobilis. M. bipunctata* can be enriched and isolated by the following procedure (Dubinina and Grabovich, 1984). A suitable inoculum (for example, the white mat found on the surface of bottom sediment in a sewage aeration tank) is added to tubes containing 10 ml portions of the following semisolid medium (g/l distilled water): sodium acetate, 1; $CaCl_2$, 0.1; casein hydrolysate, 0.1; yeast extract, 0.1; agar, 1.0. After sterilization, vitamins and trace elements (Pfennig and Lippert, 1966) are added, along with 200 mg freshly precipitated FeS; pH 7.2–7.4. After 2–3 d at 28°C, a white surface film should appear. A suspension of this film is streaked on plates containing the above medium solidified with 10 g agar/l. After 2–3 d, flat colonies of *Macromonas* should appear, and these can be subcultured on solid medium.

Maintenance Procedures

Cultures of *M. bipunctata* can be maintained in semisolid (0.15% agar) medium without FeS but supplemented with thiosulfate (1 g/l), but they should be transferred at about one-month intervals. Lyophilization with cells suspended in skimmed milk has proven to be unsuccessful: the cells remain viable for no more than one or two months.

Taxonomic Comments

Phylogenetic analyses based on 16S rDNA–RNA sequence comparisons demonstrate that *Macromonas bipunctata* belongs to the *Betaproteobacteria* and clusters within the radiation of the genera *Hydrogenophaga*, *Comamonas*, *Acidovorax*, *Variovorax*, and *Rhodoferax*, with its closest relatives being the species of the genus *Hydrogenophaga* (Fig. BXII.β.38).

The 16S rDNA sequence of *Macromonas bipunctata* strain VKM 1366[T] has 92.8–96.2% similarity to the 16S rDNA sequences of the type strains of each of the species of the genera *Hydrogenophaga*, *Comamonas*, *Acidovorax*, *Variovorax*, and *Rhodoferax*. The highest 16S rDNA sequence similarities of the *Macromonas bipunctata* sequence are found to members of the genus *Hydrogenophaga*: 95.9% to *H. taeniospiralis*, 95.9% to *H. pseudoflava*, 96.1% to *H. flava*, and 96.2% to *H. palleronii*. The 16S rDNA sequence similarity values between the species of the genus *Hydrogenophaga*

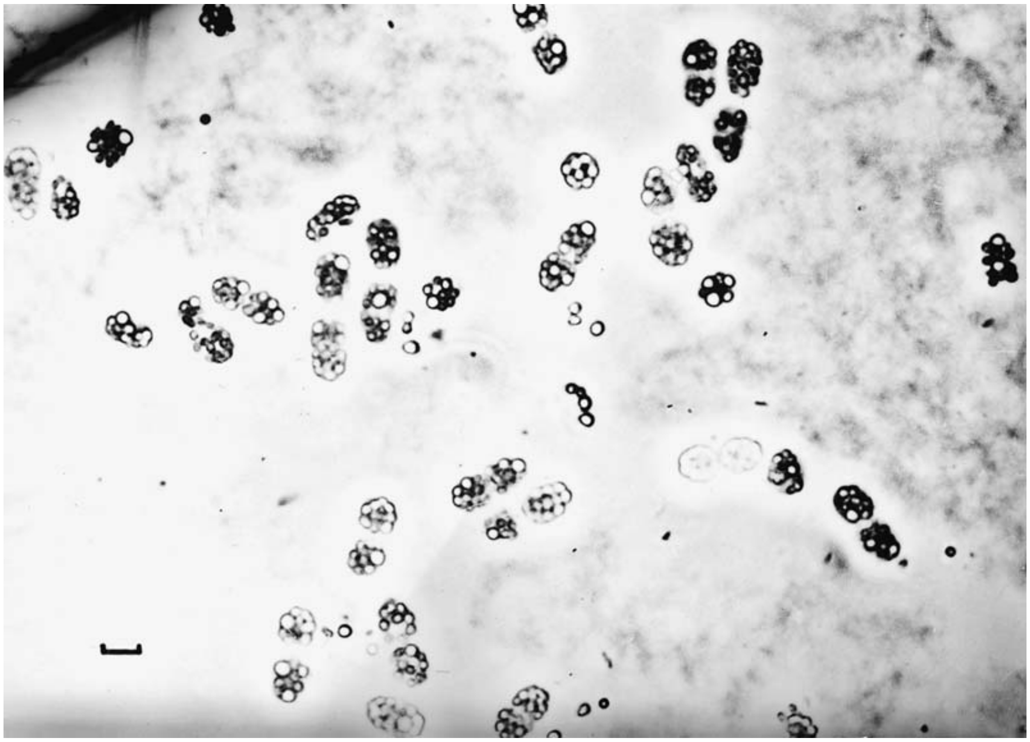

FIGURE BXII.β.37. Phase-contrast and electron micrographs of *M. bipunctata* VKM 1366^T showing inclusions of calcium oxalates in cells grown on medium with succinate; Bar = 5 μm.

are in the range of 97.3–99.0%, and so, as shown in the phylogenetic dendrogram (Fig. BXII.β.38), *Macromonas bipunctata* is related to the *Hydrogenophaga* species cluster, but branches off at the deepest point of the cluster.

Although the phylogenetic position of the species *Macromonas bipunctata* is clearly demonstrated by the 16S rDNA analysis of the type strain VKM 1366^T (which exists as a pure culture), the phylogenetic position of *Macromonas mobilis* (the as yet uncultured type species of the genus) is still unknown. Until the 16S rDNA sequence of *Macromonas mobilis* is determined and analyzed, the phylogenetic position of the genus is unclear. However, considering the high degree of similarity between *Macromonas bipunctata* and *Macromonas mobilis* in terms of morphology and ecology, the genus *Macromonas* is probably a member of the *Betaproteobacteria*, with a close phylogenetic relationship to species of the genus *Hydrogenophaga*. Future comparisons of the physiological characteristics of *Macromonas bipunctata* are required to further establish the relationship to the genus *Hydrogenophaga*.

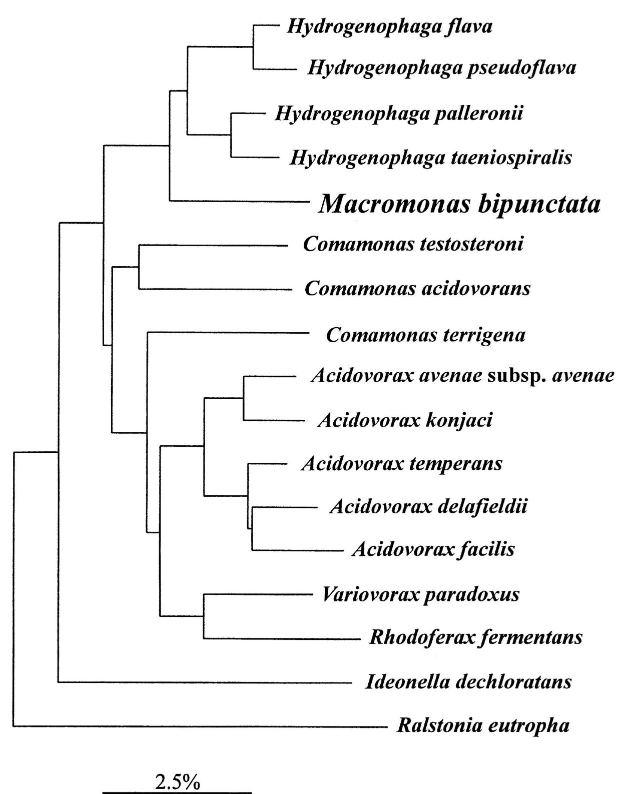

FIGURE BXII.β.38. Phylogenetic dendrogram, based on comparison of 16S rDNA sequences, indicating the position of *Macromonas bipunctata* strain VKM 1366^T and its closest relatives within the *Betaproteobacteria*. The dendrogram was reconstructed from evolutionary distances (Jukes and Cantor, 1969) by the neighbor-joining method (Saitou and Nei, 1987). Bar = 2.5 inferred nucleotide changes per 100 nucleotides.

List of species of the genus Macromonas

1. **Macromonas mobilis** (Lauterborn 1915) Utermöhl and Koppe *in* Koppe 1924, 632[AL] (*"Achromatium mobile"* Lauterborn 1915)
mo' bi.lis L. fem. adj. *mobilis* motile.

The main feature by which this species is currently distinguished from *M. bipunctata* is its large cell size, which is usually 9 × 20 µm, and sometimes 6–14 × 10–30 µm. Its polar tuft of flagella is 20–40 µm long. For further description see that of genus.

The mol% G + C of the DNA is: unavailable.
Type strain: no culture isolated.

2. **Macromonas bipunctata** (ex Utermöhl and Koppe *in* Koppe 1924, 632) Dubinina and Grabovich 1989, 496[VP] (Effective publication: Dubinina and Grabovich 1984, 754.)
bi.punc.ta' ta. L. *bis* twice; L. part. adj. *punctatus* punctate, dotted; M.L. fem. adj. *bipunctata* twice punctate.

Cells single or in pairs, pear-shaped, cylindrical or slightly curved, 2.2–4 × 3.3–6.5 µm, motile by means of a polar tuft of flagella made up of 16–20 fine flagella and ranging in length from 20–30 µm.

Electron micrographs of ultrathin sections of *M. bipunctata* cells reveal the typical structure of Gram-negative bacteria. The cytoplasm is surrounded by a three-layered cell membrane that occasionally forms invaginations. The five-layered cell wall, with a thin layer of peptidoglycan, is separated from the protoplast by a periplasmic space. The cells are covered by a thin layer of fibrillar polysaccharide. In cells grown under intense aeration, this layer may increase in thickness up to 200–500 nm and form slime capsules (Fig. BXII.β.39).

At least four types of inclusion have been observed in *M. bipunctata* cells. These are calcium oxalate, calcium polyphosphate, S^0, and poly-β-hydroxybutyrate. When *M. bipunctata* is grown on media containing succinate or malate, refractile irregularly-shaped calcium oxalate inclusions (previously believed to be calcium carbonate) accumulate in the cells. In *M. bipunctata*, calcium oxalate is synthesized mainly via oxaloacetate conversion to acetate and oxalate, with the participation of oxaloacetate hydrolase in the TCA cycle (Grabovich et al., 1995). Depending on the concentration of organic compounds in the medium, oxalates may appear as ballast or serve as a pool of reserve organic matter that can maintain metabolism under unfavorable conditions. When used as ballast, the oxalates may be removed from the cells by oxidation to CO_2 using oxalate oxidase. The reaction is not associated with either biosynthetic or energy metabolism.

S^0 accumulates in cells grown in media containing FeS or CaS, but not in cells grown with thiosulfate. Sulfur globules also appear in cells that have been grown in the absence of sulfides and then incubated for 20 minutes in a 0.005–0.01% polysulfide solution. Electron micrographs of ultrathin sections show that the sulfur globules are located in the periplasm and within the invaginations formed by the cell membrane.

Colonies on solid media are non-pigmented, of a fine-grained structure, slightly opalescent, and flat, measuring 0.5–4 mm. Growth in static liquid occurs in the upper 3–5 mm layer.

M. bipunctata strains thus far isolated have been chemoorganotrophic, but they do not tolerate or utilize high concentrations of organic compounds. Low concentrations of growth substrates (5–10 mM) are apparently optimal. High concentrations induce rapid autolysis of cells due to hydrogen peroxide accumulation in the periplasm. The addition of sulfides, thiosulfate, or catalase to the growth medium increases the biomass yield by 20–40% and extends the survival of stored cultures from several days to a month. Acetate, succinate, malate, fumarate, oxalacetate, benzoate, and pyruvate are good substrates, but sugars, alcohols (with the exception of ethanol), and amino acids are not used. Ammonium salts and organic nitrogen compounds can serve as nitrogen sources. Vitamins are required for growth. Further physiological and biochemical characterization of *M. bipunctata* is shown in Table BXII.β.55.

Optimal temperature 28°C, optimal pH 7.5–8.2.

The complete TCA cycle functions in *M. bipunctata*, its only unusual feature being a low fumarate hydratase activity, leading to the accumulation of fumarate in the cells. The glyoxylate cycle also functions in *M. bipunctata*, regardless of the carbon source used. It has been suggested that the glyoxylate cycle compensates for the low fumarate hydratase activity, shunting fumarate to be converted to malate. Calcium oxalate formation and its intracellular accumulation have been shown to be another peculiarity of carbon metabolism in *M. bipunctata* (Grabovich et al., 1993).

M. bipunctata oxidizes sulfide to S^0, and thiosulfate to tetrathionate by means of hydrogen peroxide, a process that does not provide useful energy for the cells (Dubinina and Grabovich, 1984; Chekanova and Dubinina, 1990).

Isolated from the sediment in an aeration tank of a sewage treatment plant.

The mol% G + C of the DNA is: 67.6 (T_m).
Type strain: DSMZ 12705, VKM 1366.

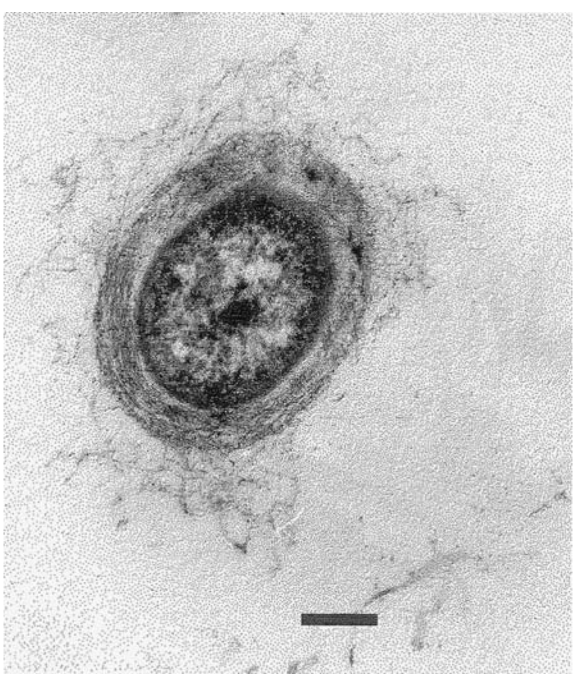

FIGURE BXII.β.39. Electron micrographs of ultrathin sections of ruthenium red-stained *M. bipunctata* VKM 1366[T]. The ruthenium red has stained the extracellular polysaccharides. Bar = 0.5 µm.

TABLE BXII.β.55. Characterization of *Macromonas bipunctata* strains[a]

Characteristics	Reaction
Use as a sole carbon source:	
Organic acids:	
Acetate, benzoate, fumarate, malate, oxaloacetate, succinate	+
Citrate, isocitrate, aconitate, malonate, glycolate	−
α-Ketoglutarate, glyoxylate, lactate, formate, pyruvate, propionate, oxalate	d
Alcohols:	
Ethanol	d
Methanol, butanol, isobutanol, glycerol	−
Amino acids:	
Serine, aspartate, lysine, cysteine, tryptophan, alanine, histidine, phenylalanine, asparagine, methionine, proline, tyrosine	−
Peptone	−
Casein hydrolysate, yeast extract	+
Use as a sole nitrogen source:	
Ammonium	+
Peptone, casein hydrolysate	+
Nitrate and nitrite	−
Glutamate	+
Alanine, aspartate, serine, cysteine, cystine, methionine	d
Reduction of NO_3^- to NO_2^-	−
N_2 fixation	−
H_2S production from cysteine or $S_2O_3^{2-}$	−
S^0 production from sulfide	+
Hydrolysis of gelatin, starch, casein	−
Indole production	−
Catalase activity	+[b]
Oxidase activity	+
Urease activity	+
Anaerobic growth with nitrate, sulfate, thiosulfate, or fumarate as acceptors of electrons	−
Mol% G + C of DNA (T_m)	66–68

[a]Symbols: +, 90% or more of the strains are positive; −, 90% or more of the strains are negative; d, 11–89% of the strains are positive.

[b]Activity of catalase is weak.

Genus VIII. **Polaromonas** *Irgens, Gosink and Staley 1996, 825*[VP]

JOHN J. GOSINK

Po' lar.o.mo' nas. M.L. adj. *polaris* pertaining to the geographic poles; Gr. fem. n. *monas* unit; M.L. fem. n. *Polaromonas* polar bacterium.

Cigar-shaped rods, 0.8 × 2.0–3.0 μm. Gram negative and encapsulated. Motile by a polar flagellum. Aerobic. Chemoorganotrophic, catalase and oxidase positive. Require amino acids, but not vitamins for growth. **Cellular fatty acids predominantly (74–79%) $C_{16:1\ \omega7c}$, and $C_{16:0}$ (14–17%), and some (7–9%) $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, or $C_{18:1\ \omega12t}$. Organisms may contain gas vesicles.** Psychrophilic; growth temperature maximum of known strains is 15°C. 16S rDNA-based phylogeny shows this is a member of the *Comamonadaceae* in the *Betaproteobacteria*.

The mol% G + C of the DNA is: 52–57.

Type species: **Polaromonas vacuolata** Irgens, Gosink and Staley 1996, 825.

FURTHER DESCRIPTIVE INFORMATION

Five putative strains (34-P, 41-P, 54-P, JA, and JB) of *Polaromonas* have been isolated from Antarctic waters. Only one strain, 34-P, has been examined in depth by phenotypic, genotypic, and phylogenetic methods and hence officially recognized as a member of this genus.

Phylogenetic trees of *Polaromonas* and closely related taxa have been generated using distance, parsimony, and maximum likelihood methods. Analyses using various forms of parsimony (Swofford, 1991; Maddison and Maddison, 1992), with different character weighting masks and substitution matrix weights, give a number of different trees with similar structures (Fig. BXII.β.40A). Distance (Fig. BXII.β.40B) and likelihood (Fig. BXII.β.40C) have also been performed on the data, using a transition to transversion ratio of 1.3 (Felsenstein, 1981, 1989; Olsen et al., 1994).

The results of these analyses show slightly different trees, depending on which assumptions for the model of evolution are used. All of these methods show that *Polaromonas* is a member of the *Betaproteobacteria* and shares a moderately close relationship with *Rhodoferax fermentans* (Hiraishi et al., 1991a), *Variovorax paradoxus*, (Davis et al., 1969; Willems et al., 1991a) and the environmental sequence "str. Stripa" (Ekendahl et al., 1994). Recent inspection of the Ribosomal Database Project (Maidak et al., 1999) small subunit database reveals additional partial "environmental population shotgun" sequences closely related to those of these organisms. More accurate or reproducible phylogenetic trees would be produced if full length sequences were available from the environmental clones. In addition, since these sequences have been obtained from uncultured bacteria, there are no phenotypic data available for the bacteria that produced these sequences, so comparison with these organisms can not proceed beyond the phylogenetic stage. The exact phylogenetic relationship among these taxa remains unclear pending future detailed examination.

Polaromonas strains appear as short, unicellular, Gram-negative rods (0.8 × 2–3 μm) that typically produce gas vacuoles, which

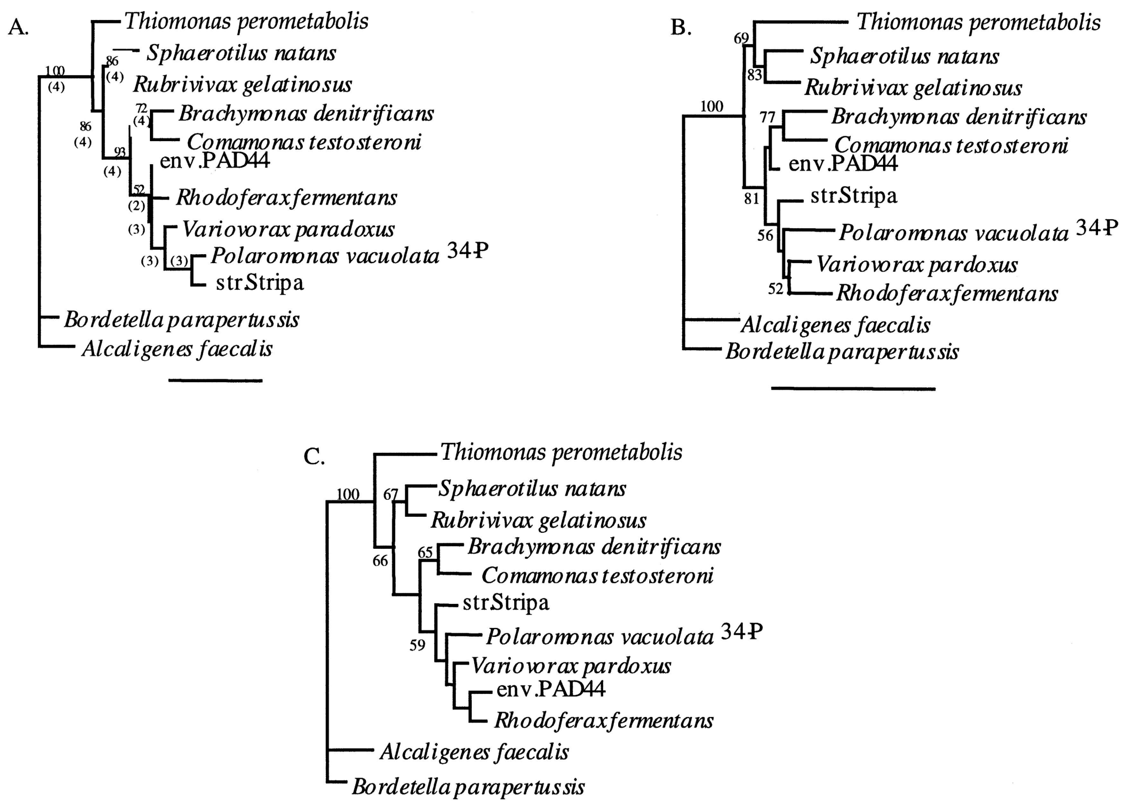

FIGURE BXII.β.40. The phylogenetic relatedness of *Polaromonas vacuolata* strain 34-P to the most closely related species. Numbers near the branches but not in parentheses indicate percent bootstrap support for that clade from 100 bootstrap resamplings. Only bootstrap values of 50% or greater are shown. Bars = 0.1 changes/average nucleotide position. A maximum parsimony tree (*A*), was determined using PAUP 3.0s by an exact (branch and bound) search, using a substitution matrix to correct for the various rates of nucleotide substitutions (Swofford, 1991; Maddison and Maddison, 1992). Numbers in parentheses near the branches indicate how many of the four equally most parsimonious trees share that branch structure. A neighbor joining tree (*B*) was made using PHYLIP 3.2 and a maximum likelihood tree (*C*) was made with fast DNAmL; both were made with a Kimura 2 parameter correction, using a transition to transversion ratio of 1.3 (Felsenstein 1989; Olsen et al., 1994).

appear as bright refractile areas within the cells. Gas vesicles are confirmed by transmission electron microscopy (Fig. BXII.β.41). Although cells are nonmotile under usual culture conditions, they produce polar flagella in addition to gas vacuoles (Fig. BXII.β.41). These bacteria produce circular, convex colonies with a smooth, glistening surface and an entire edge on agar plates. The colonies are chalky white in pigmentation. All strains produce large amounts (74–79%) of $C_{16:1\ \omega 7c}$ and smaller amounts of $C_{16:0}$ (14–17%) (Irgens et al., 1996). A third fatty, $C_{18:1\ \omega 7c}$, $C_{18:1\ \omega 9t}$, $C_{18:1\ \omega 12t}$, or possibly a combination of more than one of these, is present in lower amounts (7–9%). Such predominance of a single fatty acid is unusual in bacteria, and this is among the highest level of $C_{16:1\ \omega 7c}$ in any bacterial species. Additional features are shown in Table BXII.β.56.

Although many members of the *Alphaproteobacteria* and *Gammaproteobacteria* have been shown to produce gas vesicles, this is the first described gas vacuolate member of the *Betaproteobacteria*, though there are likely many more gas vacuolate members among this phylogenetic group. Although gas vacuolate heterotrophic bacteria are well known inhabitants of aquatic ecosystems, until recently, none had been observed or isolated from marine habitats. In 1989, several types from Antarctica were reported growing in association with the sea ice microbial community (Irgens, et al., 1989; Staley et al., 1989). The ecological role of *Polaromonas* and the function that gas vesicles serve in that role are unknown.

isolated by plating water samples onto SWCm (Staley et al., 1989) agar plates and incubating at 6°C for 6 weeks. Gas vacuolate colonies can be identified by their chalky appearance. *Polaromonas* strains are delineated from other gas vacuolate strains by their color, colony morphology, and fatty acid composition.

Maintenance Procedures

Stocks are maintained for general work on SWCm (Staley et al., 1989) at 4°C. Care must be taken when transferring or working with the strains to keep them and the growth media at 4°C. These cultures can be killed by leaving them out at room temperature for several hours or overnight. Long-term storage is best done by transferring cells to SWCm (Staley et al., 1989) broth with 25% glycerol or 10% DMSO and freezing at −80°C.

Differentiation of the genus *Polaromonas* from other genera

Analyses of 16S rDNA sequences using various phylogenetic methods produce slightly different trees. For all the trees, however, it is clear that strain 34-P is most closely related to *Rhodoferax fermentans* (Hiraishi et al., 1991a), *Variovorax paradoxus* (Davis et al., 1969; Willems et al., 1991a), "str. Stripa", and "env. PAD44" (Ueda, unpublished results). It is, however, phenotypically and genotypically quite different from these organisms. Strain 34-P is not photosynthetic and does not grow as a nonsulfur purple bacterium under conditions used for the growth of *R. fermentans*. Strain 34-P differs by 5% and 7% in 16S rDNA base homology from *V. paradoxus* (Davis et al., 1969; Willems et al., 1991a) and *R. fermentans* (Hiraishi et al., 1991a), respectively. Furthermore, other genotypic and phenotypic differences indicate marked differences among *Polaromonas vacuolata*, *V. paradoxus*, and *R. fermentans* (Table BXII.β.57). For example, the mol% G + C values are 52–57 versus 67–69 and 60, respectively (Davis et al., 1969; Irgens et al., 1989; Hiraishi et al., 1991a; Willems et al., 1991a). In addition, *V. paradoxus* and *R. fermentans* are both pigmented, are not gas vacuolate, and differ from *P. vacuolata* in cell shape and motility (Table BXII.β.57).

Taxonomic Comments

The complete region of 16S rDNA phylogeny delineated by this genus remains uncertain pending nucleotide sequence analysis of additional members. In addition, the large number of partial nucleotide sequences closely related to the 16S rDNA sequence of this genus may blur resolution of this region of the phylogenetic tree.

List of species of the genus Polaromonas

1. **Polaromonas vacuolata** Irgens, Gosink and Staley 1996, 825[VP]

va.cu.o.la′ta. L. adj. *vacuus* empty; N.L. part. adj. *vacuolata* equipped with gas vacuoles.

Cells contain gas vesicles. Temperature for optimum growth is 4°C, with a range of 0–12°C. Colonies are snowy white, circular, and convex, with a smooth surface and an entire edge. The more gas vesicles within the cells, the whiter the colony. Grows on fumarate, glucose, alanine, glutamate, and aspartate. Does not grow on sucrose, lactose, or arginine. There is good growth in media with NaCl concentrations ranging from 0–6.0% but no growth at 7.0%. Fatty acid composition is 75% $C_{16:1\ \omega7c}$, 17% $C_{16:0}$, and 8% $C_{18:1\ \omega7c}$, $C_{18:1\ \omega9t}$, or $C_{18:1\ \omega12t}$.

The mol% G + C of the DNA is: 52.0 (T_m).

Type strain: 34-P, ATCC 51984.

GenBank accession number (16S rRNA): U14585.

Genus IX. **Rhodoferax** *Hiraishi, Hoshino, and Satoh 1992a, 192[VP] (Effective publication: Hiraishi, Hoshino, and Satoh 1991a, 334)*

Akira Hiraishi and Johannes F. Imhoff

Rho.do.fe′rax. Gr. n. *rhodon* rose; L. adj. *ferax* fertile; M.L. masc. n. *Rhodoferax* red and fertile.

Cells are curved or vibrioid rods, motile by means of polar flagella, that multiply by binary fission and do not form endospores and capsules. **Gram negative, belonging to the *Betaproteobacteria*.** Internal membrane systems are poorly developed or absent. **Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series. Contain ubiquinones and rhodoquinones with eight isoprene units (Q-8 and RQ-8). Straight-chain $C_{16:1}$ and $C_{16:0}$ acids are the major components of cellular fatty acids. $C_{8:0\ 3OH}$ acid is present.** Membrane-bound fumarate reductase activity occurs with $FMNH_2$ as the electron donor.

Growth is possible by photosynthesis, aerobic respiration, or fermentation. Photoheterotrophy with various organic compounds as carbon sources is the preferred mode of growth. Cells grow well with simple organic compounds as electron donors and carbon sources and in complex media containing peptone, yeast extract, or Casamino acids. **Mesophilic and psychrophilic, neutrophilic fresh water bacteria.** Habitat: ditchwater, activated sludge, Antarctic microbial mats.

The mol% G + C of the DNA is: 59.8–61.5.

Type species: **Rhodoferax fermentans** Hiraishi, Hoshino and Satoh 1992a, 192 (Effective publication: Hiraishi, Hoshino and Satoh 1991a, 334.)

Further descriptive information

According to 16S rDNA sequences, the closest phylogenetic relative to the *Rhodoferax* species is the purely chemotrophic *Variovorax paradoxus* (sequence similarity of 96%). The nearest phototrophic phylogenetic neighbor is *Rubrivivax gelatinosus* (91% sequence similarity; see Fig. 4 [p.132] of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A).

In addition, the aerobic, bacteriochlorophyll-containing bacterium *Roseateles depolymerans* is within the same phylogenetic group.

R. fermentans is a facultatively photoheterotrophic bacterium that grows anaerobically in the light and aerobically in darkness at full atmospheric oxygen tension and exhibits a doubling time of 3–4 h under optimal growth conditions. Colonies grown on agar media are of intermediate size (2–4 mm after one week of incubation), round, smooth, circular, convex, and peach brown. However, rigid colonies frequently occur upon subculture. Phototrophic liquid cultures become peach brown, whereas aerobic, chemotrophic cultures are colorless or faintly pink. Absorption spectra of phototrophically grown cells or membrane preparations show major absorption maxima at around 800 and 850 nm, indicating that the cells contain the core light-harvesting complex (LH I), together with the photosynthetic reaction center and the peripheral light-harvesting complex (LH II).

One of the most remarkable properties of *Rhodoferax fermentans* is its capability of anaerobic fermentation in darkness. In Hugh-Leifson's OF test, which is commonly used to characterize chemoorganotrophic bacteria, *R. fermentans* produces acid from glucose in both open and sealed tubes within a few days of incubation (Hiraishi and Kitamura, 1984). Such a rapid glucose fermentation has not been found in other species of phototrophic bacteria described so far. Fermentative growth in darkness occurs on pyruvate and sugars, among which fructose is the best substrate. The addition of bicarbonate significantly enhances anaerobic growth in the dark. The doubling time for fermentative growth on 20 mM fructose plus 30 mM bicarbonate is 4–5 h (Hiraishi, 1988b). The end products of fructose fermentation are acetate, formate, lactate, succinate, and ethanol. Hypophosphite, a potent inhibitor of pyruvate–formate lyase, completely suppresses the production of formate and increases the amount of succinate excreted. These observations suggest that the bicarbonate-dependent fermentative growth may be linked to CO_2 fixation via part of the reductive TCA cycle and the subsequent reduction of fumarate to succinate. GDP-dependent phosphoenolpyruvate carboxykinase has been suggested to function as a key enzyme for CO_2 fixation (Hiraishi, 1988b), and reduced FMN-linked fumarate reductase activity that is possibly associated with a low-potential rhodoquinone within the cells has been found in the membrane preparations (Hiraishi, 1988a).

While many species of phototrophic purple nonsulfur bacteria exhibit anaerobic growth in darkness coupled with reduction of trimethylamine-*N*-oxide or dimethylsulfoxide as the terminal electron acceptor, *R. fermentans* lacks these properties. Most strains of this species are also devoid of nitrate reductase activity, although strain DSM 10139 is highly active at nitrate reduction (Hougardy and Klemme, 1995).

Some information has been available on the components of the respiratory and photosynthetic electron transport systems of *R. fermentans*. Cells produce two quinone molecules, Q-8 and RQ-8, constitutively. The RQ/Q molar ratio is 0.5–0.7 under phototrophic growth conditions with malate as the carbon source (Hiraishi and Hoshino, 1984). This ratio is higher (0.9–1.7) in cells grown fermentatively or phototrophically and becomes much lower (0.1–0.2) in aerobically grown cells (Hiraishi et al., 1991a). It has been shown that the oxidative electron transport chain is branched at the ubiquinone level and does not involve rhodoquinone (Hochkoeppler et al., 1995b). Aerobically grown cells contain four *b*-type and three *c*-type membrane-bound cytochromes but lack soluble *c*-type cytochromes. A soluble, high-potential iron-sulfur protein (HiPIP) functions as an alternative to the soluble cytochrome *c* in linking the bc_1 complex to the terminal oxidase in respiratory electron transfer (Hochkoeppler et al., 1995a). Phototrophic cells contain the reaction center complex with tetraheme *c* as direct electron donors to the bacteriochlorophyll dimer. HiPIP is also competent as an alternative to the soluble *c*-type cytochrome in photosynthetic electron transfer (Hochkoeppler et al., 1995a, 1996).

The genes (*puf*) coding for the L and M protein subunits of the photosynthetic reaction center have been analyzed by PCR cloning (Nagashima et al., 1997a). The deduced amino acid sequences of the puf proteins of *R. fermentans* are most similar to those of *Rubrivivax gelatinosus* (77% identity). A phylogenetic analysis based on the nucleotide sequences of DNA fragments coding for the L and M subunits has shown that the sequences of *R. fermentans* and of two other species of the *Betaproteobacteria*, *Rubrivivax gelatinosus* and *Rhodocyclus tenuis*, are positioned among those of *Alphaproteobacteria*. This contrasts with their phylogenetic relations, as based on 16S rDNA sequences (see Fig. 4 [p. 132] in the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A). The inconsistency is explained by possible horizontal transfer of the genes encoding the reaction center during evolution of photosynthesis.

As with other phototrophic *Betaproteobacteria*, the major phospholipid components of *Rhodoferax fermentans* are cardiolipin, phosphatidylethanolamine, and phosphatidylglycerol (A. Hiraishi, unpublished data). Straight-chain $C_{16:1}$ and $C_{16:0}$ acids are the main components of cellular fatty acids (see Table BXII.β.58).

Rhodoferax antarcticus is characterized by its preference for low temperatures and grows optimally at 12–18°C, but not above 25°C (Madigan et al., 2000b).

Enrichment and Isolation Procedures

The natural habitats of *Rhodoferax* species are freshwater environments that are rich in organic matter. Sulfide-rich water bodies may not provide favorable conditions for *R. fermentans* because of its inability to use sulfide as the electron donor for growth and its weak tolerance toward sulfide. Strains of *Rhodoferax fermentans* have been isolated from pond water, sewage, and activated sludge. *R. antarcticus* was isolated from an Antarctic microbial mat.

Enrichment and isolation are possible under conditions also suitable for most of the species of phototrophic purple nonsulfur bacteria. Although it is not easy to perform selective enrichment of *Rhodoferax fermentans* from environmental samples, the addition of 0.5 mM EDTA to the enrichment medium may be effective for suppressing the overgrowth of possibly co-existing, fast growing phototrophic species, such as *Rhodobacter capsulatus* and *Rhodobacter sphaeroides* (Hougardy and Klemme, 1995). A suitable enrichment medium consists of basal mineral medium, one or more simple organic compounds (e.g., 0.1% acetate or 0.2% glucose), and a vitamin mixture or 0.01% yeast extract. Incubation is under anoxic conditions under incandescent illumination at 1000–2000 lux at 28°C for *R. fermentans* or at 12–18°C for *R. antarcticus*.

A simple medium for growth and purification of *Rhodoferax* is MYCA medium (Hiraishi et al., 1991a), which contains 0.1% DL-malate, 0.3% yeast extract, 0.2% Casamino acids, and 0.05% $(NH_4)_2SO_4$ and is adjusted to pH 6.6–6.8.

Maintenance Procedures

Cultures are well-preserved in liquid nitrogen or by lyophilization. Preservation is also possible in a mechanical freezer at −80°C.

DIFFERENTIATION OF THE GENUS *RHODOFERAX* FROM OTHER GENERA

The genus *Rhodoferax* is differentiated from other genera of phototrophic *Proteobacteria* by its phylogenetic position and its unique physiological and chemotaxonomic properties. The characteristic features of *Rhodoferax* include fructose fermentation, Q-8 and RQ-8 production, and relatively low mol% G + C contents of the DNA. Differential characteristics of *Rhodoferax* species and other phototrophic *Betaproteobacteria* are given in Tables 6 (p. 130) and 7 (p. 131) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. The phylogenetic relationships of the phototrophic *Betaproteobacteria* are shown in Fig. 4 (p. 132) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. *Rhodoferax* is compared to *Rubrivivax gelatinosus* in Tables BXII.β.58 and BXII.β.59.

TAXONOMIC COMMENTS

Strains of *R. fermentans* were first recognized as the "*Rhodocyclus gelatinosus*-like (RGL)" group (Hiraishi and Hoshino, 1984), because they were phenotypically similar to *Rubrivivax gelatinosus* (at that time known as *Rhodocyclus gelatinosus*), in particular appearing to resemble *Rubrivivax gelatinosus* subgroup II (Weckesser et al., 1969). More detailed physiological, chemotaxonomic, and genetic studies revealed major differences between the RGL group and *Rubrivivax gelatinosus*, and these observations led to the proposal for the classification of the RGL group into the new genus *Rhodoferax* (Hiraishi et al., 1991a) as *R. fermentans*. Later, a phylogenetic study based on 16S rDNA sequences showed that the genera *Rhodoferax*, *Rubrivivax*, and *Rhodocyclus* are phylogenetically distinct groups within the *Betaproteobacteria* (Hiraishi, 1994).

List of species of the genus Rhodoferax

pairs (Fig. BXII.β.42), 0.6–0.9 × 2–5 μm under optimal growth conditions. Long chains and helical filaments may be produced, especially when cells are grown with sugars under phototrophic or fermentative growth conditions. Spheroplast-like coccoid cells occasionally occur as cultures age (see Fig. BXII.β.42). **Motile by single polar flagella** (Fig. BXII.β.43). Internal membrane systems are poorly developed or absent (Fig. BXII.β.44). The color of photosynthetic cultures and colonies is peach brown. Absorption spectra of living cells show maxima at 377–378, 457–458, 484–485, 589–590, 799–801, and 850–851 nm. **Photosynthetic pigments are bacteriochlorophyll *a* esterified with phytol and carotenoids of the spheroidene series** with spheroidene, spirilloxanthin, and OH-spheroidene are present as major components.

Photoheterotrophic growth under anoxic conditions in the light or chemotrophic growth under oxic conditions in the dark at full atmospheric oxygen tension is possible. Photoorganotrophy with sugars, peptone, yeast extract, and Casamino acids as electron donors and carbon sources is the preferred mode of growth. In addition, simple organic compounds, such as acetate and intermediates of the tricarboxylic acid cycle, also support growth as carbon sources. The carbon sources utilized are listed in Table BXII.β.59. Also utilized are xylose, arabinose, galactose, gluconate, and asparagine. Bicarbonate-dependent dark fermentative growth is also possible. Sulfide, thiosulfate, and other reduced sulfur compounds do not serve as electron donors for photoautotrophic growth. Sulfide tolerance is weak; only 0.2 mM sulfide inhibits growth in the presence of 0.05% yeast extract. Ammonium salts and glutamate, but not nitrate, serve as nitrogen sources. The capacity for nitrogen fixation appears to be present, as suggested by the observation that nitrogenase-dependent H_2 production occurs in an ammonium-deficient medium. Sulfate is assimilated as a sulfur source. Catalase is negative or weakly positive. Oxidase reaction is positive. Proteolytic activities are present, but weak compared to those of the phylogenetic relative *Rubrivivax gelatinosus*. Gelatin is weakly hydrolyzed. Thiamine and biotin are required as growth factors.

Mesophilic and neutrophilic fresh water bacterium with optimal growth at 25–30°C (no growth at 37°C) and pH 6.5–7.0 (pH-range: pH 5–9). No growth occurs in the presence of 1.5% NaCl. Habitat: freshwater ponds, sewage ditches, and activated sludge. Major quinone components are Q-8 and RQ-8.

The mol% G + C of the DNA is: 59.8–60.3 (HPLC); type strain, 60.1 (HPLC).

Type strain: FR2, ATCC 49787, DSM 10138, JCM 7819.

GenBank accession number (16S rRNA): D16211.

2. **Rhodoferax antarcticus** Madigan, Jung, Woese, Achenbach 2000b, 275[VP]

ant.arc′ ti.cus. M.L. adj. *antarcticus* belonging to, coming from Antarctica.

Cells are curved or vibrioid rods, 0.7 × 2–3 μm under optimal growth conditions. Highly motile by polar flagella. Internal membrane systems are poorly developed or absent. The color of photosynthetic cultures and colonies is peach brown. Absorption spectra of living cells show maxima at 427, 452, 487, 518, 582, 799, 819, and 866 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids, most likely of the spheroidene series.

Photoheterotrophic growth under anoxic conditions in the light or chemotrophic growth under oxic conditions in the dark at full atmospheric oxygen tension is possible. Acetate pyruvate, lactate, succinate, malate, fumarate, glucose, fructose, sucrose, citrate, and aspartate support growth as carbon sources. Not utilized are methanol, ethanol, propanol, butanol, mannitol, glycerol, lactose, benzoate, formate, propionate, butyrate, valerate, caproate, heptanoate, glutamate, glutamine, and oxoglutarate. Bicarbonate-dependent dark fermentative growth with glucose and fructose is not possible. Sulfide at 2 mM inhibits growth. Photoautotrophic growth with hydrogen is slow. Ammonium salts, glutamate, glutamine, and aspartate serve as nitrogen sources. The capacity for dinitrogen fixation is present. Sulfate is assimilated as a sulfur source. Biotin is required as growth factor.

Psychrophilic and neutrophilic freshwater bacterium with optimal growth at 12–18°C (range: 0–25°C, no growth above 25°C). NaCl is not required and growth inhibitory above 2%.

Habitat: Antarctic microbial mat.

The mol% G + C of the DNA is: 61.5 (T_m).

Type strain: ATCC 700587.

GenBank accession number (16S rRNA): AF084947.

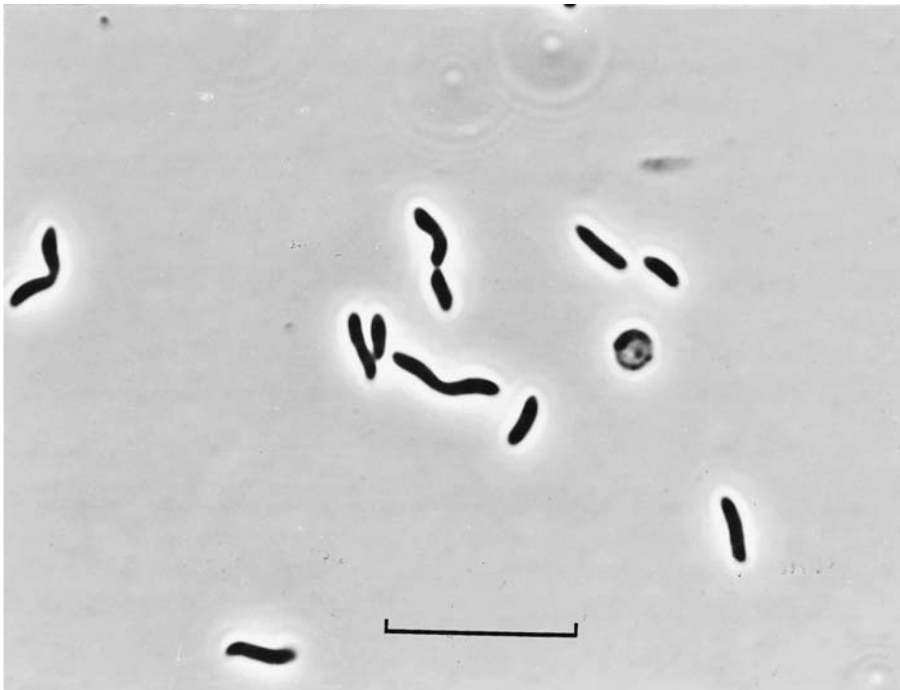

FIGURE BXII.β.42. Phase-contrast micrograph showing cell morphology of *Rhodoferax fermentans* (strain FR2). Curved rods occurring singly and in pairs and a spheroplast-like cell are observed. Bar = 10 µm.

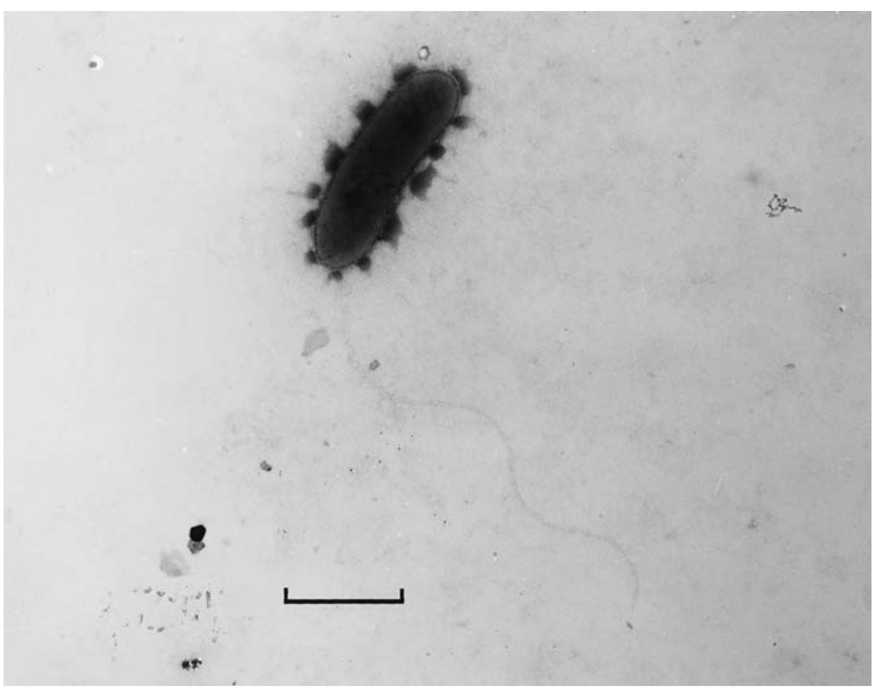

FIGURE BXII.β.43. Electron micrograph of a negatively stained cell of *Rhodoferax fermentans* (strain FR2) with a polar flagellum. Bar = 1 µm.

Genus X. **Variovorax** *Willems, De Ley, Gillis and Kersters 1991a, 446*[VP]

ANNE WILLEMS, JORIS MERGAERT AND JEAN SWINGS

Va.ri.o'vo.rax. L. adj. *varius* various; L. adj. *vorax* voracious; M.L. masc. n. *Variovorax* (bacteria) devouring a variety (of substrates).

Straight to slightly curved rods, 0.5–0.6 × 1.2–3.0 μm, occurring singly or in pairs. **Gram negative**. **Motile by means of sparse, peritrichous flagella**. Colonies are yellow due to the presence of carotenoid pigments. **Aerobic, having a strictly respiratory type of metabolism with O_2 as the terminal electron acceptor**. **Oxidase and catalase positive**. **Chemoorganotrophic**. **Some strains are capable of lithoautotrophic growth**, using H_2 as an energy source. These are referred to as biotype I, whereas nonlithoautotrophic strains are referred to as biotype II (Davis et al., 1969). Good growth occurs on media containing carbohydrates, organic acids, amino acids, or peptone.

The mol% G + C of the DNA is: 66.8–69.4.

Type species: **Variovorax paradoxus** (Davis 1969) Willems, De Ley, Gillis and Kersters 1991a, 447 (*Alcaligenes paradoxus* Davis *in* Davis, Doudoroff, Stanier and Mandel 1969, 387.)

FURTHER DESCRIPTIVE INFORMATION

Flagellation In a study of the cell morphology and flagellation of Gram-negative hydrogen bacteria, Aragno et al. (1977) defined three types of flagella based on electron microscopy. They reported that *V. paradoxus* cells have one to three laterally inserted type II flagella. This oligotrichous flagellation was originally described as "degenerately peritrichous" (Davis et al., 1969). The flagella have diameters of 15–17 nm. Flagellar wavelengths have been observed to be of two distinct types, one about half as long (1.2–1.3 μm) as the other (2.2–2.5 μm) occurring in the same culture (Aragno et al., 1977). Pili are inserted at the polar caps (Aragno et al., 1977).

Cell wall composition Walther-Mauruschat et al. (1977) have studied the cell envelopes of Gram-negative hydrogen bacteria and distinguished three types of cell walls, differing mainly in visibility and location of the peptidoglycan layer. *Variovorax* possesses type I cell walls, typical of most Gram-negative bacteria and characterized by a multilayered structure, consisting of an outer membrane and a cytoplasmic membrane of similar dimensions and appearance, which are separated by a dense layer of peptidoglycan.

Ultrastructure Intracellular mesosome-like membrane systems with a spiral appearance are present and often located in the area of cell division or at the cell poles (Walther-Mauruschat et al., 1977). Their significance is unclear, and they are now regarded mainly as artifacts resulting from the preparation of cells for electron microscopy. Intracellular inclusions of poly-3-hydroxybutyrate and polyphosphate are present, and translucent, glycogen-like inclusions may also be detected (Walther-Mauruschat et al., 1977). Cytochromes of the *a*, *b*, and *c* types are present, including a cytochrome *a2* with a peak at 625 nm in the reduced/oxidized spectrum (Davis et al., 1969).

Colonial characteristics Colonies on nutrient agar are glistening and shiny, yellow or greenish yellow. Occasionally, two types of colonies may occur in a single culture. Often, these types prove to be unstable and cannot be separated. Sometimes, non-mucoid variants may be separated from mucoid strains, but SDS–polyacrylamide electrophoregrams of whole-cell proteins of such types are always identical. The yellow pigments are carotenoids with absorption maxima in acetone of approximately 405 and/or 425 nm (Davis et al., 1969). More recently, Urakami et al. (1995a) have reported an absorption maximum of 420 nm for the carotenoid pigments of *V. paradoxus* DSM 30034^T.

Nutrition and metabolism A large variety of organic compounds may be used as sole carbon sources (Table BXII.β.60). Of a total of 143 organic compounds tested, 99 are used by *V. paradoxus* strains (Davis et al., 1969). No growth factors are required. Two biotypes are recognized. Strains of biotype I are able to grow autotrophically using the aerobic oxidation of hydrogen as an energy source. The hydrogenase is membrane-bound and does not reduce NAD (Schneider and Schlegel, 1977). It is similar to that of *Ralstonia eutropha* in that PCR tests with primers specific for the *R. eutropha* hydrogenase gene yield products of the correct size for *V. paradoxus* but no product for other hydrogen bacteria (Lechner and Conrad, 1997). No soluble hydrogenase is present (Schneider and Schlegel, 1977). Strains of biotype II cannot grow autotrophically or oxidize hydrogen (Davis et al., 1969).

Nitrate, but not atmospheric nitrogen, can be used by many strains as a nitrogen source. *Meta-* and *para-*hydroxybenzoate are metabolized via the *ortho* cleavage of protocatechuate. A new pathway for the degradation of homovanillic acid, distinct from that of *Pseudomonas putida*, has been reported for a *V. paradoxus* strain isolated from farmyard soil by enrichment on vanillylpyruvate. Homovanillic acid is degraded via ring hydroxylation to a dihydroxymonomethoxyphenylacetic acid, which is then cleaved by homogentisate 1,2-dioxygenase (Allison et al., 1995). Catechol 1,2-dioxygenase from *V. paradoxus* has been purified and characterized (Matevosyan et al., 1989).

Biosynthesis of aromatic amino acids *V. paradoxus* strains possess prephenate dehydrogenase and arogenate dehydrogenase that are reactive with either NAD or NADP. Arogenate dehydratase activity is absent; prephenate dehydratase is present, and its activity is increased 2–3-fold by 0.5 mM L-tyrosine (Byng et al., 1983). 3-Deoxy-D-arabinoheptulosonate 7-phosphate synthetase is inhibited by phenylalanine and chorismate (Whitaker et al., 1981). The various pathways for the biosynthesis of aromatic amino acids and their regulation have been shown to be useful indicators for the differentiation of different groups of pseudomonad bacteria (Byng et al., 1983).

Chemotaxonomic characteristics *Variovorax* possesses a Q-8 ubiquinone system (Urakami et al., 1995a). Major fatty acids (representing at least 5% of total fatty acids) are palmitic acid ($C_{16:0}$), a cyclopropane substituted fatty acid ($C_{17:0\ cyclo}$), *cis*-vaccenic acid ($C_{18:1}$), palmitoleic acid ($C_{16:1}$), 3-hydroxydecanoic acid ($C_{10:0\ 3OH}$), and 2-hydroxytetradecanoic acid ($C_{14:0\ 2OH}$). (Willems et al., 1989; Urakami et al., 1995a). Characteristic polyamines are putrescine and 2-hydroxyputrescine (Busse and Auling, 1988).

TABLE BXII.β.60. Characteristics of *Variovorax paradoxus*[a,b]

Characteristic	Reaction
Oxidase, catalase, urease	+
Denitrification	–
Nitrite reduction	–
Intracellular accumulation of poly-3-hydroxybutyrate	+
Extracellular hydrolysis of poly-3-hydroxybutyrate, Tween 80	+
Hydrolysis of starch, gelatin	–
Growth with D-glucose, D-fructose, D-galactose, L-arabinose, D-fucose, D-xylose, D-mannose, sorbitol, D-mannitol, D-arabitol, ethanol, glycerol, D,L-glycerate, citrate, mesaconate, succinate, fumarate, D,L-lactate, L-malate, D,L-3-hydroxybutyrate, α-ketoglutarate, D-gluconate, 5-ketogluconate, acetate, pyruvate, sebacate, mesaconate, pantothenate, adipate, pimelate, hydroxymethylglutarate, quinate, *m*-hydroxybenzoate, *p*-hydroxy-benzoate, L-leucine, L-histidine, L-α-alanine, L-glutamate, L-proline, L-aspartate, L-phenylalanine, L-ornithine, D,L-4-aminobutyrate[c]	+
Growth with L-xylose, L-sorbose, D-melibiose, sucrose, trehalose, melezitose, D-raffinose, maltose, lactose, D-turanose, D-tagatose, β-gentiobiose, α-methylxyloside, α-methyl-D-mannoside, α-methyl-D-glucoside, amygdalin, arbutin, esculin, salicin, inulin, starch, glycogen, dulcitol, *meso*-erythritol, heptanoate, caprylate, pelargonate, caprate, oxalate, anthranilate, nicotinate, testosterone, benzoate, *o*-hydroxybenzoate, benzylamine, 2-aminobenzoate, 3-aminobenzoate, 4-aminobenzoate, D-mandelate, isophthalate, terephthalate, L-valine, L-lysine, L-norleucine, L-cysteine, L-methionine, D-tryptophan, L-citrulline, L-arginine, D,L-kynurenine, D,L-2-amino-butyrate, δ-aminovalerate, trigonellin, urea, amylamine, ethylamine, diaminobutane, glucosamine, putrescine, spermine, histamine, tryptamine, betaine, sarcosine, creatine, acetamide, *N*-acetylglucosamine [c,d]	–
Utilization of D-fucose, L-fucose, cellobiose, D-ribose, L-rhamnose, D-arabinose, D-lyxose, adonitol, *meso*-inositol, xylitol, L-arabitol, 2-ketogluconate, saccharate, malonate, suberate, D-malate, *meso*-tartrate, D-tartrate, L-tartrate, mucate, glycolate, propionate, butyrate, isobutyrate, valerate, isovalerate, malonate, caproate, maleate, glutarate, azelate, levulinate, aconitate, citraconate, itaconate, L-mandelate, phthalate, phenylacetate, kynurenate, 2,3-butylene glycol, phenol, D-α-alanine, β-alanine, L-tryptophan, L-serine, L-threonine, L-isoleucine, L-tyrosine, L-tryptophan, D,L-norvaline, D,L-3-aminobutyrate, butylamine, pentylamine, glycine, ethanolamine[d,e]	d
Susceptible to:	
Chloramphenicol (30 μg/disk), tetracycline (30 μg/disk), kanamycin (30 μg/disk), neomycin (30 μg/disk), polymyxin B (300 U/disk)	+
Erythromycin (15 μg/disk), streptomycin (10 μg/disk)	d
Ampicillin (10μg/disk), methicillin (5 μg/disk), novobiocin (30μg/disk)	–

[a]For symbols see standard definitions.

[b]Data taken from Davis et al. (1969, 1970) (14 strains), Auling et al. (1978), Kersters and De Ley (1984b) (14 strains), and Aragno and Schlegel (1992).

[c]Aragno and Schlegel (1992) reported 11–89% of strains grew on citrate, acetate, *p*-hydroxybenzoate, L-leucine, L-histidine, L-α-alanine, L-glutamate, L-aspartate, L-phenylalanine, L-valine, and δ-aminovalerate in API auxanographic galleries.

[d]Aragno and Schlegel (1992) reported all strains grew on oxalate, 2–ketoglutarate, and glutarate in API auxanographic galleries.

[e]Aragno and Schlegel (1992) reported all strains failed to grow on cellobiose, *meso*-inositol, butylamine, and ethanolamine in API auxanographic galleries.

Plasmids Plasmid DNA is regarded as particularly important for the genetic adaptation of microorganisms in the natural environment, because as a mobile form of DNA, it can provide new phenotypes, allowing bacteria to survive and even thrive under changing and often adverse environmental conditions (Leahy and Colwell, 1990). Pathways for the degradation of various complex organic molecules have been shown to be plasmid encoded in *Pseudomonas*-like bacteria (Chakrabarty, 1976). Since *V. para-*

doxus strains are soil and water bacteria, it is not surprising that various plasmids have been reported to occur. Strains isolated from soil samples contaminated with the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) contain plasmids pJP2, which carries genes for the degradation of 2,4-D, and pJP3, which carries genes conferring resistance to merbromin, phenyl-mercury acetate, and mercuric ions, and the ability to degrade *m*-chlorobenzoate (Don and Pemberton, 1981). Another 2,4-D-degradative plasmid has been isolated from a *V. paradoxus* strain from agricultural soil and is capable of integrating in the chromosome without loss of the 2,4-D$^+$ phenotype. In the same study, a very similar plasmid pKA4 was found in a 2,4-D-degrading *Ralstonia pickettii* strain, suggesting natural horizontal gene transfer among genera (Ka and Tiedje, 1994). This has been supported by use of *V. paradoxus* as the recipient organism for the large catabolic plasmid pJP4 of *Ralstonia eutropha* in a study of horizontal gene transfer in soil (Neilson et al., 1994).

Di Giovanni et al. (1996) have observed that several different plasmids may occur per strain in a study of 32 strains of 2,4-D-degrading *V. paradoxus* isolates from a sample of contaminated soil. Based on the size and number of plasmids, they have distinguished 6 groups among the strains, with each group containing identical and unique plasmids of diverse size. Curing of the plasmids results in the loss of the ability to break down 2,4-D. Comparison of restriction patterns of plasmids from 2,4-D $^+$ and 2,4-D$^-$ strains shows that plasmids involved in 2,4-D-degradation in different strains can have different origins. The data suggest that plasmids are frequently exchanged within a population, enhancing gene transfer and recombination events (Di Giovanni et al., 1996).

Hydrogen metabolism and autotrophic growth are thought to be, at least in part, plasmid-linked, because exposure of a *V. paradoxus* strain to the plasmid-curing agent mitomycin C results in the loss of the autotrophic phenotype (Lim et al., 1980).

Antibiotic sensitivity Auling et al. (1978) have studied the susceptibility to antibiotics of five *V. paradoxus* strains and reported all strains to be sensitive to five of the ten antibiotics tested (see Table BXII.β.60).

Ecology *Variovorax* is a common soil inhabitant, also occurring in contaminated soils, where it may harbor plasmids carrying genes involved in the breakdown of complex chemicals and resistance to toxic compounds. *Variovorax* strains dominate the 2,4-dichlorophenoxyacetic acid (2,4-D)-degrading population in agricultural soil amended with this herbicide (Dunbar et al., 1995). A strain of *V. paradoxus* capable of degrading 2,4-D has been isolated from pristine Hawaiian volcanic soil. It has been found to contain a *tfdA* gene (encoding the enzyme for the first step of 2,4-D mineralization) that is transmissible to *Ralstonia eutropha* JMP228 carrying a plasmid with a mutant *tfdA* gene (Kamagata et al., 1997). In an analysis of a bacterial community decomposing polyethylene glycol, *V. paradoxus* has been identified as the most active decomposer (Sedina and Ivanov, 1991). *V. paradoxus* is able to degrade poly(3-hydroxybutyrate) (PHB), poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV), and polypropiolactone plastics *in vitro* (Mergaert and Swings, 1996; Kobayashi et al., 1999). *V. paradoxus* is among the most frequently isolated species of polyhydroxyalkanoate-degrading microorganisms from PHB and PHBV plastics buried in soils and sludge, and is sporadically isolated from PHB and PHBV plastics buried in household compost or immersed in fresh water (Mergaert and Swings, 1996). An extracellular PHB depolymerase from *V. paradoxus* S2 has been isolated and characterized (Shiraki et al., 1995; Kobayashi et al., 1999). *Variovorax* strains from river water have been reported to degrade the aliphatic polycarbonates polyhexamethylene carbonate and polytetramethylene carbonate (Suyama et al., 1998a). *Variovorax* also has been detected in a mixed culture capable of degrading metal–EDTA complexes, isolated from water from the river Mersey (UK) mixed with sludge from an industrial effluent treatment plant (Thomas et al., 1998). In a study of the influence of different chemical treatments on the transport of bacteria through porous media, *V. paradoxus* has been used as a model organism. Retention of bacteria is reduced by treatments making cells more hydrophobic and less electrostatically charged. Such effects may be important in improving the penetration of bacteria used in bioremediation programs of subsurface pollutants (Gross and Logan, 1995). *V. paradoxus* has been found to be a major bacterial group in the rhizosphere of chicory (*Cichorium intybus* L. var. *foliosum* Hegi), mainly early in the growing season (Van Outryve et al., 1988).

Enrichment and Isolation Procedures

Facultatively chemolithotrophic, hydrogen-oxidizing strains of *V. paradoxus* can be isolated from soil, mud, and water by enrichment in the liquid basal mineral medium[1] described by Palleroni and Doudoroff (1972). After inoculation, cultures are incubated at 30°C under an atmosphere of $H_2/O_2/CO_2/N_2$ (50:4–20:5:25–41) (Davis et al., 1970). Heterotrophic strains can be isolated from soil by enrichment with pantothenate (Davis et al., 1970) or poly-3-hydroxybutyrate (Delafield et al., 1965). Other strains have been isolated from soil and water samples using various complex chemicals for enrichment (Ka and Tiedje, 1994; Kamagata et al., 1997; Suyama et al., 1998a; Thomas et al., 1998).

Maintenance Procedures

For heterotrophic growth, convenient media, such as nutrient agar, can be used. Biotype I strains can be maintained under autotrophic or heterotrophic conditions. No reports are available regarding the preservation of autotrophic properties after prolonged periods of heterotrophic growth. However, Aragno and Schlegel (1992) have reported autotrophic cultures to remain viable at 4°C for longer periods (up to 6 months) than do heterotrophic ones.

Variovorax strains can be lyophilized in skim milk in the presence of a suitable cryoprotectant, such as 5% glutamate, 5% *meso*-inositol, or 10% honey (Aragno and Schlegel, 1992). For the preservation of autotrophic properties, the use of autotrophically grown cultures for lyophilization is preferred. Cells can also be stored at −80°C in nutrient broth (or another suitable medium) plus 10% glycerol.

Differentiation of the genus *Variovorax* from other genera

See Table BXII.β.42 for the family *Comamonadaceae* for features differentiating *Variovorax* from the other genera of this family.

Taxonomic Comments

In their phenotypic study of 65 hydrogen bacteria and related nonautotrophic bacteria, Davis et al. (1969) described a group of yellow pigmented, peritrichously flagellated organisms comprising both facultatively autotrophic and nonautotrophic

1. Basal mineral medium contains: Na-K phosphate buffer (pH 6.8) 0.033 M; NH_4Cl, 0.1%; $MgSO_4 \cdot 7H_2O$, 0.05%; ferric ammonium citrate, 0.005%; $CaCl_2$, 0.0005% (Palleroni and Doudoroff, 1972).

strains. The authors proposed that the genus *Hydrogenomonas*, which until then had been used to group all Gram-negative facultatively autotrophic, hydrogen-oxidizing bacteria, be abandoned because its type species, *Hydrogenomonas pantropha*, was considered a *nomen dubium*, of which no strains were available or could be isolated. Most of the polarly flagellated *Hydrogenomonas* species could be accommodated in the genus *Pseudomonas*, but the choice was less evident for the peritrichously flagellated species because of the lack of a broadly defined genus with a good type species. By elimination, the only acceptable existing peritrichously flagellated genus with a well defined type species was *Alcaligenes*. Thus, *Alcaligenes paradoxus* was created to comprise the yellow-pigmented, peritrichously flagellated strains, even though these strains did not have a true peritrichous type of flagellation, but rather an oligotrichous flagellation with 1–3 laterally inserted flagella (Aragno et al., 1977). Within *A. paradoxus*, two biotypes were proposed to accommodate the facultatively autotrophic and heterotrophic strains, respectively (Davis et al., 1969). Based on immunological comparisons of glutamine synthetase (Baumann and Baumann, 1978) and DNA–rRNA hybridizations (De Vos and De Ley, 1983), it became clear that *A. paradoxus* was more closely related to the *Pseudomonas acidovorans* group of species than to *Alcaligenes faecalis* and *Alcaligenes eutrophus*. More extensive DNA–rRNA hybridizations and further polyphasic characterization of the acidovorans group finally led to a proposal to transfer *Alcaligenes paradoxus* to a new genus *Variovorax* as *Variovorax paradoxus* (Willems et al., 1991a).

Variovorax is a member of the so-called "acidovorans rRNA complex" (Kersters and De Ley, 1984b), now the family *Comamonadaceae* (Willems et al., 1991a), in the *Betaproteobacteria*. Within this group, it is equidistantly related to each of the other taxa by DNA–rRNA hybridizations. No significant DNA binding is detected between *Variovorax* and representative strains of the other yellow pigmented genera *Hydrogenophaga* and *Xylophilus* (Willems et al., 1991a). In a recent phylogenetic analysis of the 16S rRNA gene sequences of members of the family *Comamonadaceae*, *V. paradoxus* has been found to group with *Xylophilus ampelinus*, a yellow pigmented pathogen of grapevine. The level of 16S rDNA similarity of 97.9% suggests that both species may belong to the same genus (Wen et al., 1999). Until further evidence of genotypic similarities is provided, the phenotypic differences between the slow-growing plant pathogen *Xylophilus* and the more versatile hydrogen-oxidizing *Variovorax* justify maintaining both as separate genera.

List of species of the genus Variovorax

1. **Variovorax paradoxus** (Davis 1969) Willems, De Ley, Gillis and Kersters 1991a, 447[VP] (*Alcaligenes paradoxus* Davis *in* Davis, Doudoroff, Stanier and Mandel 1969, 387.)
pa.ra.dox' us. Gr. prep. *para* amis, contrary to; Gr. n. *doxus* an opinion; M.L. n. *paradoxus* contrary to expectation, in reference to the chemolithotrophic and/or organotrophic metabolism of the organism.

The morphological and cellular characteristics are as described for the genus. Additional descriptive information is presented in Table BXII.β.60, which is based on data from Davis et al. (1969, 1970), Kersters and De Ley (1984b), and Aragno and Schlegel (1992).

Biotype I comprises facultatively autotrophic strains that reduce nitrate to nitrite in organic media. Some strains isolated under low partial pressures of oxygen have been reported to show "oxygen sensitivity" and initially do not grow autotrophically with 20% O_2. These strains can produce mutants indistinguishable with respect to oxygen sensitivity from other strains initially isolated with 20% or 30% O_2 (Davis et al., 1969). Wilde and Schlegel (1982) have reported strains to be tolerant to 80% O_2 when grown autotrophically and 100% O_2 when grown heterotrophically. Autotrophic cultures produce a characteristic unpleasant odor similar to that of soapy water in a laundry (Davis et al., 1969). Typical biotype I strains are the type strain of the species, as well as strains ATCC 17712, ATCC 17715, ATCC 17716, ATCC 17722, and ATCC 17723.

Biotype II strains are nonautotrophic and rarely reduce nitrate to nitrite. A typical biotype II strain is strain ATCC 17549; other strains are ATCC 17716, ATCC 17719, and ATCC 11720 (Davis et al., 1969). More strains are available in several culture collections, but it is not always known which biotype they represent.

Isolated by enrichment from soil, mud and water.

The mol% G + C of the DNA is: 66.8–69.4 (T_m).

Type strain: ATCC 17713, DSM 30034, IFO 15149, LMG 1797.

Genus Incertae Sedis XI. **Aquabacterium** *Kalmbach, Manz, Wecke and Szewzyk 1999, 775*[VP]

Werner Manz, Sibylle Kalmbach and Ulrich Szewzyk

A.qua.bac' te.ri.um. L. n. *aqua* water; Gr. n. *bakterion* rod; *Aquabacterium* a rod-shaped bacterium isolated from drinking water biofilms.

Rod-shaped cells, 0.5 × 1–4 μm. **Motile** by means of **monotrichous polar flagella**. Gram negative. **Polyalkanoate** and **polyphosphate** inclusion bodies have been frequently observed as storage materials. **Extracellular polymeric substances are formed,**

even under oligotrophic conditions. **Oxidase positive. Catalase negative. Microaerophilic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nitrate can be used as an alternate electron acceptor for anaerobic respiration, but nitrite, chlorate, sulfate, and iron (III) are not used as electron acceptors. **Growth by fermentation does not occur. Manganese is not oxidized**. **Carbohydrates are not used.** Tweens 20, 40, 60, and 80, acetate, butyrate, valerate, caproate, caprylate, succinate, adipate, pimelate, azelate, sebacate, fumarate, β-hydroxybutyrate, malate, and butanol can be used as carbon sources. Starch, esculin, gelatin, and DNA are not hydrolyzed. NaCl levels are tolerated up to 1.8%. Optimal pH, ~7; pH growth range, 5.5–10, depending on the species. Optimal temperature, ~20°C; temperature range, 6–36°C. Habitat: drinking water biofilm originating from various raw water sources (groundwater, surface water, artificially recharged groundwater) used for drinking water production.

The mol% G + C of the DNA is: 65–66.

Type species: **Aquabacterium commune** Kalmbach, Manz, Wecke and Szewzyk 1999, 776.

Further descriptive information

Aquabacterium is a slow-growing organism forming colonies of 1.5–3 mm in diameter on solid media after 10 d at 20°C. Colonies on modified R2A agar[1] are flat, transparent, white to cream-white, with a smooth margin and transparent edges. Cells are notable for the presence of both polyphosphate and polyalkanoate inclusion bodies (Figs. BXII.β.45 and BXII.β.46).

In a survey of drinking water biofilms grown on different raw water sources in Europe for the occurrence of *Aquabacterium*, *in situ* probing with fluorescently labeled, rRNA-targeted oligonucleotide probes have shown *Aquabacterium commune* to be a widespread bacterial species (Kalmbach et al., 2000).

Enrichment and Isolation Procedures

For the enrichment and isolation of *Aquabacterium*, bacteria have been detached from young drinking water biofilms that had been grown on glass and polyethylene slides in a modified Robbins device installed in a house installation system at the Technical University of Berlin (Kalmbach et al., 1997). The temperature in the Berlin drinking water varies from 9.4°C to 15.6°C and the pH values ranges from 7.2 to 7.7. Detached bacteria are pooled in a total volume of 2 ml sterile drinking water and vigorously mixed with a vortex mixer. Pure cultures are obtained by plating serial dilutions of the bacterial suspension on R2A agar (Reasoner and Geldreich, 1985) with subsequent incubation at 20°C for 10 d in the dark. Liquid cultures are agitated constantly at 100 rpm at 20°C. For routine cultivation of strains, R2A medium is modified by replacing starch with 0.1% (v/v) Tween 80.

Maintenance Procedures

Aquabacterium can be cultivated on either R2A agar or broth (Reasoner and Geldreich, 1985) that is modified by replacing starch with 0.1% (v/v) Tween 80 (Sigma). Strains grow well in liquid cultures under constant agitation at 100 rpm and 20°C. Storage is possible in the frozen state in culture medium containing 50% (v/v) glycerol. For long-term preservation of *Aquabacterium*, freeze-drying is recommended.

1. Modified R2A agar (Kalmbach et al., 1999) has the following composition (g/l of distilled water): yeast extract, 0.5; Difco protease peptone no. 3, 0.5; Casamino acids, 0.5; glucose, 0.5; Tween 80, 0.1% (v/v); sodium pyruvate, 0.3; K_2HPO_4, 0.3; $MgSO_4 \cdot 7H_2O$, 0.05; agar, 15. Adjust the medium at final pH 7.2 with crystalline K_2HPO_4 or KH_2PO_4 before adding agar, and sterilize for 15 min at 121°C.

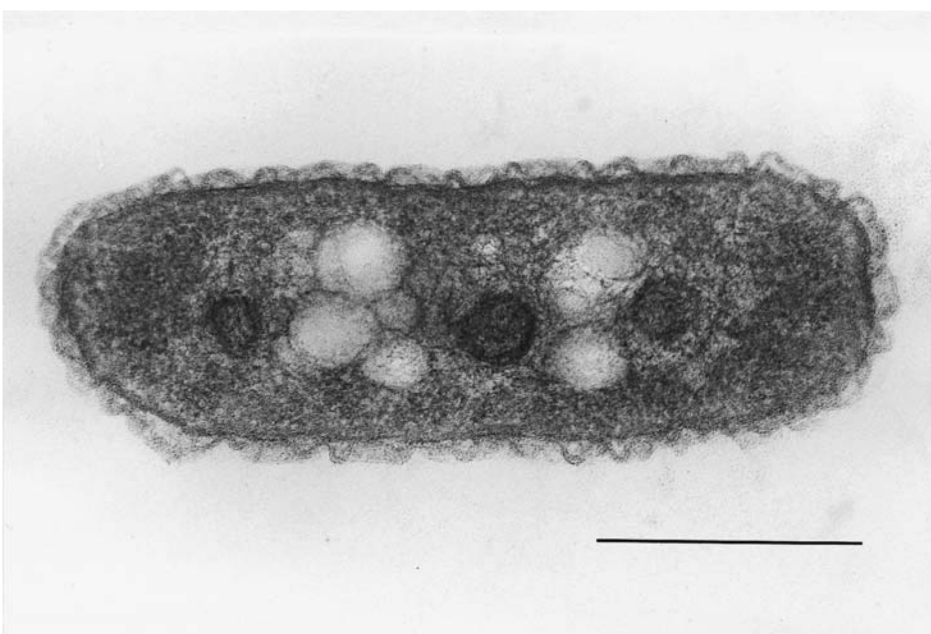

FIGURE BXII.β.45. Transmission electron micrograph of longitudinal thin section of an *A. commune* cell grown in modified R2A liquid medium, showing the typical cell morphology with polyphosphate (black) and polyalkanoate (white) inclusion bodies. Bar = 0.5 μm.

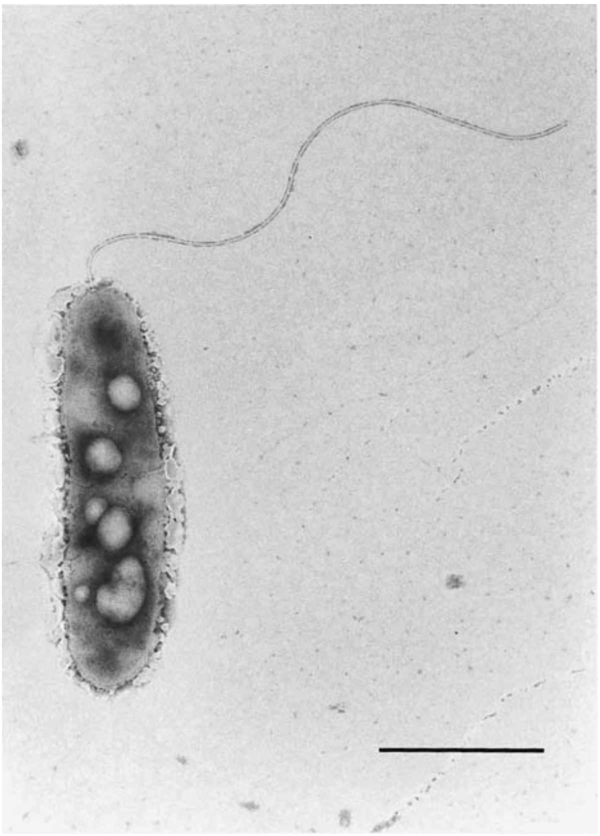

FIGURE BXII.β.46. Thin-section transmission electron micrograph of a negatively stained cell of *A. citratiphilum* showing the polar flagellum, polyphosphate (black), and large polyalkanoate inclusion bodies (white). Flagellation is similar for *A. parvum* and *A. commune*. Bar = 1.0 μm. (Reprinted with permission from S. Kalmbach et al., International Journal of Bacteriology, *49:* 769–777, 1999, ©International Union of Microbiological Societies.)

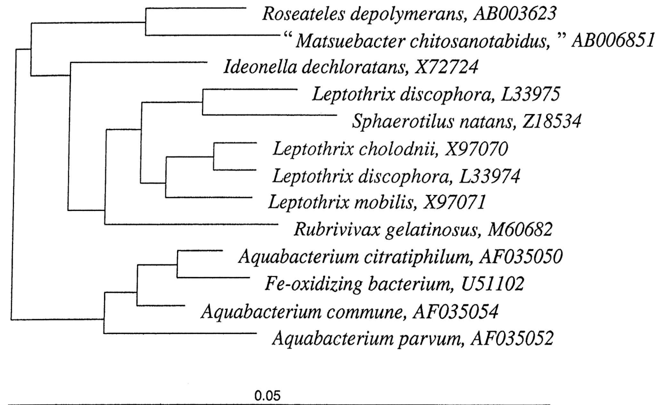

FIGURE BXII.β.47. Phylogenetic tree reflecting the affiliation of the three species of the genus *Aquabacterium* among the next closely related genera within the *Comamonadaceae*. The phylogenetic tree was reconstructed on the basis of full-length 16S rDNA sequences by the maximum parsimony algorithm, using the ARB software package (Strunk and Ludwig, 1998). Bar = 5% sequence divergence.

Differentiation of the genus *Aquabacterium* from other genera

The genus *Aquabacterium* can be differentiated from closely related genera within the family *Comamonadaceae*—particularly the genera *Ideonella* and *Leptothrix*—by its inability to metabolize carbohydrates. In addition, in contrast to *Ideonella dechloratans*, *Aquabacterium* shows no catalase activity and does not reduce chlorate. Members of the genus *Leptothrix* are morphologically characterized by sheath formation, whereas *Aquabacterium* does not form sheaths. *Leptothrix* can be further differentiated from *Aquabacterium* by its ability to oxidize manganese.

Taxonomic Comments

From a phylogenetic perspective, *Aquabacterium* is placed within the class *Betaproteobacteria*, the order *Burkholderiales*, and the family *Comamonadaceae*. At present, a total of 16 genera are included in this family. The genera most closely related to *Aquabacterium* are shown in Fig. BXII.β.47.

Spectrophotometrically determined reassociation rates of the genomic DNA (De Ley et al., 1970a) among the *Aquabacterium* species show the following levels of DNA–DNA relatedness: 44.9% between *A. citratiphilum* and *A. commune*, 45.4% between *A. citratiphilum* and *A. parvum*, and 51.3% between *A. parvum* and *A. commune*. 16S rDNA sequence similarity values are 98.2% between *A. citratiphilum* and *A. commune*, 97.2% between *A. parvum* and *A. commune*, and 96.5% between *A. citratiphilum* and *A. parvum*.

The genus *Aquabacterium* is characterized by an oligonucleotide signature (sequence 5′-CUUGCUGUUCAGUAACGAAGC-3′) within the 16S rRNA located at position 841 according to the *E. coli* numbering (Brosius et al., 1981).

Acknowledgments

The preparation of ultrathin sections, staining, and electron microscopy were kindly performed by J. Wecke at the Robert Koch-Institute, Berlin, Germany.

Differentiation of the species of the genus *Aquabacterium*

The differential characteristics of *A. citratiphilum*, *A. parvum*, and *A. commune* are summarized in Table BXII.β.61. Other characteristics of the species are listed in Table BXII.β.62.

Genus Incertae Sedis XII. **Ideonella** *Malmqvist, Welander, Moore, Ternström, Molin, Stenström 1994b, 595[VP] (Effective publication: Malmqvist, Welander, Moore, Ternström, Molin, Stenström 1994a, 63)*

Åsa Malmqvist, Edward R.B. Moore and Anders Ternström

I.de.o.nel′la. M.L. fem. n. derived from *Ideon* the research center where the bacterium was isolated and described; M.L. dim. ending *ella*.

Cells are straight or slightly curved rods, 0.7–1.0 × 2.5–5.0 μm, occurring singly, in pairs or in short filaments of four to five cells. When occurring in pairs or filaments, individual cells have a fusiform appearance with pointed ends. **Motile by two or more polar or subpolar flagella.** Gram negative. Prosthecae, sheaths, or endospores are not produced. No resting stages are known. Bacteriochlorophyll, carotenoids, or other pigments are not produced. **Aerobic**, having a strictly respiratory metabolism with ox-

ygen as the terminal electron acceptor; however, **chlorate can serve as an alternate terminal electron acceptor under anaerobic conditions**. **Oxidase positive. Weakly catalase positive;** catalase is produced only in minute amounts and the conventional agar colony test may be interpreted as negative. Chemoorganotrophic, utilizing organic acids, amino acids, and carbohydrates as carbon sources. Mesophilic, growing in the temperature range of 12–42°C. Belongs to the class *Betaproteobacteria*.

The mol% G + C of the DNA is: 68.1.

Type species: **Ideonella dechloratans** Malmqvist, Welander, Moore, Ternström, Molin, Stenström 1994b, 595 (Effective publication: Malmqvist, Welander, Moore, Ternström, Molin, Stenström 1994a, 63.)

Further descriptive information

Growth of *Ideonella dechloratans* occurs in a simple mineral medium containing an appropriate carbon source, but the growth yield in an anaerobic environment, using chlorate as the electron acceptor, is increased by the addition of 50 mg/l beef extract.

Chlorate is reduced to chloride in an anaerobic environment. The highly oxidized chlorate ion is an excellent electron acceptor for *I. dechloratans*, being even more efficient, theoretically, than oxygen ($\Delta G° = -132$ kJ/mol and -110 kJ/mol of electrons exchanged, respectively), and chlorate-contaminated wastewater effluents have been detoxified by a bacteria-mediated, anaerobic reduction of chlorate to chloride (Malmqvist et al., 1991). In practice, however, *I. dechloratans* prefers oxygen, which is evidenced by the fact that chlorate is not reduced in aerobic conditions.

Nitrate can serve as an alternative electron acceptor, but this ability is frequently lost after repeated subcultures on chlorate. Nitrate is reduced to nitrite.

Enrichment and Isolation Procedures

Ideonella dechloratans was originally enriched anaerobically from a chemostat of chlorate-containing sewage at 37°C, using a defined medium of 10 mM $NaClO_3$, 25 mM acetic acid, 3 mM NH_3, 0.25 mM KH_2PO_4, 0.1 mM $MgSO_4$, 0.1 mM $Ca(OH)_2$, 0.05 mM $FeSO_4 \cdot 7H_2O$, 0.05 mM $MnSO_4 \cdot H_2O$, 5 μM $NiCl \cdot 6H_2O$, 5 μM $CoCl_2 \cdot 6H_2O$, 5 μM $ZnSO_4 \cdot 7H_2O$, 0.1 μM H_3BO_3, 0.1 μM Na_2SeO_4, 0.1 μM Na_2WO_4, and 0.1 μM Na_2MoO_4. The pH was 7.0. Samples were taken from the reactor and streaked onto the same medium supplemented with 1.5% agar and incubated anaerobically in a GasPak jar (BBL), at 37°C. After 4 d, nonpigmented colonies were observed.

Differentiation of the genus *Ideonella* from other genera

Ideonella is recognized to be related genotypically (i.e., as determined by 16S rRNA gene sequence analysis) to the genera *Aquabacterium* (Kalmbach et al., 1999), *Leptothrix* (Siering and Ghiorse, 1996), and *Roseateles* (Suyama et al., 1999), within the *Betaproteobacteria*. Phenotypically, all of the species of the genera composing the *Ideonella–Aquabacterium–Leptothrix–Roseateles* 16S rDNA phylogenetic lineage produce Gram-negative, motile, rod-shaped cells. They are all chemoorganotrophic, collectively being able to utilize a range of organic acids, amino acids, and carbohydrates. They are all aerobic, possessing a strictly respiratory metabolism. *Ideonella dechloratans* may be distinguished from the species of *Aquabacterium*, *Leptothrix*, and *Roseateles* by its unique ability to reduce chlorate and by the production of catalase. It is differentiated from *Aquabacterium* species in its ability to metabolize carbohydrates and its ability to grow at temperatures as high as 42°C. It is differentiated from *Leptothrix* species by the absence of sheaths, by possessing more than one polar or subpolar flagellum, and by failing to oxidize Mn^{2+}. It is differentiated from *Roseateles* species by failing to produce bacteriochlorophyll or carotenoids, but is able to reduce nitrate and grow anaerobically.

Taxonomic Comments

Ideonella dechloratans was recognized initially as a typical "pseudomonad", i.e., a Gram-negative, respiring, cytochrome *c* oxidase positive, motile rod, capable of utilizing a wide spectrum of organic molecules. At that time, however, the genus *Pseudomonas* was being acknowledged as comprising a range of phylogenetically diverse species, which would be ultimately reclassified in different genera. Analysis of the 16S rDNA gene sequence and estimation of the phylogenetic position (Malmqvist et al., 1994a) demonstrated that *Ideonella* belonged within the β-subclass (Woese et al., 1984c) of the *Proteobacteria* (Stackebrandt et al., 1988b) and was most closely related to species of the *Comamonadaceae* or "acidovorans rRNA complex" (Willems et al., 1991a). However, the analysis shown in Fig. BXII.β.48 indicates that *I. dechloratans* belongs within a phylogenetic lineage related to, yet

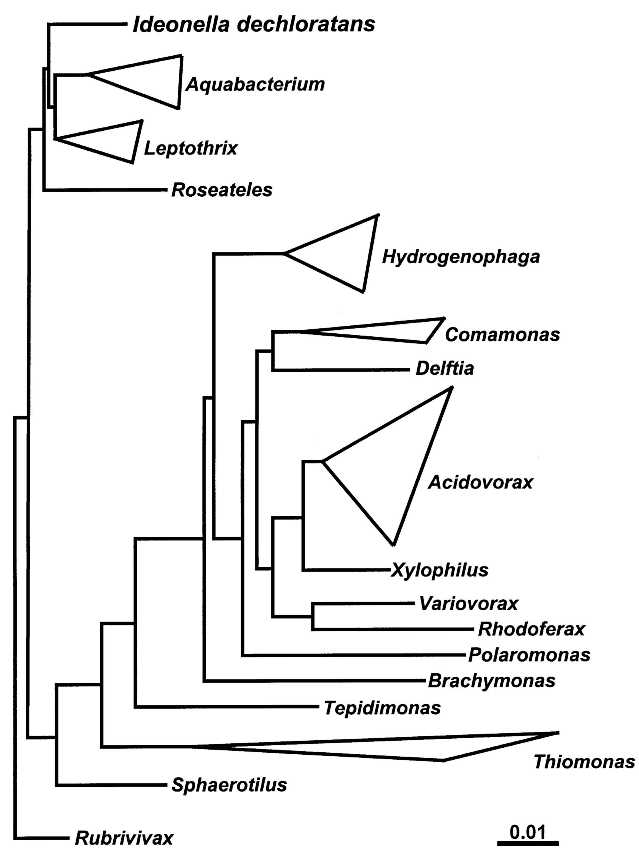

FIGURE BXII.β.48. The inferred phylogenetic position of *Ideonella dechloratans* among other genera of the *Betaproteobacteria*. Evolutionary distances were derived from pair-wise dissimilarities of 16S rRNA gene sequences. The unrooted dendrogram was generated using the neighbor-joining algorithm. The sequences used were obtained from the EMBL Nucleotide Sequence Database (Stoesser et al., 2001) and included those for all validly published species of each genus depicted in the dendrogram. The cluster length for each genus is depicted as the estimated length of the longest branch within each cluster.

distinct from, the *Comamonadaceae* and more closely related to species of the genera *Aquabacterium*, *Leptothrix*, and *Roseateles*.

The species of the genera composing the *Ideonella–Aquabacterium–Leptothrix–Roseateles* 16S rDNA phylogenetic lineage possess DNA composition values ranging from 65 to 71 mol% G + C (*Ideonella*, 68%; *Aquabacterium*, 65–68%; *Leptothrix*, 69–71%; *Roseateles*, 66%). However, *I. dechloratans* is distinguished from the species of *Aquabacterium*, *Leptothrix*, and *Roseateles*, possessing a monophyletic lineage with 16S rDNA gene sequence differences of 3–4%.

It is not clear whether the ability to utilize chlorate as an energy-yielding terminal electron acceptor is limited to a specialized group of bacteria or whether it is distributed throughout different bacterial taxa, as is the ability to grow with nitrate as terminal electron acceptor. Observations of enriched chlorate-reducing bacteria with cell morphologies different from that of *I. dechloratans* (Malmqvist et al., 1991) suggest that other chlorate reducers exist, although it is not possible to draw conclusions as to their relatedness to *I. dechloratans*. Other studies have identified N_2-fixing bacteria associated with rice, which are closely related to *I. dechloratans*, as determined by 16S rDNA sequence similarities greater than 99% (unpublished, sequence data deposited in the EMBL nucleotide sequence database). The ability to fix N_2 has not been determined for *I. dechloratans*. Yet other studies have detected 16S rDNA sequence types (unpublished, sequence data deposited in the EMBL nucleotide sequence database) similar to that of *I. dechloratans* in samples of an industrial, nitrifying/denitrifying activated sludge and in petroleum-contaminated groundwater. Such analyses suggest that other bacteria related to *I. dechloratans* exist within a range of different ecosystems and may or may not have the capability of utilizing chlorate as a terminal electron acceptor.

List of species of the genus Ideonella

1. **Ideonella dechloratans** Malmqvist, Welander, Moore, Ternström, Molin, Stenström 1994b, 595^{VP} (Effective publication: Malmqvist, Welander, Moore, Ternström, Molin, Stenström 1994a, 63.)
de.chlor.at′ ans. L. *de* from; M.L. adj. *chloratans* referring to chlorate; M.L. adj. *dechloratans* derived from chlorate; i.e., chlorate-utilizing bacterium.

The description of the species is the same as that for the genus, with the following additional information. Cells may contain several inclusions of unknown composition. Colonies are circular, smooth, and nonpigmented. Chlorate is reduced to chloride in an anaerobic environment. Nitrate can serve as an alternative electron acceptor, being reduced to nitrite. Nitrite and sulfate do not serve as electron acceptors. Acetate, alanine, asparagine, butyrate, fructose, glucose, lactate, propionate, pyruvate, and succinate are utilized as sole sources of carbon in mineral medium, both aerobically and anaerobically, in the latter case with chlorate as the electron acceptor. Adipate and fumarate are also utilized, with chlorate, but not with oxygen. Aminobenzoate, phenol, and phenylalanine are not utilized. No acid is produced from cellobiose, glucose, or maltose in Hugh–Leifson medium. Proteolytic activity is produced against casein but not against egg yolk. Lipolytic activity is evident against egg yolk, Tween 20, Tween 40, Tween 60, and Tween 80, but not against Tween 85.

Mesophilic, growing in the temperature range of 12–42°C; no growth occurs at 10–46°C. No growth occurs in media with 3% NaCl.

Isolated from anaerobic enrichments of chlorate-containing sewage in a chemostat reactor.

The mol% G + C of the DNA is: 68 (HPLC) (Mesbah et al., 1989).

Type strain: CCUG 30898.

GenBank accession number (16S rRNA): X72724.

Genus Incertae Sedis XIII. **Leptothrix** *Kützing 1843, 184*^{AL}

Stefan Spring and Peter Kämpfer

Lep′ to.thrix. Gr. adj. *leptus* fine, small; Gr. n. *thrix* hair; M.L. fem. n. *Leptothrix* fine hair.

Straight rods, 0.6–1.5 × 2.5–15 μm, occurring in chains within a sheath or free swimming as single cells, pairs, or short chains. Most strains are motile by **one polar flagellum**. One species is characterized by holdfasts[1] and a subpolar tuft of flagella. Poly-β-hydroxybutyrate is stored in globules as reserve material. Gram negative. **Sheaths can become encrusted by the deposition of iron and manganese oxides**.

Chemoorganotrophic. Strictly aerobic, respiratory metabolism. Good growth at low oxygen tensions. The optimal temperature for growth is around 25°C, and the optimal pH is 6.5– 7.5. A variety of sugars and organic acids can be used as carbon and energy sources by most species. The need for additional growth factors, including vitamin B_{12}, biotin, thiamine, adenine, and guanine, has been reported for several strains (Rouf and Stokes, 1964; Stokes and Johnson, 1965).

Widely distributed in a variety of freshwater habitats, ranging from unpolluted springs and slowly running water rich in soluble iron and manganese compounds to sediments and sewage.

Type species: **Leptothrix ochracea** (Roth 1797) Kützing 1843, 198 (*Conferva ochracea* Roth 1797.)

Further descriptive information

For several species of the genus *Leptothrix*, including *L. discophora*, *L. mobilis*, and *L. cholodnii*, 16S rRNA gene sequences have been determined. In phylogenetic trees, these species cluster together with a group of diverse bacteria including *Sphaerotilus natans*, *Ideonella dechloratans*, *Rubrivivax gelatinosus*, *Alcaligenes latus*, *Roseateles depolymerans*, and *Aquabacterium* species. This branch of bacteria is phylogenetically distinct from the *Comamonadaceae* as defined by Willems et al. (1991a) and is also referred to as the *Rubrivivax* subgroup of the *Betaproteobacteria* (Wen et al., 1999). No 16S rRNA gene sequences are currently available for *Leptothrix ochracea*, the type species of the genus, and *L. lopholea*.

Cells are straight rods, which may be as long as 15 μm. They

1. Evaginations or blebs formed at one cell pole by which organisms attach to walls of containers, submerged plants, stones, and other surfaces.

occur as filaments within characteristic sheaths or free swimming as single cells or short chains. Enlarged cells and coccoid bodies are formed in older cultures of some strains. A typical trait of several strains is false branching, which develops if a cell attaches to an existing filament and forms a new filament.

Sheaths formed by *Leptothrix* species are tube-like, extracellular structures that resemble those of *Sphaerotilus natans*. The sheath consists of a matrix of heteropolysaccharide and protein fibrils associated with the outer membrane of the Gram-negative wall (Emerson and Ghiorse, 1993b). The heteropolysaccharides contain a mixture of uronic acids and amino sugars and are negatively charged. The sheath proteins contain a high proportion of cysteine residues, which covalently cross-link the fibrils by disulfide bonds, resulting in a stable, mesh-like fabric. Numerous free sulfhydryl and carboxyl groups are distributed throughout the sheath and provide sites for binding of metal cations (Emerson and Ghiorse, 1993a).

During growth in media containing iron and manganese, sheaths become impregnated with metal oxides, which give them a yellow to dark-brown appearance. In this way, cells within the sheaths are protected from inhibitory concentrations of soluble iron or manganese compounds in the environment (Rogers and Anderson, 1976a, b). Further deposition of metal oxides can lead to massive incrustations, thereby increasing the diameter of the bare sheaths several fold (Fig. BXII.β.49). The deposition of iron and manganese oxides by *Leptothrix* species appear to be separate processes, which are catalyzed by proteins. The corresponding enzymes are excreted into the medium or bound to the extracellular sheath (Adams and Ghiorse, 1987; Corstjens et al., 1992). Several studies have shown that *Leptothrix* species do not gain energy from the oxidation of iron or manganese (Van Veen et al., 1978). Nevertheless, it has been observed that the addition of Mn^{2+} to the medium stimulates growth. It has been postulated that this beneficial effect may be mainly due to the oxidation product, MnO_2, which catalytically inactivates H_2O_2, which is excreted in toxic amounts by *Leptothrix* species during growth (Dubinina, 1978a, b).

Isoprenoid quinone Q-8 is the predominant quinone type of *L. discophora* and *L. cholodnii* (Kämpfer, 1995). The fatty acid composition, as determined by gas chromatographic analysis, of strains representing *L. discophora*, *L. cholodnii*, and *L. mobilis* differ only slightly (Spring et al., 1996). All strains contain the fatty acids dodecanoic acid, hexadecanoic acid, *cis*-9-hexadecenoic acid, *cis*-9,11-octadecenoic acid, and 3-hydroxydecanoic acid; this fatty acid profile is typical among members of the *Betaproteobacteria*.

The size and shape of colonies depends largely on the ability of the respective strain to form sheaths (Fig. BXII.β.50). Rough and filamentous colonies (Fig. BXII.β.50a) are characteristic of sheath-forming cells, whereas smooth and regular colonies (Fig. BXII.β.50b) consist mainly of sheathless cells. Due to the oxidation of iron and manganese, a black-brown precipitate is formed within the colonies and occasionally also as a halo around them. Cells tend to aggregate and form flocs in liquid culture.

Enrichment and Isolation Procedures

Several methods for the enrichment of *Leptothrix* species from the environment are based on the tendency of these filamentous organisms to attach to surfaces. Mulder and van Veen (1963) have used continuous-flow devices in order to imitate the natural growth conditions of these organisms. A continuous flow of a dilute nutrient solution that has been enriched with soluble iron and manganese compounds is guided through an apparatus consisting of several vessels arranged one after the other. As in unpolluted, slowly running water, bacteria that are able to attach to solid surfaces have a selective advantage within this device, because they obtain more nutrients than do bacteria moving with the medium. An alternative method that is less laborious has been applied by Spring et al. (1996). Microscope slides are put into a sample of freshwater sediment, and after several weeks,

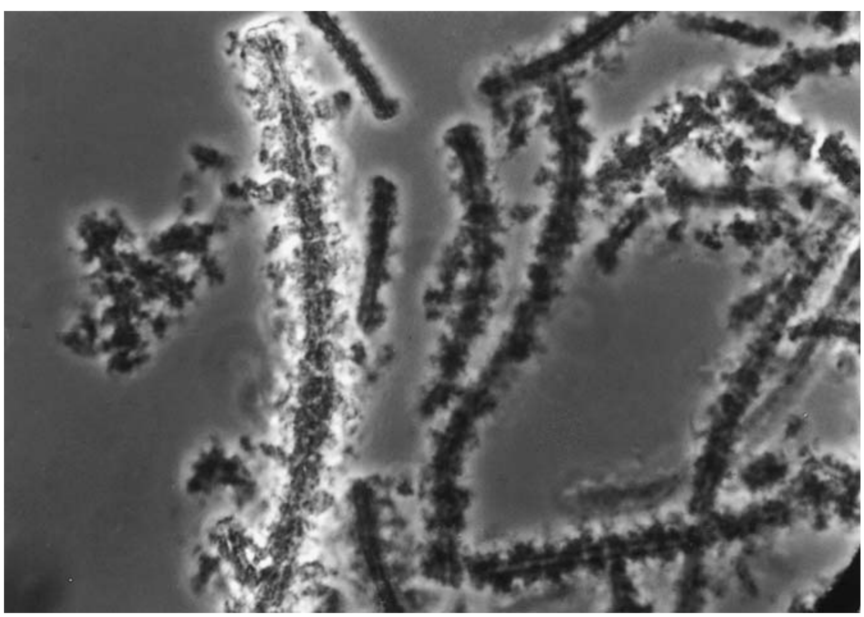

FIGURE BXII.β.49. Unknown strain, presumably belonging to *L. discophora*, grown under laboratory conditions in slowly running iron- and manganese-containing soil extract. Sheaths are covered with Fe(III) and Mn(IV) oxides. Light micrograph (× 1268).

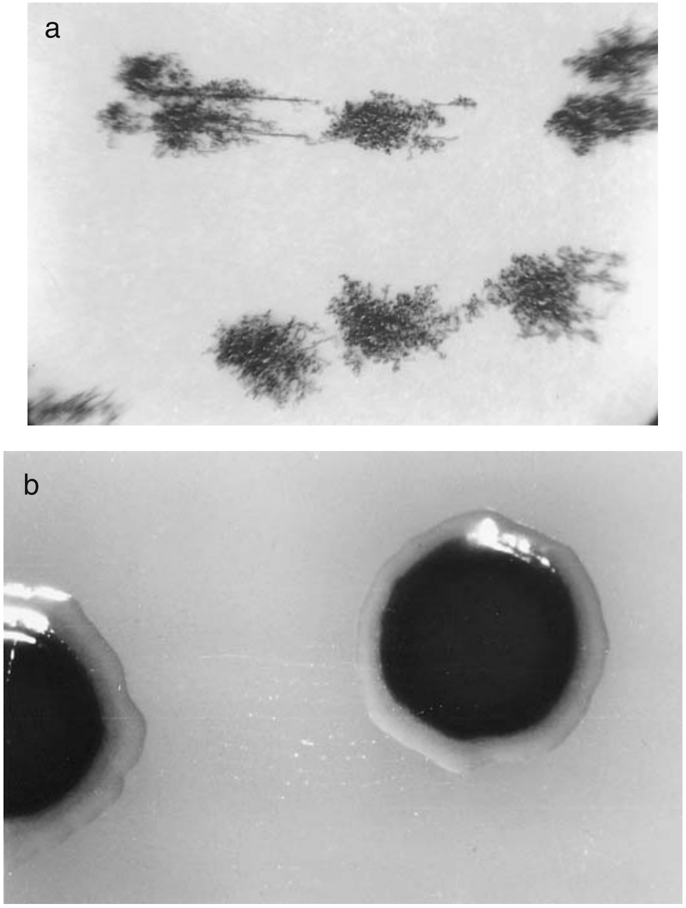

FIGURE BXII.β.50. Examples of various colony morphologies of *Leptothrix* strains grown on Mn(II)-containing agar media. (*a*) Filamentous colonies of an unknown strain presumably belonging to *L. discophora.* Light micrograph (× 18). (*b*) Smooth colonies of *L. mobilis* Feox-1 (DSM 10617). Light micrograph (× 29)

sheaths of filamentous bacteria encrusted with iron and manganese oxides covered parts of the slides. Subsequently, the slides may be removed from the sediment and used for isolation. Another simple enrichment method has been introduced by Rouf and Stokes (1964), who filled glass cylinders with water taken from the environment and added extracted alfalfa straw as a nutrient source, as well as $MnCO_3$ and freshly precipitated $Fe(OH)_3$. After several days, the flocculent growth of sheathed bacteria adhering to the walls of the cylinder indicates the enrichment of *Leptothrix* bacteria.

Isolation of pure cultures may be achieved by streaking material from enrichment cultures on previously dried agar plates containing low levels of nitrogen and carbon sources. The isolation medium used by Rouf and Stokes (1964) has the following composition (per liter tap water): peptone, 5.00 g; ferric ammonium citrate, 0.15 g; $MgSO_4{\cdot}7H_2O$, 0.20 g; $CaCl_2$, 0.05 g; $MnSO_4{\cdot}H_2O$, 0.05 g; $FeCl_3{\cdot}6H_2O$, 0.01 g; agar, 12.00 g.

Colonies of *Leptothrix* strains can be easily distinguished from most contaminating bacteria on this medium by their dark-brown color.

Enrichment cultures may not be necessary if natural environments are studied where *Leptothrix* bacteria can be detected by their flocculent growth. Flocculent cell material from these sites may be washed several times with sterile tap water and streaked directly on solid media.

Maintenance Procedures

Stock cultures can be stored on agar slants of the medium of Rouf and Stokes (1964) at 4°C for about three months. Most *Leptothrix* strains do not survive lyophilization. For the long-term preservation of these strains, freezing in liquid nitrogen is recommended.

Differentiation of the genus *Leptothrix* from other genera

The genus that is most closely related to *Leptothrix* is *Sphaerotilus.* Traits that distinguish both genera are discussed in the corresponding section of the genus *Sphaerotilus* and listed in Table BXII.β.66 of that chapter.

Taxonomic Comments

Some distinguishing characteristics of *Leptothrix* species are not very stable and are regularly lost upon cultivation. The ability to form sheaths has been irreversibly lost by most strains available from public culture collections, with the exception of *Leptothrix cholodnii* LMG 8142. The manganese-oxidizing activity is independent from the formation of sheaths and is more stable in most strains, but loss of this trait has also been reported.

A major problem in the taxonomy of the genus *Leptothrix* is the availability of reference strains. The type species of the genus *Leptothrix, L. ochracea*, has not been cultured, and the description is based only on morphological observations. The type strains of *Leptothrix lopholea*, LVMW 124, and *L. cholodnii*, LVMW 99, are not available from public culture collections and have apparently been lost. The strain LMG 7171 may be used as reference strain for *L. cholodnii* until a neotype is designated, but for *L. lopholea*, no other strains are available, preventing detailed taxonomic studies on this species.

Thus, species descriptions of *L. ochracea*, *"L. pseudo-ochracea"*, and *L. lopholea* have not been emended and adopted from the first edition of *Bergey's Manual of Systematic Bacteriology* (Mulder, 1989a). Emended or new descriptions of *L. discophora*, *L. cholodnii*, and *L. mobilis* are based on the work of Spring et al. (1996).

List of species of the genus Leptothrix

1. **Leptothrix ochracea** (Roth 1797) Kützing 1843, 198[AL] (*Conferva ochracea* Roth 1797.)
o.chra' ce.a. Gr. n. *ochra* yellow-ochre; M.L. adj. *ochracea* like ochre.

L. ochracea is probably the most common iron-precipitating ensheathed bacterium all over the world, occurring in slowly running ferrous iron-containing waters poor in readily decomposable organic matter. Its contribution to

the oxidation of Fe^{2+} is uncertain, since (a) the organism normally grows at a pH value of 6–7, at which Fe (II) is readily oxidized nonbiologically, and (b) pure cultures of this bacterium have never been obtained. For the latter reason, its Mn (II)-oxidizing capacity, which probably occurs under natural conditions, has never been confirmed. The pronounced development and activity of *L. ochracea* in iron- and manganese- containing waters give rise to the accumulation and deposition of large masses of ferric oxide and, probably, MnO_2, which are thought to be responsible for the formation of bog ore (see, for instance, Ghiorse and Chapnick, 1983).

Authors who have studied and described *L. ochracea* under natural conditions have been unable to obtain pure cultures (Cholodny, 1926; Charlet and Schwartz, 1954). Those who thought they had isolated *L. ochracea* had, in fact, described one of the other species of this genus (Winogradsky, 1888, 1922; Molisch, 1910; Lieske, 1919; Cataldi, 1939; Präve, 1957).

The most typical characteristic of *L. ochracea* is the formation of large numbers of almost empty sheaths within a relatively short time. The mechanism of this procedure can be followed under a phase-contrast microscope in a slide culture of the organism in an iron-containing soil extract medium. In this way, the behavior of *L. ochracea* in crude culture can be observed continuously. Chains of cells leave their sheaths at the rate of 1–2 μm/min, continuously producing new hyaline sheaths connected with the old envelope (Fig. BXII.β.51). Impregnation and covering of the sheaths with iron probably take place after the cells have left the envelopes. Aged, golden-brown sheaths are brittle and easily broken into relatively short fragments (Fig. BXII.β.52).

Isolation of *L. ochracea* has not been achieved, either from natural enrichments or in the laboratory from enrichment cultures of slowly running soil extract, so few details of the organism are available. In some instances, an organism resembling *L. ochracea* has been isolated, viz. *"L. pseudo-ochracea"*.

The mol% G + C of the DNA is: not available.

Type strain: No culture available.

2. **Leptothrix cholodnii** Mulder and van Veen 1963, 137[AL]
cho.lod' ni.i. M.L. gen. n. *cholodnii* of Cholodny, named for N. Cholodny, a Russian bacteriologist.

Cells of freshly isolated strains are usually found in long chains inside the sheaths. Single, motile cells may be seen outside the sheaths. In the presence of Mn^{2+}, the cells become covered with granular MnO_2 (Fig. BXII.β.53). At some sheath locations, the MnO_2 deposits may even exceed 10 μm. *L. cholodnii*, in contrast to other *Leptothrix* species, responds to an increased supply of organic nutrients (Table BXII.β.63), resulting in relatively large colonies (up to 5 mm in diameter) on nutrient-rich agar media. On manganese (II)-containing agar, black-brown hairy colonies are formed, particularly when the organism is seeded densely. Most strains display a strong tendency to dissociate spontaneously and to produce smooth, rather than the typical rough, colonies. Such mutant strains are largely sheathless and oxidize manganese slightly or not at all (Mulder and van Veen, 1963; Rouf and Stokes, 1964; Stokes and Powers, 1965).

Growth takes place between 10 and 35°C; the pH range for growth is from pH 6.5 to 8.5. Oxidase positive. The following compounds support growth in GMBN medium (Kämpfer et al., 1995): DL-3-hydroxybutyrate, DL-lactate, L-glutamate, L-leucine, L-proline, phenylpyruvate, and quinate; no growth is obtained with D-fucose, fumarate, or glutarate. Poly-β-hydroxybutyrate granules are formed.

Major fatty acids (>5% each) present in all strains are

[b]Growth was determined in GMBN medium supplemented with the respective carbon source (Kämpfer et al., 1995).

hexadecanoic acid, *cis*-9-hexadecenoic acid, dodecanoic acid, and *cis*-9,11-octadecenoic acid. Tetradecanoic acid is found in small amounts in all strains, whereas other minor fatty acids have not been detected.

Results of DNA–DNA hybridization experiments have indicated that, currently, three different strains belong to this species, viz. LMG 8142, LMG 8143, and LMG 7171, sharing DNA–DNA similarity values well above 70% (Spring et al., 1996). The strain LMG 7171 served as the reference strain in this study, because the original designated type strain has apparently been lost.

In agreement with its nutritional requirements, *L. cholodnii* is found in slowly running iron- and manganese-containing, unpolluted waters or in polluted waters, particularly in activated sludge.

The mol% G + C of the DNA is: 68–70 (T_m).

Type strain: LVMW 99 (not available).

3. **Leptothrix discophora** Spring, Kämpfer, Ludwig and Schleifer 1997, 601[VP] (Effective publication: Spring, Kämpfer, Ludwig and Schleifer 1996, 640.)
dis.co'phor.a. Gr. n. *discos* a disk; Gr. adj. *phoros* bearing; M.L. adj. *discophora* disk-bearing.

Cells are relatively small compared to those of the other *Leptothrix* species described (Table BXII.β.63). They may occur in narrow sheaths or be free swimming; free cells are motile by thin polar flagella at one or both poles. The manganese-oxidizing and ferric oxide-storing capacities of this organism are very pronounced. In enrichment cultures containing nutrient media with Mn (II) salts, the sheaths are heavily but irregularly encrusted with MnO_2, giving rise to sheaths of up to 10 μm thickness. In media with both

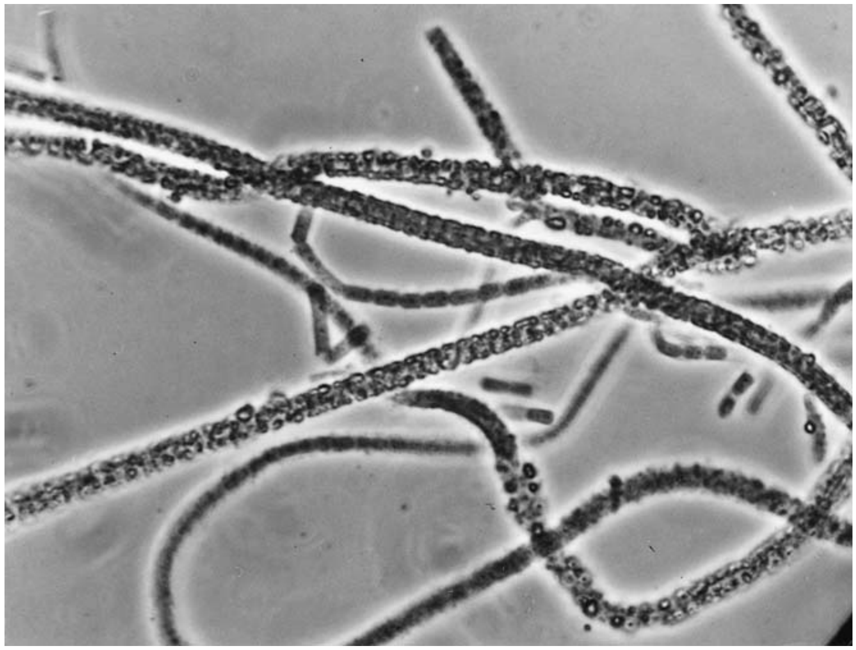

FIGURE BXII.β.53. *L. cholodnii* sheaths encrusted with granulated MnO_2 (× 1280). (Reproduced with permission from E.G. Mulder and W.L. van Veen, Antonie van Leeuwenhoek Journal of Microbiology and Serology *29:* 121–153, 1963, ©Kluwer Academic Publishers.)

Mn (II) and Fe (II), as in slowly flowing soil extract, the sheaths become covered with a thick, dark brown, fluffy layer of ferric oxide and MnO_2, which may increase the diameter of the trichomes to up to about 20–25 μm (Fig. BXII.β.49). Under these conditions, the sheaths may taper toward the growing tips. Following isolation, the ability to form sheaths is easily lost in this species (Adams and Ghiorse, 1986). False branching is regularly observed, even with sheathless strains. In older cultures, coccoid bodies and cell evaginations are formed.

Colonies on the solid medium of Rouf and Stokes are about 1 mm in diameter, irregular in shape, flat, and dark-brown. Under certain conditions, filamentous colonies may be formed. Increasing the supply of nutrients, such as glucose, peptone, methionine, purine bases, vitamin B_{12}, biotin, and thiamine, only increases growth slightly. Visible aggregates are formed when cells are grown in liquid media.

Growth occurs between 15 and 33°C; the pH range for growth is from pH 6.0 to 8.0. Oxidase positive. D-fucose, L-proline, and protocatechuate support growth in GMBN medium; no growth is obtained with fumarate, glutarate, DL-3-hydroxybutyrate, DL-lactate, L-glutamate, L-leucine, phenylpyruvate, and quinate. Poly-β-hydroxybutyrate granules are formed. Major fatty acids (>5%) are hexadecanoic acid, *cis*-9-hexadecenoic acid and dodecanoic acid.

Minor fatty acids are *cis*-9,11-octadecenoic acid, 3-hydroxydecanoic acid and octadecanoic acid.

The normal habitat is slowly running, unpolluted, iron- and manganese-containing water of ditches, rivers, and ponds.

The mol% G + C of the DNA is: 71 (T_m).

Type strain: SS-1, LMG 8141.

GenBank accession number (16S rRNA): L33975.

4. **Leptothrix lopholea** Dorff 1934, 33[AL]

loph.o.le' a. Gr. n. *lophos* a crest; M.L. dim. fem. adj. *lopholea* somewhat crested or tufted.

L. lopholea resembles *S. natans* to a greater extent than do the other *Leptothrix* species. It produces polytrichous, subpolar flagellation and forms holdfasts and false branches. Strains may also grow in rich media. Cells usually develop short, sheathed filaments radiating from a cluster of holdfasts, giving rise to many tiny flocs when the cells are grown in liquid media (Fig. BXII.β.54). Deposition of iron and manganese oxides is more pronounced on holdfasts than on filaments. On Mn (II)-containing agar media, encrustation of sheaths with MnO_2 is retarded, so that colonies are white at first and later become black-brown. Cell growth responds poorly to an increased supply of organic nutrients. Strains that do show a good response oxidize manganese more slowly.

This species may be isolated from slowly flowing, unpolluted or polluted freshwater and from activated sludge.

The mol% G + C of the DNA is: not available.

Type strain: LVMW 124 (not available).

5. **Leptothrix mobilis** Spring, Kämpfer, Ludwig and Schleifer 1997, 601[VP] (Effective publication: Spring, Kämpfer, Ludwig and Schleifer 1996, 640.)

mo' bi.lis. L. adj. *mobilis* motile, movable.

Cells are similar in width to those of *L. discophora*, but are usually shorter. They are highly motile by single polar flagella. Sheaths are not formed under laboratory conditions. Colonies on the agar medium of Rouf and Stokes are about 1 mm in diameter, circular, flat, smooth, and dark-brown. Visible aggregates are formed when cells are grown in liquid media.

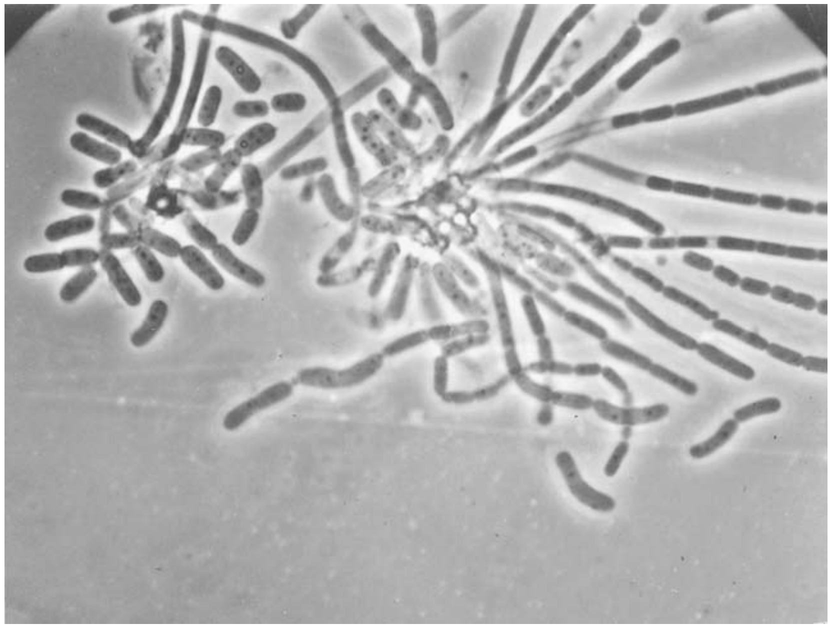

FIGURE BXII.β.54. *L. lopholea* in culture solution. Many trichomes can be seen radiating from common holdfasts. Light micrograph (× 1316). (Reproduced with permission from E.G. Mulder and W.L. van Veen, Antonie van Leeuwenhoek Journal of Microbiology and Serology *29:* 121–153, 1963, ©Kluwer Academic Publishers.)

Growth takes place between 10 and 37°C; the pH range for growth is from pH 6.5 to 8.5. Oxidase positive. Fumarate and glutarate support growth in GMBN medium; no growth is obtained with D-fucose, DL-3-hydroxybutyrate, DL-lactate, L-glutamate, L-leucine, L-proline, phenylpyruvate, protocatechuate, and quinate. Poly-β-hydroxybutyrate granules are formed.

Major fatty acids (>5%) are hexadecanoic acid, *cis*-9-hexadecenoic acid, and *cis*-9,11-octadecenoic acid. Minor fatty acids are 3-hydroxydecanoic acid, dodecanoic acid, octadecanoic acid, tetradecanoic acid, and *cis*-9,10-methyleneoctadecanoic acid.

Isolated from the sediment of a freshwater lake (Chiemsee) in Upper Bavaria, Germany.

The mol% G + C of the DNA is: 68 (T_m).

Type strain: Feox-1, LMG 17066, DSM 10617.

GenBank accession number (16S rRNA): X97071.

6. **"Leptothrix pseudo-ochracea"** Mulder and van Veen 1963, 135.

pseu.do.o.chra' ce.a. Gr. adj. *pseudes* false; M.L. adj. *ochracea* specific epithet; M.L. adj. *pseudo-ochracea* not the true *L. ochracea.*

Cells are more slender than those of the other *Leptothrix* species (Table BXII.β.63), and are very motile by single, thin, polar flagella. Even chains of 6–10 cells may show an undulatory locomotion after leaving their sheaths. This characteristic may account for the relatively large number of empty sheaths in culture, as compared with the number found in most *Leptothrix* species; however *L. ochracea* possesses even more empty sheaths. In slowly flowing ferrous iron-containing soil extract, the sheaths become impregnated with ferric oxide and appear yellow-brown. In this respect, the organism resembles *L. ochracea.* In media with added manganese compounds, the sheaths are covered with small granules of MnO_2. On manganese (II)-containing agar, the black-brown colonies are very filamentous and may exceed a width of 10 mm. On basal agar media containing 0.1% peptone and 0.1% glucose, the organism may grow in concentric rings.

The normal habitat of *"Leptothrix pseudo-ochracea"* is the slowly running, unpolluted, iron- and manganese-containing freshwater of ditches and brooklets. This species may also be found in slightly polluted water.

Deposited strain: none designated.

Genus Incertae Sedis XIV. **Roseateles** *Suyama, Shigematsu, Takaichi, Nodasaka, Fujikawa, Hosoya, Tokiwa, Kanagawa and Hanada 1999, 455[VP]*

Akira Hiraishi and Johannes F. Imhoff

Ro.se.a.te' les. L. adj. *roseus* rose-colored, pink; Gr. adj. *ateles* defective, incomplete; M.L. masc. n. *Roseateles* the rose-colored incomplete (photosynthetic bacterium).

Cells are straight slender rods, 0.5–0.6 µm wide, motile by means of polar flagella, reproduce by binary fission. Gram negative. **Belong to the *Betaproteobacteria.*** Do not form any type of internal membranes. **Synthesize bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.**

Strictly aerobic, chemoorganoheterotrophic bacteria. Do not grow and produce photosynthetic pigments under anoxic conditions in the light. Carbon sources and electron donors supporting growth are simple organic compounds, Casamino acids, peptone, skim milk, and yeast extract. Accumulate poly-β-hy-

droxybutyrate. Catalase negative, oxidase positive. **The major respiratory quinone is ubiquinone-8.**

Mesophilic and neutrophilic freshwater bacteria.

The mol% G + C of the DNA is: 66.2–66.3.

Type species: **Roseateles depolymerans** Suyama, Shigematsu, Takaichi, Nodasaka, Fujikawa, Hosoya, Tokiwa, Kanagawa and Hanada 1999, 455.

Further descriptive information

The genus *Roseateles* is at this time monotypic, with *R. depolymerans* as the type species (Suyama et al., 1999). Based on 16S rDNA sequence analysis, *R. depolymerans* belongs to the *Betaproteobacteria*, with *Rubrivivax*, *Ideonella*, *Leptothrix*, and *Sphaerotilus* species as phylogenetic neighbors. The 16S rDNA sequence of the phototrophic, purple, nonsulfur bacterium *Rubrivivax gelatinosus* is 96.3% similar to that of *Roseateles depolymerans*.

Colonies on agar media are circular, smooth, and soft. Rough and opaque colonies occur in some cases. The color of colonies is white at the early stage of cultivation but becomes pink in older cultures due to the production of carotenoids. Liquid cultures exhibit no or little pigmentation. The intensity of colony pigmentation depends upon the growth medium. The best medium for pigment production is an agar medium containing 0.02% Casamino acids. Thin-section electron microscopy indicated the absence of any type of internal membranes and the presence of poly-β-hydroxybutyrate granules (cells stained positively with Nile blue A).

Photosynthetic pigments are bacteriochlorophyll *a* esterified with phytol and carotenoids. The major carotenoid of *R. depolymerans* is spirilloxanthin (88–89 mol% of the total content). Biosynthetic precursors of spirilloxanthin, OH-spirilloxanthin, anhydrorhodovibrin, and 3,4-dehydrorhodopin are present as minor components. The molar ratios of total carotenoids/bacteriochlorophyll *a* were 0.58–0.65 (Suyama et al., 1999). Ultrasonically disrupted cells have absorption maxima at 482, 515, 550, 590, 800, and 870 nm. The spectral pattern in the near-infrared region indicates that the cells contain a core light-harvesting complex (B870, LH I), together with the photosynthetic reaction center, but lack a peripheral light-harvesting complex (LH II). Like other aerobic bacteriochlorophyll-containing bacteria, *R. depolymerans* produces BChl *a* only under aerobic growth conditions in darkness.

R. depolymerans is an obligately aerobic chemoorganoheterotrophic bacterium, which is unable to grow under anaerobic conditions, neither in the dark nor in the light. The doubling time exhibited under optimal growth conditions is approx. 2 h. One of the most characteristic features of *Roseateles depolymerans* is the ability to degrade aliphatic polycarbonates, including poly(tetramethylene carbonate), poly(hexamethylene carbonate), and poly(ε-caprolactone), which are known as biodegradable plastics. On polycarbonate agar plates, clear zones are produced around the colonies and the turbidity of opaque polycarbonate suspension in liquid culture is reduced within a few days of incubation. Gel permeation chromatography showed that poly(hexamethylene carbonate) was degraded via the production of diester, di(6-hydroxyhexyl) carbonate (Suyama et al., 1998a). The accumulation of diesters as intermediate products suggests that lipolytic enzymes may be the key enzymes in this degradation process.

Strains of *R. depolymerans* were isolated together with other polycarbonate-degrading bacteria from Hanamuro River in Ibaraki Prefecture, Japan (Suyama et al., 1998a). Polycarbonate-degrading pigmented strains that are phylogenetically very close to *R. depolymerans* have also been isolated from soil environments (Suyama et al., 1998b). In view of these results, *R. depolymerans* and related bacteria may inhabit a wide variety of freshwater and terrestrial environments.

Enrichment and Isolation Procedures

Surface water of freshwater environments is a possible source for *Roseateles.* For selective enrichment and isolation, the use of mineral medium supplemented with poly(hexamethylene carbonate) is recommended (Suyama et al., 1998a). The polycarbonate liquid medium is inoculated with a suitable water sample and incubated with shaking at 35°C in darkness. Cultures positive for reducing the turbidity of polycarbonate are transferred to agar media of the same composition. After incubation for at least one week, pink colonies with clear zones may appear on the agar medium. Growth media and cultural conditions commonly used for the isolation of freshwater aerobic bacteria can be used for the isolation of *R. depolymerans.*

Maintenance Procedures

Cultures are well-preserved in liquid nitrogen or by lyophilization. Preservation in a mechanical freezer at −80°C is also possible.

Differentiation of the genus *Roseateles* from other genera

Differential characteristics of the genus *Roseateles* and related genera are shown in Table BXII.β.64.

Taxonomic Comments

Strains of *Roseateles depolymerans* were first isolated as obligately aerobic chemoorganotrophic bacteria capable of degrading aliphatic polycarbonates (Suyama et al., 1998a). Detailed phenotypic studies showed that these polycarbonate-degrading strains produce bacteriochlorophyll *a* and carotenoids with spirilloxanthin as the main component. However, photosynthetic pigments were formed only under aerobic growth conditions, as found in other obligately aerobic bacteriochlorophyll-containing bacteria. 16S rDNA-based sequence analysis indicated that the polycarbonate-degrading, bacteriochlorophyll-producing strains were closely related to the phototrophic, purple, nonsulfur bacterium *Rubrivivax gelatinosus.* However, major phenotypic differences between the polycarbonate-degrading strains and *Rubrivivax gelatinosus* and other phylogenetically related bacteria led to the proposal of a new genus and species, *Roseateles depolymerans* (Suyama et al., 1999). The genus *Roseateles* belongs to the *Betaproteobacteria* and is the first described genus of aerobic bacteriochlorophyll-containing bacteria that does not fall within the *Alphaproteobacteria.*

Acknowledgments

The authors are indebted to T. Suyama for his helpful comments and discussions.

by means of a single flagellum or several polar flagella. Motility is observed only in the early exponential phase of growth. Spores and sheaths are not formed. Cell suspensions and colonies are white to pink. Pigmentation varies depending upon growth media and culture age. Absorption maxima of living cells are at 482, 515, 550, 590, 800, and 870 nm. Bacteriochlorophyll *a* and carotenoids with spirilloxanthin as the major component are synthesized as photosynthetic pigments only under aerobic conditions in the dark.

Obligately aerobic chemoorganoheterotrophic bacteria producing photosynthetic pigments. Do not grow phototrophically under anoxic conditions in the light. Do not grow by anaerobic respiration with nitrate, dimethyl sulfoxide, or trimethylamine *N*-oxide as the terminal electron acceptors. Autotrophic growth with hydrogen is absent. Good carbon sources for growth are D-glucose, D-fructose, D-galactose, mannitol, pyruvate, lactate, citrate, succinate, and L-malate. Good growth also occurs with Casamino acids, peptone, skim milk, and yeast extract. Most characteristic is the ability to co-metabolize and degrade aliphatic polycarbonates. Not utilized are D-ribose, sucrose, glycerol, and sorbitol. Hydrolytic activities against starch and gelatin are present. Acid production from glucose in Hugh–Leifson's OF medium is weak or negative. Oxidase and β-galactosidase (ONPG), but not catalase, are produced. Nitrate is not reduced to nitrite. Nitrogen fixation is negative. No growth factors are required.

Optimal growth occurs at 35°C (range: 5–43°C) and pH 6.5 (range: pH 5–8).

Habitat: wide variety of freshwater environments.

The mol% G + C of the DNA is: 66.2–66.3 (HPLC).

Type strain: Suyama 61A , DSM 11813.

GenBank accession number (16S rRNA): AB003623.

Genus Incertae Sedis XV. **Rubrivivax** *Willems, Gillis and De Ley 1991b, 70*[VP]

JOHANNES F. IMHOFF

Rub.ri.vi' vax. L. neut. adj. *rubrum* red; L. masc. adj. *vivax* long living; M.L. masc. n. *Rubrivivax* the red and long living (bacterium).

Cells are straight or curved rods, are motile by means of polar flagella, and multiply by binary fission. **Gram negative and belonging to the *Betaproteobacteria*.** Internal membrane systems are poorly developed or absent. **Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spheroidene series. Ubiquinones and menaquinones with eight isoprene units (Q-8 and MK-8) are present. Straight-chain $C_{16:1}$ and $C_{16:0}$ are the major components of cellular fatty acids. $C_{10:0\ 3OH}$ is present.**

Photoautotrophic and photoheterotrophic growth may occur with hydrogen and a variety of carbon compounds as electron donors. **Chemotrophic growth is possible** by respiration under microoxic to oxic conditions in the dark or by fermentation. Cells grow well with simple organic compounds as electron donors and carbon sources, as well as in complex media containing peptone, yeast extract or Casamino acids. Growth factors are required. **Mesophilic and neutrophilic freshwater bacteria.** Habitat: freshwater ponds, sewage ditches, activated sludge.

The mol% G + C of the DNA is: 70.5–72.4 (Bd), 71.2–72.1 (HPLC).

Type species: **Rubrivivax gelatinosus** (Molisch 1907) Willems, Gillis and De Ley 1991b, 71 (*Rhodocyclus gelatinosus* (Molisch 1907) Imhoff, Trüper and Pfennig 1984, 341; *Rhodopseudomonas gelatinosa* (Molisch 1907) van Niel 1944, 98; *Rhodocystis gelatinosa* Molisch 1907, 22.)

FURTHER DESCRIPTIVE INFORMATION

Characteristic of *Rubrivivax gelatinosus* is the liquefaction of gelatin, which is catalyzed by an extracellular protease (Klemme and Pfleiderer, 1977). *R. gelatinosus* grows well with citrate as the carbon source and thereby excretes large amounts of acetate, which serves as the carbon source after citrate is exhausted (Schaab et al., 1972). Citrate lyase, the key enzyme for growth on citrate, has been characterized in this species (Giffhorn et al., 1972; Beuscher et al., 1974). *R. gelatinosus* can also be adapted to grow with CO as the sole energy and carbon source under anoxic conditions in the dark (Uffen, 1976). Under these conditions, the activities of ribulosebisphosphate carboxylase and enzymes of the serine pathway are enhanced (Uffen, 1983).

As with other phototrophic *Betaproteobacteria*, the major phospholipid components of *Rubrivivax gelatinosus* are cardiolipin, phosphatidylethanolamine, and phosphatidylglycerol (Imhoff and Bias-Imhoff, 1995). Straight-chain $C_{16:1}$ and $C_{16:0}$ acids are the main components of cellular fatty acids (see Table BXII.β.58 of the chapter on the genus *Rhodoferax*).

ENRICHMENT AND ISOLATION PROCEDURES

R. gelatinosus is widely distributed in freshwater habitats where purple nonsulfur *Bacteria* occur. Media for enrichment, isolation, and growth generally employed for freshwater purple nonsulfur *Bacteria* are also suitable for *Rubrivivax* species. Though citrate is not a commonly utilized substrate among purple nonsulfur *Bacteria*, it can be used by several species. Nevertheless, it has been proven to be useful for the selective enrichment of *R. gelatinosus*. Standard techniques for the isolation of anaerobic bacteria in agar dilution series and on agar plates also can be applied for *Rubrivivax* (see Biebl and Pfennig, 1981; Trüper and Imhoff, 1992).

MAINTENANCE PROCEDURES

Rubrivivax species are readily maintained by standard procedures in liquid nitrogen. Preservation is also possible by lyophilization or storage at −80°C in a mechanical freezer.

DIFFERENTIATION OF THE GENUS *RUBRIVIVAX* FROM OTHER GENERA

Rubrivivax is clearly distinguished from other phototrophic purple bacteria by its separate phylogenetic line within the *Betaproteobacteria*. The high mol% G + C content of >70 is quite characteristic. Properties to differentiate *Rubrivivax* species from other phototrophic *Betaproteobacteria* are given in Tables 6 (p. 130) and 7 (p. 131) of the introductory chapter "Anoxygenic Phototrophic Purple Bacteria", Volume 2, Part A. The phylogenetic relationships of the phototrophic *Betaproteobacteria* are shown in Fig. 4 (p. 132) of that same chapter.

TAXONOMIC COMMENTS

Currently, only one species is known. *Rubrivivax gelatinosus* has been reported to occur in two distinct morphological forms (Biebl and Drews, 1969). Form I cells are clearly curved, 0.4–0.7 μm in diameter, and produce little slime during active growth. Form II cells are more or less straight rods, although they are sometimes also bent, and produce more slime during active growth, causing sedimentation of the cells in a gelatinous layer. Exemplified by two strains from each of the morphological groups, form I cells utilize a greater variety of carbon sources and have a much shorter doubling time than do form II cells (Weckesser et al., 1969). Another strain of this species, described by Klemme (1968), is intermediate in carbon substrate utilization with respect to the two groups established by Weckesser et al. (1969). Furthermore, the lipopolysaccharides of *R. gelatinosus* show two different serotypes, which do not cross-react with each other (Weckesser et al., 1975). It is not known whether correlations exist between serotypes, morphological types, and nutritional types. Detailed and careful studies are required to clarify the taxonomic status of the strains assigned to this species.

Further information is required on the specificity of gelatin liquefaction by *Rubrivivax gelatinosus*. Siefert et al. (1978) have identified about half of the strains with this property as belonging to *Rhodobacter capsulatus*, while other strains, with the morphology typical of *Rubrivivax gelatinosus*, do not liquefy gelatin. Weak hydrolytic activity of gelatin is also present in *Rhodoferax fermentans*.

List of species of the genus Rubrivivax

1. **Rubrivivax gelatinosus** (Molisch 1907) Willems, Gillis and De Ley 1991b, 71[VP] (*Rhodocyclus gelatinosus* (Molisch 1907) Imhoff, Trüper and Pfennig 1984, 341; *Rhodopseudomonas gelatinosa* (Molisch 1907) van Niel 1944, 98; *Rhodocystis gelatinosa* Molisch 1907, 22.)

ge.la.ti.no' sus. L. part. adj. *gelatus* frozen, stiffened; M.L. n.

gelatinum gelatin, that which stiffens; M.L. masc. adj. *gelatinosus* gelatinous.

Cells are rod shaped, straight, or slightly curved, 0.4–0.7 × 1–3 µm and in older cultures up to 15 µm long and irregularly curved. Most strains show abundant mucous production in all media, which causes the cells to clump together and appear immotile. In young cultures, cells are highly motile by means of polar flagella. Internal photosynthetic membranes appear as small fingerlike intrusions of the cytoplasmic membrane. Cultures grown anaerobically in the light are pale peach to dirty yellowish brown; aerobically grown cells appear colorless to light yellowish brown. Cells contain bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spheroidene series, with spheroidene, OH-spheroidene and spirilloxanthin as major components.

Preferably grow photoheterotrophically under anoxic conditions in the light, with a variety of organic compounds as electron and carbon sources. Photoautotrophic growth is also possible with hydrogen as electron source in the presence of growth factors. Chemotrophic growth is possible under microoxic to oxic conditions in the dark. Some strains can also adapt to grow anaerobically in the dark, with CO as sole carbon and energy sources. Pyruvate is fermented anaerobically in the dark. The carbon sources utilized are listed in Table BXII.β.59 of the chapter on the genus *Rhodoferax*. In addition, a variety of amino acids, yeast extract, and peptone are used. Most characteristic is the liquefaction of gelatin. Fatty acids are utilized only at low concentrations. Suitable nitrogen sources are ammonia, dinitrogen, and a number of amino acids; some strains may also utilize uracil, thymine, guanine, and uric acid both anaerobically in the light and aerobically in the dark, but xanthine and adenine only under oxic conditions. Sulfate can be used as the sole sulfur source. Biotin and thiamine are required as growth factors; some strains also require pantothenate.

Mesophilic freshwater bacterium, with optimal growth at 30°C and pH 6.0–8.5. Habitat: freshwater ponds, sewage ditches, and activated sludge. Major quinone components are Q-8 and MK-8.

The mol% G + C of the DNA is: 70.5–72.4 (Bd), 70.2–72.0 (T_m), 71.2–72.1 (HPLC); type strain, 71.9 (T_m).

Type strain: ATCC 17011, DSM 1709, LMG 4311.

GenBank accession number (16S rRNA): D16213, M60682.

Genus Incertae Sedis XVI. **Sphaerotilus** *Kützing 1833, 386*[AL]

Peter Kämpfer and Stefan Spring

Sphae.ro' ti.lus. Gr. n. *sphaera* a sphere; Gr. n. *tilus* anything shredded, floc, down; M.L. masc. n. *Sphaerotilus* spherical flock.

Straight rods, 1.2–2.5 × 2–10 µm, usually arranged in single chains within sheaths of uniform width, which may be attached by means of holdfasts to walls of containers, submerged plants, stones, and other surfaces. True, rather than false, branching of the filaments does not occur. **Single or paired cells released from the sheaths are motile by means of a bundle of subpolar flagella**, sometimes so intertwined as to give the appearance of a single large "unit flagellum". Sheaths usually thin without encrustation by ferric and manganic oxides. They cannot always be easily recognized when completely filled with cells, but if parts of the sheaths are vacated by the cells, recognition of the organism cannot be misinterpreted. Resting stages are not known. Gram negative. Has a propensity for storing **poly-β-hydroxybutyrate** in granules. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Can grow at very low concentrations of dissolved oxygen (below 0.1 mg/l). Temperature range: 10–40°C; optimum: between 20° and 30°C. pH range: 5.4–9; Optimal pH: between 6.5 and 7.5. **Chemoorganotrophic.** Alcohols, organic acids, and sugars are used as sources of carbon and energy. Ammonium salts and nitrates may serve as nitrogen source in the presence of vitamin B_{12} or methionine. Peptone, Casamino acids, and mixtures of aspartic and glutamic acids, and vitamin B_{12}, or methionine give better results.

The mol% G + C of the DNA is: 70.

Type species: **Sphaerotilus natans** Kützing 1833, 386.

Further descriptive information

Pure cultures, upon prolonged incubation, may sometimes show large, circular bodies resembling protoplasts. Their formation is probably due to the production of enzymes involved in the decomposition of the cell walls during the death phase. Incorporation of 0.4 g glycine per liter of nutrient medium favors this phenomenon (Phaup, 1968).

Fig. BXII.β.55 illustrates partly filled and empty sheaths. The surface of the sheaths has a smooth structure, which is in contrast with the rough structure of the sheath surface of *Leptothrix* species (Fig. BXII.β.56). The sheaths of *S. natans* are covered with a cohering slime layer of variable thickness. For the composition of the slime, see Gaudy and Wolfe (1962). The composition of the sheath was investigated by Romano and Peloquin (1963), Petitprez et al. (1969), and Hoeniger et al. (1973). Takeda et al. (1998) found carbohydrate (54.1%), protein (12.2%), and lipid (1–3%) in the sheaths by colorimetric reactions and solvent extraction. Gas-liquid chromatography showed glucose and galactosamine to be present in the molar ratio of 1:4. The most abundant amino acids in the sheath protein were glycine (49.2 mol%) and cysteine (24.6 mol%). The sheaths were resistant to agents that reduce disulfide bonds (dithiothreitol and 2-mercaptoethanol) and to protease treatment. Sheaths could be degraded completely by hydrazine, and a heteropolysaccharide composed of glucose and galactosamine (1:4) was released. A specific enzyme produced by a *Paenibacillus* sp. acting on the polysaccharide moiety was described in detail by Takeda et al. (2000).

The size and shape of colonies depends largely on the ability of the respective strain to form sheaths. Typical colonies are rough (Fig. BXII.β.57). Often the colonies are characterized by a smooth central region and a "short-haired" periphery (Pellegrin et al., 1999). In broth cultures, the organisms often develop a pellicle on the broth surface composed of long, unbranched, sheathed filaments.

The normal habitat of *S. natans* is slowly running freshwater that is heavily contaminated with sewage or wastewater from pa-

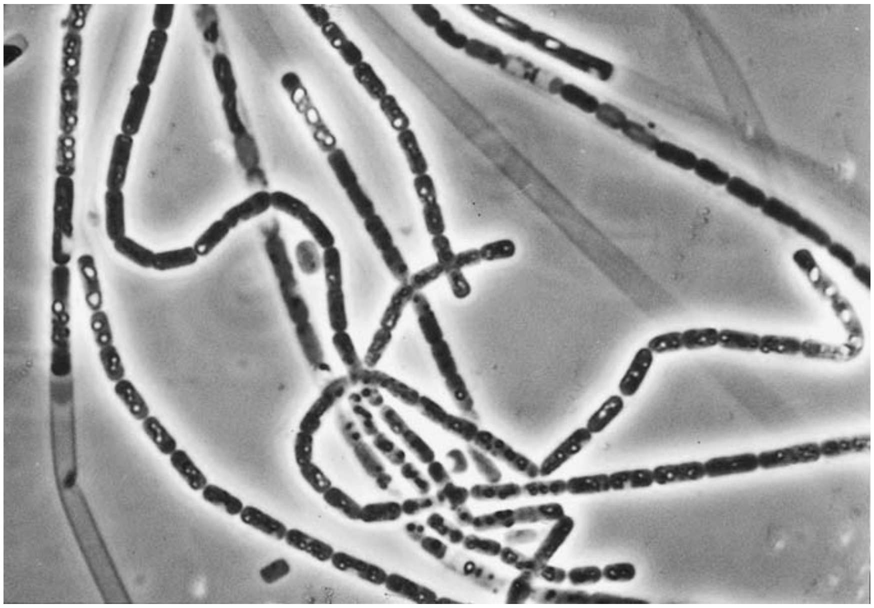

FIGURE BXII.β.55. *S. natans* filaments from a rough colony grown on agar medium containing glucose and peptone at 1 g/l each. Partly filled and empty sheaths can be seen. FIGURE BXII.β.57. Rough colony of *S. natans.* × 22. (Reproduced with permission from E.G. Mulder and W.L. van Veen, Antonie van Leeuwenhoek Journal of Microbiology and Serology. *29:* 121–153, 1963, ©Kluwer Academic Publishers. Dordrecht.)

per, potato, dairy, or other agricultural industries. The organism also occurs regularly in activated sludge, particularly when this material is settling poorly—so-called bulking. The relatively good growth under conditions of low oxygen concentrations and its capability to utilize a large number of organic carbon sources may be responsible for its relative dominance in biological deposits (Stokes, 1954; Dondero, 1975), including paper mill slimes (Väisänen et al., 1994; Pellegrin et al., 1999).

S. natans is one of several types of filamentous bacteria that may cause pipe clogging and bulking of activated sludge (Eikelboom, 1975). A ready settling of sludge flocs is one of the requisites for the successful operation of the activated-sludge process, which includes the aerobic biological purification of sewage and industrial wastewater. After absorption of the soluble wastes by the sludge organisms, the sludge flocs should readily settle, so that flocs and purified water can be separated. When the sludge flocs are densely populated by *S. natans* or some other filamentous organism, they are voluminous with many trichomes protruding into the surrounding water, thereby preventing a ready settling. This phenomenon is the cause of bulking sludge. Several different factors may cause the dominant growth of filamentous bacteria in activated sludges, among them: (a) low or high concentrations of available nutrients found in systems continuously fed with wastewater and (b) the low oxygen tensions that occur in such systems. With respect to the relatively high proportion of cell surface to cell contents of protruding filamentous bacteria compared with clumps of floc-forming bacteria, the former organisms occupy a more favorable position for nutrient uptake and growth. The ability of *S. natans* to thrive at very low pO_2 values is an additional factor favoring the competition with floc-forming bacteria. According to Wanner and Grau (1989), *Sphaerotilus* prefers environmental conditions with high sludge retention times and low concentrations of dissolved oxygen combined with high substrate concentrations. The organism does not often occur in anaerobic/aerobic selector plants. However, other factors may also lead to sludge bulking by other organisms. More details can be found in Eikelboom (1975), Jenkins et al. (1986), Wanner and Grau (1989), and Kämpfer (1997).

Although *S. natans* prefers a growth medium containing adequate amounts of easily assimilable organic nutrients, the organism is found sporadically in unpolluted water of brooklets, ditches, and ponds, where unknown compounds are the substrate. In the former habitat, the sheaths are thin and colorless; in the latter, particularly in the presence of soluble iron compounds, they may turn yellow-brown and sometimes become encrusted with ferric oxide. This characteristic can be clearly observed in a laboratory apparatus in which *S. natans* is grown in slowly running soil extract enriched with Fe (II). Under these conditions, the sheaths of *S. natans* resemble those of *Leptothrix ochracea*, and a number of authors (Pringsheim, 1949a, b; Stokes, 1954; and others) have assumed that both organisms are identical. However, 16S rRNA sequencing studies have shown the separate position of organisms belonging to both genera, although an unambiguous pattern of the respective branches of both genera is not possible on the basis of the available data set (Pellegrin et al., 1999), mainly because the 16S rRNA sequence of *L. ochracea*, which has not been cultivated in pure cultures until now, is not available.

Isoprenoid quinone Q-8 is the predominant quinone type for *S. natans* (Kämpfer et al., 1995, 1998). In a study of the fatty acid composition as determined by gas chromatographic analysis, the composition of 15 strains differed only slightly (Kämpfer, 1998). All strains contain the fatty acids $C_{12:0}$, $C_{16:0}$, $C_{16:1\ \omega 7c}$, $C_{17:1}$, and $C_{18:1\ \omega 7,\ 9c}$, and $C_{10:0\ 3OH}$; a fatty acid profile that is very similar to that of *Leptothrix* species and typical for members of the *Betaproteobacteria* (Table BXII.β.65).

Enrichment and Isolation Procedures

Several isolation techniques for *Sphaerotilus* have been described. When slimy masses of the organism—attached to submerged surfaces in polluted, slowly running water—are available, direct isolation of *S. natans* may succeed. Pellegrin et al. (1999) collected slime samples from paper machines that were rinsed fivefold in sterile distilled water. The deposits were placed on the surface of FIL agar containing 0.005 g/l cycloheximide and incubated 72 h at 30°C. For details see Pellegrin et al. (1999). Rough colonies (Fig. BXII.β.57) were selected and further investigated. A similar procedure can be applied to activated sludge containing many filaments of the organism (i.e., bulking sludge). When the sheathed bacteria occur in low numbers in activated sludge or in nonpolluted water samples, the use of enrichment cultures may be desirable (Mulder and Deinema, 1981). Mulder (1989b) described a technique, based on extracted alfalfa straw (Stokes, 1954) or extracted pea straw (Mulder and van Veen, 1963, 1965), which can serve as the nutrient material. Most of the soluble organic matter should be removed to prevent the accumulation of undesirable organisms. This can be achieved by boiling and extracting the straw after it has been cut into pieces of about 2 cm. In the case of alfalfa straw, a 1% suspension is extracted three or four times by boiling with large amounts of tap water. The extracted straw medium is distributed in 50-ml quantities in 125-ml Erlenmeyer flasks, which are then inoculated with about 10 ml of water from various sources. The preparation of the pea straw medium differs slightly from the preceding technique. The straw is extracted for 10 h at 100°C with tap water that is renewed every hour. One or 2 g of extracted pea straw (dry weight) in 25 ml of tap water is autoclaved twice (15 min at 110°C) and used as an enrichment medium. After inoculation with small amounts of river or ditch water or activated sludge and subsequent incubation for about 1 week at 22–25°C, tufts of filaments of *S. natans* may be seen after microscopic observation.

Isolation may be achieved by streaking the enrichment cultures on previously dried agar plates containing low levels of nitrogen and carbon sources. Activated sludge containing many filaments of *S. natans* is streaked directly on such plates. Slimy masses of sheathed bacteria grown in slowly running, polluted water are washed several times with sterile water. Homogenization of the washed flocs by blending for a very short time may be advisable.

The use of a nutritionally poor agar medium limits the size

of undesirable bacterial colonies, leaving large areas for the filamentous organisms. This medium has the following basal composition (per liter of glass-distilled water): KH_2PO_4, 27 mg; K_2HPO_4, 40 mg; $Na_2HPO_4 \cdot 2H_2O$, 40 mg; $CaCl_2$, 50 mg; $MgSO_4 \cdot 7H_2O$, 75 mg; $FeCl_3 \cdot 6H_2O$, 10 mg; $MnSO_4 \cdot H_2O$, 5 mg; $ZnSO_4 \cdot 7H_2O$, 0.1 mg; $CuSO_4 \cdot 5H_2O$, 0.1 mg; $Na_2MoO_4 \cdot 2H_2O$, 0.05 mg; cyanocobalamin, 0.005 mg. This medium is enriched with peptone, 1 g/l; glucose, 1 g/l; and agar (Davis), 7.5 g/l. To inhibit the rapid spreading of contaminating bacteria, the excess surface moisture of the sterile agar plates should be evaporated by overnight storage of these plates at a temperature of 37–45°C. Upon inoculation and incubation of these plates at 20–25°C, colonies of *S. natans* may be seen and tentatively identified within a few days by their characteristically flat, dull, cotton-like appearance. The edges of the colonies are irregular, owing to curly filamentous growth extending in all directions (Fig. BXII.β.57). Confirmation of the identification may be achieved by microscopic observation (Fig. BXII.β.55).

Sphaerotilus may also be isolated by spread plate techniques with or without centrifugation or vortex treatment (Williams and Unz, 1985; Ziegler et al., 1990). Growth has been reported on I and SCY media (Eikelboom, 1975), SS media (Williams and Unz, 1985), R2A agar (Seviour et al., 1994), and GMBN-Agar (Kämpfer et al., 1995).

Maintenance Procedures

Stock cultures of *S. natans* on agar slants of the previously described media can be stored for about 3 months at 4°C. Addition of 2–3 ml of sterile tap water to the agar slants may prolong the viability for another 3 months. Preservation for longer periods is accomplished by common lyophilization techniques; however, it must be stressed that some *Sphaerotilus* strains do not survive lyophilization. Freezing in liquid nitrogen can be used for the long-term preservation of these strains.

Differentiation of the genus *Sphaerotilus* from other genera

Differential characteristics of the genera belonging to the *Rubrivivax gelatinosus–Leptothrix discophora* rRNA cluster of the *Betaproteobacteria* group are listed in Table BXII.β.66, and the main characteristics of the genera *Sphaerotilus* and *Leptothrix* are given in Tables BXII.β.65 and BXII.β.67. It can be seen that *Sphaerotilus* is closely related to *Leptothrix*. This applies to the motility of separate cells when released from the sheaths, to the formation of poly-β-hydroxybutyrate as reserve material, to the accumulation of ferric oxide on the sheaths, the quinone type and the fatty acid patterns, and to the mol% G + C of the DNA. However, several other properties are clearly different. They include morphological as well as physiological characteristics, such as size of cells; flagellation; structure of sheath surface; ability of the *Leptothrix* species to oxidize Mn^{2+} to Mn^{4+} (MnO_2), which is absent in *Sphaerotilus*; and the pronounced response of *S. natans* to organic nutrients as contrasted with no or poor response of most *Leptothrix* species to added nutrients; the latter factor is especially of considerable ecological significance. *S. natans* thrives in water heavily contaminated with organic nutrients (wastewater); *Leptothrix* species are never found in such environments, except *L. cholodnii* and *L. lopholea*, which respond more clearly to added nutrients than do the other *Leptothrix* species. Pellegrin et al. (1999) found that *Sphaerotilus* isolates from paper-mill slimes were adapted to the specific environmental conditions, regarding temperature tolerance and utilization of cellulose and starch.

Taxonomic Comments

The only known species of the genus is *S. natans*. The 16S rRNA gene sequences have been determined for several reference strains and isolates of *Sphaerotilus* (Corstjens and Muyzer, 1993; Siering and Ghiorse, 1996, 1997; Pellegrin et al., 1999) and are highly similar to each other (>99.5%). In phylogenetic trees, the highest similarities are found with *Leptothrix* species. Together with *Ideonella dechloratans*, *Rubrivivax gelatinosus*, *Alcaligenes latus*, *Roseateles depolymerans*, and *Aquabacterium* species (sequence similarities between 16S rRNA genes within this group are above 93%), they form a branch of bacteria that is phylogenetically distinct from the *Comamonadaceae* as defined by Willems et al. (1991b), and that is also referred to as the *Rubrivivax* subgroup of the *Betaproteobacteria* (Wen et al., 1999). A phylogenetic tree of members of the *Rubrivivax gelatinosus–Leptothrix discophora* rRNA cluster of the *Betaproteobacteria* is presented in Fig. BXII.β.58.

As with the genus *Leptothrix*, some characteristics that distinguish *Sphaerotilus natans* from *Leptothrix* species are not very stable and regularly lost upon cultivation. The ability to form sheaths has been lost by some strains available from public culture collections. In addition, it has been pointed out by Pellegrin et al. (1999) that based on comparison of 16S rDNA sequences, no unambiguous branching of *Sphaerotilus* and *Leptothrix* have been obtained with different treeing methods.

However, in view of the pronounced differences between *Sphaerotilus natans* and *Leptothrix* species, the genus allocation seems to be firm.

[f]Most G + C values were determined by use from thermal denaturation curves; the exception was the value for *Leptothrix cholodnii*, which was taken from Van Veen et al. (1978).

Wolfe, 1961; Mulder and van Veen, 1963). When the organism is grown on a basal medium with glucose and peptone at 1 g/l each, normal hairy colonies are formed (Fig. BXII.β.57), as contrasted with the smooth, almost circular colonies formed when 5 g of these nutrients are supplied. High concentrations of peptone are more effective in producing this effect than are sugars. Smooth colonies consist of sheathless cells that have larger dimensions than cells in sheaths. Transfer of the former cells to a poor medium restores sheath formation. Growth is supported on several media (see genus description).

False branching of the filaments occurs in every strain of *S. natans*, but it occurs in some strains more than others. Its occurrence depends on cultural conditions (relatively poor media) rather than on strain specificity (Pringsheim, 1949a).

Utilization of fructose, glucose, maltose, sucrose, lactate, pyruvate, and succinate as sole sources of carbon has been reported by Stokes (1954), Höhnl (1955), Mulder and van Veen (1963), Kämpfer (1998), and Pellegrin et al. (1999). Numerous other carbon sources can be utilized (for details see Kämpfer, 1998 and Pellegrin et al., 1999). Strains of *S.*

natans differ widely in their capacity to utilize other carbon compounds. In contrast to most *Leptothrix* strains, *S. natans* utilizes relatively high concentrations of assimilable substrates, from which it synthesizes considerable amounts of cellular material.

Cells may contain large amounts of poly-β-hydroxybutyrate either as numerous small globules or as a few large globules. Polysaccharides may also accumulate. The synthesis of both reserve compounds is stimulated by a high carbon/ nitrogen ratio in the medium (Mulder and van Veen, 1963) and by oxygen deficiency.

The major quinone is ubiquinone Q-8. Major fatty acids (>5%) are hexadecanoic acid, *cis*-9-hexadecenoic acid, and *cis*-9,11-octadecenoic acid. Minor fatty acids are 3-hydroxydecanoic acid, dodecanoic acid, octadecanoic acid, tetradecanoic acid, and *cis*-9,10-methyleneoctadecanoic acid.

The mol% G + C of the DNA is: 70 (T_m).

Type strain: ATCC 13338, DSM 6575.

GenBank accession number (16S rRNA): L33980.

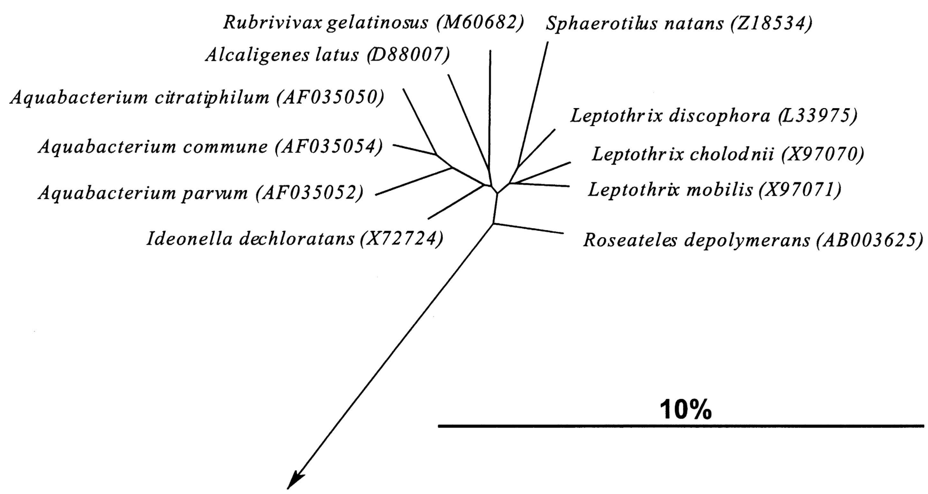

FIGURE BXII.β.58. Phylogenetic tree showing members of the *Rubrivivax gelatinosus–Leptothrix discophora* rRNA cluster of the *Betaproteobacteria*. This tree is based on a distance matrix analysis of almost complete sequences of 16S rRNA genes (at least 1300 nucleotides, GenBank accession numbers are given in parentheses). Phylogenetic distances were calculated as described by Felsenstein (1982). The sequence of *Escherichia coli* (L10328) was used as an outgroup (not shown). The scale bar represents 10% estimated sequence divergence.

Genus Incertae Sedis XVII. **Tepidimonas** *Moreira, Rainey, Nobre, da Silva and da Costa 2000, 741*[VP]

Milton S. da Costa, M. Fernanda Nobre and Fred A. Rainey

Te.pi.di.mo'nas. L. adj. *tepidus* warm; Gr. n. *monas* unit; N.L. fem. n. *tepidimonas* warm monad.

Short rod-shaped cells 0.5–1.0 × 1.0–2.0 μm. Motile by means of one polar flagellum. Endospores are not formed. Cells stain Gram negative. Colonies are not pigmented. **Strictly aerobic.** Nitrate is not used as a terminal electron acceptor. Oxidase and catalase positive. **Optimal temperature for growth, between 50 and 55°C.** Optimal pH for growth, between 7.5 and 8.5. Fatty acids are of the straight-chain type. Major polar lipids are phosphatidylethanolamine and phosphatidylglycerol; ubiquinone 8 is the major respiratory quinone. **Chemolithoheterotrophic.** Reduced sulfur compounds are oxidized to sulfate in the presence of a metabolizable organic carbon source. Organic acids and amino acids are used as carbon and energy sources, but sugars, polysaccharides and polyols are not assimilated.

The mol% G + C of the DNA is: 69.7.

Type species: **Tepidimonas ignava** Moreira, Rainey, Nobre, da Silva and da Costa 2000, 741.

Further descriptive information

The optimal growth temperature of the type strain of *Tepidimonas ignava* is between 50 and 55°C; the organism does not

grow above 60°C or below 35°C. It is interesting to note that related strains ac-15 and DhA-73 (see Other Organisms, below) also have cardinal growth temperatures in this range and that the related environmental clone tmbr15-22 (see Other Organisms) was obtained from thermophilic aerobic treatment of synthetic wastewater. These results imply that the genus *Tepidimonas* contains several slightly thermophilic species with optimal growth rates in the neighborhood of 50°C.

The optimal pH for growth of *T. ignava* is between 7.5 and 8.5.

The polar lipid pattern, the respiratory quinones, and the fatty acids of this organism, are as expected for mesophilic or slightly thermophilic members of the *Betaproteobacteria*, although $C_{16:0}$, $C_{17:0}$, and $C_{18:0}$ are the predominant fatty acids.

Perhaps the most interesting characteristic of *T. ignava*—which is not restricted to this species—among the species of the *Betaproteobacteria* relates to its inability to assimilate any of the carbohydrates or polyols examined and to grow only on amino acids and organic acids. The inability to assimilate carbohydrates and polyols has also been reported for strain DhA-73, indicating that one or more steps of glycolysis are absent in both organisms. Strain DhA-73 is capable of degrading tricyclic diterpenes such as abietic acid, dehydroabietic acid, and palustric acid, found in pulp and paper mill effluent and derived from conifer resin (Yu and Mohn, 1999). The degradation of these acids was not examined in *T. ignava*. Strain ac-15 has never been characterized and comparisons between this organism and *T. ignava* cannot be made.[1]

Like several other members of the *Betaproteobacteria*, *T. ignava* oxidizes thiosulfate and tetrathionate to sulfate. However, this organism does not appear to be chemolithoautotrophic, since the oxidation of these reduced sulfur compounds occurs only in the presence of a metabolizable carbon source, indicating that it is chemolithoheterotrophic.

Enrichment and Isolation Procedures

Only one strain of *T. ignava* was isolated from the hot spring at São Pedro do Sul in central Portugal, despite repeated attempts to isolate other strains of this organism. The isolation of this organism was achieved on a medium composed of one part of Kligler's iron agar (Difco) and four parts of *Thermus* agar. Samples of water were filtered through cellulose nitrate membrane filters (pore diameter, 0.45 μm), placed on the surface of the Kligler's iron/*Thermus* medium, and incubated for several days at 50°C. However, the isolation of *T. ignava* appears to have been completely fortuitous, since it did not show any enhanced growth on this medium. The organism grows well on several low-nutrient media containing yeast extract and tryptone, namely *Thermus* medium (Williams and da Costa, 1992) and Degryse medium 162 (Degryse et al., 1978). The addition of thiosulfate (1.0–5.0 g/l) enhances growth of the organism.

Maintenance Procedures

Stock cultures of *T. ignava* remain viable for years at −80°C in *Thermus* medium containing 15% glycerol. Cultures have also been maintained lyophilized for several years without the loss of viability.

Differentiation of the genus *Tepidimonas* from other genera

The bacteria of the genus *Tepidimonas* can be easily distinguished from all members of the family *Comamonadaceae* because of their high growth temperature range. Other characteristics, namely the polar lipids and the fatty acids, are similar.

Taxonomic Comments

Phylogenetic analysis of the 16S rRNA gene sequence (Fig. BXII.β.59) shows that *Tepidimonas ignava* clusters within the class *Betaproteobacteria*, but represents a distinct lineage along with other undescribed strains, namely strain ac-15, isolated some years ago from a hot spring microbial mat at Yellowstone National Park, USA (EMBL accession number U46749; Nold et al., 1996), and strain DhA-73 (EMBL accession number AF125877; Yu and Mohn, 1999), isolated from a bioreactor treating bleached kraft mill effluent. An environmental 16S rRNA gene clone, designated tmbr15-22 (EMBL accession number AF309815) also belongs to this lineage. *Tepidimonas ignava* shares 96.2% 16S rRNA gene sequence similarity with strain ac-15, 97.5% sequence similarity with strain DhA-73, and 97.4% sequence similarity with the environmental clone tmbr15-22. These results indicate that the undescribed organisms (strains ac-15 and strain DhA-73) and the organism detected as the environmental clone tmbr15-22 represent novel species within the genus *Tepidimonas*. Moreover, this group shares a low 16S rRNA gene sequence similarity (<94.0%) with any previously described species within the *Betaproteobacteria*, and can be considered to represent a distinct lineage of, at least, genus status within the family *Comamonadaceae*.

1. Recently a second species of the genus *Tepidimonas*, designated *Tepidimonas aquatica*, was described by Freitas et al. (2003). The new species has characteristics that are very similar to those of *T. ignava*. The major differences between the two species are in their fatty acid compositions. The 16S rRNA gene sequences of the two species have 97% similarity. This species and *T. ignava*, unlike strain DhA-73, do not degrade resinic acids.

List of species of the genus Tepidimonas

1. **Tepidimonas ignava** Moreira, Rainey, Nobre, da Silva and da Costa 2000, 741[VP]
ig.na'va L. adj. *ignavus* lazy, pertaining to the organism's trait of not using sugars for growth.

The characteristics are as described for the genus, with the following additional information. Colonies on Degryse 162 medium are not pigmented and are 1–2 mm in diameter after 60 h of incubation. Growth occurs above 35°C and below 65°C. Growth does not occur at pH 6.0 or pH 10.0. The major fatty acid is $C_{16:0}$; unsaturated fatty acids are also present in large amounts. Ubiquinone 8 is the major respiratory quinone. Yeast extract, or growth factors, are required for growth. Nitrate is not reduced to nitrite. Thiosulfate is oxidized to sulfate and serves as an energy source coupled to the assimilation of organic substrates. Chemolithoheterotrophic growth occurs on reduced sulfur compounds. Xylan, starch, casein, elastin, and fibrin are not degraded. Several amino acids and organic acids are utilized for growth, but hexoses, disaccharides, pentoses, and polyols are not used.

Isolated from the hot spring at São Pedro do Sul in central Portugal.

The mol% G + C of the DNA is: 69.7 (HPLC).

Type strain: SPS-1037, DSM 12034.

GenBank accession number (16S rRNA): AF177943.

The scale bar represents 5 inferred nucleotide substitutions per 100 nucleotides.

Other Organisms

Strain ac-15 (EMBL accession number U46749) was isolated from a hot spring microbial mat at Yellowstone National Park, USA, by Nold et al. (1996). *Tepidimonas ignava* shares 96.2% 16S rRNA gene sequence similarity with strain ac-15.

Strain DhA-73 (EMBL accession number AF125877) was isolated from a bioreactor treating bleached kraft mill effluent by Yu and Mohn (1999). *Tepidimonas ignava* shares 97.5% sequence similarity with strain DhA-73.

The environmental 16S rRNA gene clone tmbr15-22 (EMBL accession number AF309815) was obtained from the thermophilic aerobic treatment of synthetic wastewater. *Tepidimonas ignava* shares 97.4% sequence similarity with strain tmbr15-22.-

Genus Incertae Sedis XVIII. **Thiomonas** *Moreira and Amils 1997, 527*^{VP}

Donovan P. Kelly and Ann P. Wood

Thi.o.mo′nas. Gr. n. *thios* sulfur; Gr. fem. n. *monas* a unit, monad; M.L. fem. n. *Thiomonas* sulfur monad.

The phenotypic description is that of the general traits for group II of *Thiobacillus* (Kelly and Harrison, 1989; Moreira and Amils, 1997). Gram-negative, nonsporeforming, short rods that are about 0.3–0.5 × 1–3 μm. Cells motile by means of single polar flagella. Obligate aerobes. Optimal temperature 30–36°C for mesophilic species and 50°C for moderately thermophilic species. Optimal pH between 3 and 6. Facultative chemolithoautotrophs; optimal growth occurs in mixotrophic media supplemented with reduced sulfur compounds and organic supplements (yeast extract, peptone, some sugars, and amino acids). Chemoorganotrophic growth on yeast extract, Casamino acids, peptone, and meat extract. Chemolithoautotrophic on thiosulfate, tetrathionate, S^0, and H_2S. Do not oxidize ferrous iron. Sensitive to ampicillin. Contain ubiquinone Q-8. Members of the *Betaproteobacteria*.

The mol% G + C of the DNA is: 61–69.

Type species: **Thiomonas intermedia** (London 1963) Moreira and Amils 1997, 527 (*Thiobacillus intermedius* London 1963, 335.)

Further descriptive information

This genus was created by Moreira and Amils (1997), who determined complete sequences of the 5S and 16S rRNA genes for *Thiobacillus cuprinus* and compared them with homologous sequences from *Thiobacillus intermedius*, *Thiobacillus perometabolis*, and *Thiobacillus thermosulfatus*. These four species were found to form a phylogenetic cluster within the *Betaproteobacteria*, but to be only remotely related to the type species of *Thiobacillus*, *Thiobacillus thioparus*. The properties of the species of *Thiomonas* are summarized in Table BXII.β.68. All the species are moderately acidophilic and facultatively chemolithotrophic, with *Thiomonas cuprina* also able to grow autotrophically on pyrite (Huber and Stetter, 1990; Moreira and Amils, 1997). The properties, taxonomy, and differentiation of the genera of sulfur-oxidizing, che-

[b]Nitrate reduced to nitrite.

[c]Chalcopyrite, arsenopyrite, galena, sphalerite.

molithoautotrophic, Gram-negative, rod-shaped bacteria are summarized in Tables BXII.β.70 and BXII.β.71 and Fig. BXII.β.60 in the chapter on the genus *Thiobacillus*. *T. cuprina* (DSM 5495) contains a circular chromosome (3.8 Mb) and appears to contain a linear 50 Mb megaplasmid that is inducible during chemolithotrophic growth (Marín et al., 1995; Amils et al., 1998).

List of species of the genus Thiomonas

1. **Thiomonas intermedia** (London 1963) Moreira and Amils 1997, 527[VP] (*Thiobacillus intermedius* London 1963, 335.)
in.ter.me' di.a. L. prep. *inter* between, among; L. adj. *media* middle; M.L. adj. *intermedia* in between, intermediate.

Thin, short rods, 0.6–0.8 × 1.0–1.4 μm. Motile by means of a polar flagellum. On thiosulfate agar, small colonies (up to 1 mm) with raised centers develop that are yellowish and opaque with precipitated sulfur and surrounded by veil-like fringes. This organism is facultatively mixotrophic. Capable of chemolithotrophic, autotrophic growth on sulfur, thiosulfate, or tetrathionate, but not on thiocyanate. Also oxidizes sulfide. Aerobic; unable to denitrify. Unable to grow in heterotrophic media such as nutrient broth or with single organic substrates in the absence of thiosulfate. Grows very poorly on yeast extract alone but produces substantial growth (after lags of 1–10 d) on yeast extract supplemented with glucose, fructose, sucrose, maltose, aspartate, or glutamate. It is possible that a reduced sulfur compound stimulates growth under these conditions. Best growth is with mixotrophic media containing thiosulfate and yeast extract, alanine, malate, succinate, citrate, 2-oxoglutarate, serine, lactate, or the supplements listed for heterotrophic growth. This organism can use ammonium salts, nitrate, urea, glutamate, or aspartate as nitrogen sources. Optimal temperature: 30–35°C; growth range: 15–37°C. Optimal pH: 5.5–6.0; growth range pH: 5.0–7.5, although for mixotrophic media, the pH may be lowered to about 2.8. Isolated from freshwater mud; presumably widely distributed. DNA hybridization with *Thiomonas perometabolis* has been reported as 31–35 (Katayama-Fujimura et al., 1983) and 56–78 (Harrison, 1983).

The mol% G + C of the DNA is: 65–67 (T_m).
Type strain: ATCC 15466.

2. **Thiomonas cuprina** Moreira and Amils 1997, 527[VP]
cu.pri' na. L. adj. *cuprina* copper, describing its ability to extract copper ions from ores.

Cells are Gram-negative rods, about 1–4 × 0.3–0.5 μm. Each is motile by one polar flagellum. Colonies on agar plates (yeast extract medium) have a brownish color. Optimal temperature 30–36°C, no growth at 15 or 50°C. Optimal pH 3–4, no growth at pH 1 or 7.5. Facultative chemolithotroph, aerobic. Chemoorganotrophic growth on yeast extract, Casamino acids, peptone, meat extract; some strains grow on pyruvate. Chemolithoautotrophic growth on chalcopyrite, sphalerite, arsenopyrite, galena, S^0, and H_2S, forming sulfuric acid. No oxidation of ferrous iron. Sensitive to ampicillin; *meso*-diaminopimelic acid present. Contain ubiquinone Q-8 but no rusticyanin. Lives in continental solfataric fields and mines. Insignificant DNA hybridization with *Thiobacillus ferrooxidans*, *Thiobacillus thiooxidans*, *Thiobacillus thioparus*, *Thiobacillus neapolitanus*, *Thiobacillus prosperus*.

The mol% G + C of the DNA is: is 66–69 (T_m, HPLC).
Type strain: DSM 5495.
GenBank accession number (16S rRNA): U67162.

3. **Thiomonas perometabolis** (London and Rittenberg 1967) Moreira and Amils 1997, 527[VP] (*Thiobacillus perometabolis* London and Rittenberg 1967, 218.)
pe.ro.me.ta' bo.lis. Gr. adj. *peros* maimed, crippled; Gr. v. *metabole* alter, change; M.L. part. adj. *perometabolis* with a maimed metabolism.

Thin, short rods with rounded ends, 0.4–0.5 × 1.1–1.7 μm. Motile by means of a polar flagellum. Colonies grown on yeast extract–thiosulfate agar (1–3 mm after 1 week) are circular, entire, convex, smooth, creamy white,

and opaque; the center of old colonies becomes pink-orange. Colonies grown on thiosulfate agar (0.5 mm after 10 d) are circular, entire, convex, smooth, creamy white, and opaque, developing a brown center with age. The original isolate of *T. perometabolis* did not exhibit chemolithotrophically autotrophic or heterotrophic growth on single-carbon substrates (London and Rittenberg, 1967), and its "maimed metabolism" was described as "obligately mixotrophic" (Vishniac, 1974). Further study led to an emended description (Katayama-Fujimura and Kuraishi, 1983; Katayama-Fujimura et al., 1984a) on which this entry is based. Facultative chemolithoautotroph. Chemolithotrophic autotrophic growth occurs on thiosulfate, tetrathionate, or sulfur, but not on thiocyanate. Little or no tetrathionate or trithionate accumulates during growth on thiosulfate. This organism exhibits diauxic growth on a mixture of thiosulfate and glutamate, with preferential use of the thiosulfate. Grows slowly after a lag time of about 2 weeks in heterotrophic media containing one of the following: alanine, glutamate, aspartate, malate, citrate, or succinate. Lags are shortened by the presence of thiosulfate. Best growth occurs in mixotrophic media with thiosulfate and organic supplements, such as yeast extract, casein hydrolysate, 2-oxoglutarate, some sugars, and some amino acids. Probably requires a reduced inorganic sulfur compound during heterotrophic growth. Obligate aerobe. Ammonium salts, nitrate, and urea are used as nitrogen sources, and glutamate and aspartate are used as both carbon and nitrogen sources. Optimal temperature: 35–37°C; growth range: 15–42°C. Optimal pH: 5.5–6.0; growth range pH: 5.0–7.0, although for mixotrophic media, the pH is lowered to about 2.8. Isolated from soil. Distribution unknown. DNA hybridization with *T. intermedia* has been reported as both 31–35% (Katayama-Fujimura et al., 1983) and 56–78% (Harrison, 1983).

The mol% G + C of the DNA is: 65–66 (T_m).

Type strain: ATCC 23370.

4. **Thiomonas thermosulfata** (Shooner, Bousquet and Tyagi 1996) Moreira and Amils 1997, 527[VP] (*Thiobacillus thermosulfatus* Shooner, Bousquet and Tyagi 1996, 414.)
ther.mo.sul.fa'ta. Gr. n. *thermus* heat; L. n. *sulfatus* sulfur; L. adj. *thermosulfata* organism that produces sulfate and grows at high temperatures.

Cells are Gram-negative rods, 0.9 × 1.3–2.3 µm, motile by means of single polar flagella. Typically, cells contain 2–3 polyphosphate inclusions, and polyhedral bodies. Colonies on thiosulfate agar are small (<1 mm), and round and either are translucent or have sulfur deposits in the center. Strictly aerobic; grows chemolithoautotrophically on thiosulfate, tetrathionate, and sulfur, and chemoorganotrophically on yeast extract, succinate, and glutamate. Tetrathionate, trithionate, and sulfur are produced during growth on thiosulfate. Autotrophic growth on thiosulfate occurs between pH 4.3–7.8 (optimal pH 5.2–5.6) and 34–65°C (optimal 50–52.5°C). pH should be decreased to 2.5 on thiosulfate and sulfur media. Does not grow on carbohydrates, pyruvate, acetate, or formate; does not denitrify. Cells adhere to S^0 by means of a glycocalyx. Contains ubiquinone Q-8.

The mol% G + C of the DNA is: 61 (UV ratios).

Type strain: ATCC 51520.

GenBank accession number (16S rRNA): U27839.

Other Organisms

1. *Thiomonas delicata comb. nov.* (*Thiobacillus delicatus* Katayama-Fujimura, Kawashima, Tsuzaki and Kuraishi 1984a, 142.)
del.i.cat' a. L. adj. *delicata* delicate.

Rods, usually single, rarely in pairs, 0.4–0.6 × 0.7–1.6 µm. Nonmotile. Colonies grown on yeast extract–thiosulfate agar (1 mm in diameter) are smooth and circular and change from transparent to whitish-yellow with sulfur. Facultative chemolithotroph and mixotroph. Grows autotrophically with sulfur, thiosulfate, or tetrathionate, but not with thiocyanate; accumulates tetrathionate and trithionate transiently during growth on thiosulfate. Incapable of heterotrophic growth on single carbon compounds. Grows mixotrophically in thiosulfate media supplemented with tricarboxylic acid cycle intermediates or amino acids. Optimum growth requires both organic substances and thiosulfate or sulfur. Facultative anaerobe; reduces nitrate and produces nitrite in mixotrophic and autotrophic media with thiosulfate or tetrathionate. Ammonium salts, nitrate, urea, glutamate, or aspartate can be used as nitrogen sources. Optimal temperature: 30–35°C; growth range: 15–42°C (no growth at 10°C or 45°C). Optimal pH: 5.5–6.0; growth range: pH 5.0–7.0. Isolated from mine water. Distribution unknown.

The mol% G + C of the DNA is: 66–67 (T_m, chemical analysis).

Deposited strain: THI 091, IAM 12624.

Additional Remarks: This species cannot yet be firmly assigned to the genus *Thiomonas*, but its G + C content, mixotrophy, and physiological similarities to *T. perometabolis* indicate that it should be reassigned to *Thiomonas* (Y. Katayama, personal communication). Determination of its 16S rRNA sequence is essential to confirm its phylogenetic relationships (Kelly and Harrison, 1989; Moreira and Amils, 1997).

Genus Incertae Sedis XIX. **Xylophilus** *Willems, Gillis, Kersters, Van Den Broecke and De Ley 1987, 428[VP]*

ANNE WILLEMS AND MONIQUE GILLIS

Xy.lo' phi.lus. Gr. n. *xylon* wood; Gr. n. *philos* friend; M.L. masc. *Xylophilus* friend of wood.

Straight to slightly curved rods, 0.4–0.8 × 0.6–3.3 µm, occurring singly, in pairs or short chains. **Long filamentous cells may occur in older cultures** (length may be 30 µm or more). **Gram negative**. **Motile by a single polar flagellum. Aerobic, having a strictly respiratory type of metabolism with oxygen as the only terminal electron acceptor. *In vitro* growth is generally very slow** and rather

poor, even at the optimal growth temperature of 24°C. **Oxidase negative**, catalase positive. **Chemoorganotrophic** with oxidative carbohydrate metabolism. *Xylophilus* causes bacterial necrosis and canker of grapevine and can be isolated from infected plant material.

The mol% G + C of the DNA is: 68–69.

Type species: **Xylophilus ampelinus** (Panagopoulos 1969) Willems, Gillis, Kersters, Van Den Broecke and De Ley 1987, 428 (*Xanthomonas ampelina* Panagopoulos 1969, 75.)

FURTHER DESCRIPTIVE INFORMATION

As the genus contains only one species, all of the characteristics provided below describe the species *Xylophilus ampelinus*.

Colonial characteristics On nutrient agar, colonies are circular, semitranslucent, slightly raised, glistening, and pale yellow with entire margins; colony diameters are 0.2–0.3 mm after 6 d and 0.6–0.8 mm after 15 d. Better growth is obtained on GYCA medium[1] and best growth occurs on YGC medium[2]. On the latter medium colonies are yellow and a brown diffusible pigment is produced. *Xylophilus* strains may produce two stable colony types with one type (t1) consisting of relatively large yellow colonies (diameter 0.8–2.0 mm after 15 d on GYCA) and the other (t2) consisting of smaller, paler and more slowly growing colonies (diameter 0.4–1.0 mm after 15 d). Both types were highly similar microscopically and when analyzed by whole-cell protein gel electrophoresis and by DNA–DNA hybridization (Willems et al., 1987).

Pigments The yellow pigments produced by *Xylophilus* strains are different from xanthomonadins, the yellow water-soluble brominated aryl-polyene pigments produced by another plant-pathogenic genus, *Xanthomonas*. *Xylophilus* pigments appear sensitive to potassium isobutoxide but are generally very hard to purify and therefore little is known about them (Starr et al., 1977).

Growth conditions Minimum and maximum growth temperature are 6°C and 30°C, respectively (Panagopoulos, 1969). Optimal growth is obtained at 24°C. In a medium consisting only of a salt solution, ammonium chloride, and glucose or galactose, addition of 0.1% glutamic acid is required for growth (Panagopoulos, 1969).

Nutrition and metabolism *Xylophilus* strains have a strictly aerobic chemoorganotrophic metabolism. They use only a limited number of carbohydrates, organic acids, and amino acids for growth. In a study on the use of 60 substrates by nine French *Xylophilus* isolates, growth was observed on only D-glucose, D-galactose, L-glutamic acid, Na-succinate, Na-fumarate, K,Na-tartrate, Na-L-malate, Na_3-citrate, and Ca-gluconate (Van den Mooter and Swings, 1990). In general, *Xylophilus* strains show little variation from one another: strains from different geographic origin were shown to be highly similar by means of whole-cell protein gel electrophoresis, comparison of 106 enzymatic features and DNA–DNA hybridization (Willems et al., 1987). However, certain physiological characteristics do show considerable variation: the use of glucose and tartaric acid for growth and tyrosinase activity may vary between different populations (Ridé, 1996). Metabolic fingerprints using Biolog™ GN plates were produced for a limited number of strains, but the recommended sucrose peptone agar for preparation of cell cultures was replaced by nutrient agar. Under these conditions the strains oxidized only acetic acid, propionic acid, L-aspartic acid, L-glutamic acid, and L-pyroglutamic acid (Serfontein et al., 1997).

Biosynthesis of aromatic amino acids A study of the regulation mechanisms involved in the biosynthesis of aromatic amino acids has shown that 3-deoxy-D-arabinoheptulonate-7-phosphate synthetase is inhibited by tryptophan, chorismate, prephenate, phenylalanine, and tyrosine. Co^{2+} is needed for maximum activity. Prephenate-dehydrogenase is NAD^+-specific and is not inhibited by tyrosine (Whitaker et al., 1981; Byng et al., 1983).

Chemotaxonomic characteristics *X. ampelinus* contains putrescine as the main polyamine and smaller amounts of 2-hydroxyputrescine, spermidine, and spermine (Auling et al., 1991).

Phage susceptibility Various bacteriophages have been isolated from soil or water near infected vines and are differentiated by the morphology of their plaques on exponentially growing plates of *Xylophilus* strains. All strains of *Xylophilus* are sensitive to phage P *X.a.*15, which produces plaques that keep expanding over several days with the formation of a halo. Other phages are specific to certain groups of strains (Ridé, 1996).

Antibiotic sensitivity Nine *Xylophilus* strains tested were susceptible to 16 of 20 antibiotics tested (see Table BXII.β.69) and all nine strains were resistant to methicillin. Mixed results were obtained for ampicillin, colistin sulfate, and polymyxin B (Van den Mooter and Swings, 1990).

Pathogenicity *Xylophilus* strains are plant pathogens. They are responsible for bacterial necrosis and canker of grapevine (*Vitis vinifera*) in the Mediterranean region and South Africa (Panagopoulos, 1969; Erasmus et al., 1974). Although first described in France in 1895 as "Maladie d' Oléron" (Ravaz, 1895), the causal agent of bacterial necrosis of grapevine was not isolated until 1969 (Panagopoulos, 1969). The disease becomes apparent in early spring, when buds on affected shoots fail to open. Longitudinal cracks and cankers appear as they develop from hyperplasiae in the cambial tissue. Underlying vascular tissue shows a brown discoloration and will eventually die. Other parts of the plant that may be infected include petioles, flower stalks, and fruit stalks, resulting in death of leaves, flowers, or fruits. Leaves infected through hydathodes or stomata will show reddish-brown lesions. Roots can also be affected, resulting in retarded growth of shoots. Severity of symptoms may vary considerably for different varieties of grapevine (Panagopoulos, 1969; Grasso et al., 1979; Ridé, 1984, 1996; López et al., 1987). From being a rather rare disease at the beginning of the 20th century, it has now become more significant in the Mediterranean area through a combination of factors such as favorable environmental conditions, pruning procedures, and the increased mechanization of various viticultural practices (Ridé, 1996).

An *in vitro* test to assess cultivar susceptibility has been described by Peros et al. (1995). It involves inoculation of 2-month-old plantlets (having 8–12 internodes) by decapitation with scissors dipped in a bacterial suspension. After several weeks of incubation, the number of internodes with symptoms is recorded as an estimate for the progression of infection.

ENRICHMENT AND ISOLATION PROCEDURES

Isolation from affected vines is possible year round. The extremely slow and poor growth of *Xylophilus* strains often com-

1. GYCA medium (g/l distilled water): yeast extract, 5.0; glucose, 10.0; $CaCO_3$, 30.0; and agar, 20.0.

2. YGC medium (g/l distilled water): yeast extract, 10.0; galactose, 20.0; $CaCO_3$, 20.0; and agar, 20.0.

TABLE BXII.β.69. Characteristics of *Xylophilus ampelinus*[a,b]

Characteristic[c]	Reaction
Hydrolysis of Tween 80	+
Hydrolysis of starch, tributyrin	d
Polygalacturonase, tyrosinase	d
Urease, catalase	+
Alkaline reaction in litmus milk (18 days)	+
Acetoin	d
Growth at 28°C	+
Growth at pH 6.5	d
Tolerance to 1% and 0.5% NaCl	d
Tolerance to 0.01% actidione on GYCA medium	+
Tolerance to 2,3,5-triphenyltetrazolium chloride (TTC) at concentrations of 0.005%, 0.01%, and 0.02%	d
Production of H_2S from thiosulfate	+
Production of H_2S from L-cysteine, peptone	d
Acid production from L-arabinose	+
Acid production from D-galactose, glycerol, maltose	d
Growth on L-arabinose, acetate (0.2%), L-glutamic acid, sodium L-malate, trisodium citrate, potassium sodium tartrate	+
Growth on D-glucose, D-galactose, sodium succinate, sodium fumarate, calcium gluconate, calcium lactate	d
Growth on 0.5% yeast extract	+
Growth on a medium containing NH_4Cl, D-glucose, mineral salts, and vitamins	+
L-Glutamate (0.1%) required for growth	+
Stimulatory effect on growth in basal medium by:	
L-Asparagine, L-aspartic acid, L-glutamic acid, L-glutamine, L-serine, L-tryptophan	+
L-Alanine, L-arginine, glycine, L-histidine, L-hydroxyproline, L-isoleucine, L-leucine, L-methionine, L-phenylalanine, L-proline, L-threonine, L-tyrosine, L-lysine, L-valine, and L-ornithine	d
Glycine and L-lysine as sole nitrogen sources	d
L-Glutamic acid as sole nitrogen and carbon source	+
L-Glutamine as sole source of nitrogen and carbon	d
Hydrolysis of the following substrates in API enzymatic tests:[d]	
2-Naphthyl-butyrate, 2-naphthyl-caprylate, 2-naphthyl-valerate, 2-naphthyl-caproate, 2-naphthyl-phosphate (pH 5.4), L-leucine-naphthylamide, L-tyrosine-naphthylamide, L-serine-naphthylamide, L-lysine-naphthylamide, glycine-naphthylamide, L-phenylalanine-naphthylamide, L-aspartic acid-naphthylamide, L-arginine-naphthylamide, L-alanine-naphthylamide, DL-methionine-naphthylamide, L-tryptophan-naphthylamide, L-ornithine-naphthylamide, L-glutamine-naphthylamide hydrochloride, α-L-glutamic acid-naphthylamide, glycyl-glycine-naphthylamide hydrobromide, glycyl-L-phenylalanine-naphthylamide, L-seryl-L-tyrosine-naphthylamide, L-alanyl-L-arginine-naphthylamide, L-prolyl-L-arginine-naphthylamide, glycyl-L-alanine-naphthylamide, glycyl-L-arginine-naphthylamide, L-leucyl-L-alanine-naphthylamide, L-leucyl-glycine-naphthylamide, L-phenyl-alanyl-L-arginine-naphthylamide, L-seryl-L-methionine-naphthylamide, L-histidyl-L-phenylalanine-naphthylamide, 2-naphthyl-nonanoate	+
Naphthylphosphate (pH 8.5), 2-naphthyl-caprate, L-pyrrolidonyl-naphthylamide, *S*-benzyl-L-cysteine-naphthylamide, L-arginyl-L-arginine-naphthylamide, L-lysyl-L-alanine-naphthylamide, L-phenylalanyl-L-prolyl-L-alanine-naphthylamide, glycyl-L-tryptophan-naphthylamide	v
L-Phenylalanyl-L-proline-naphthylamide	d
Growth in the presence of the following metal compounds or dyes:	
0.01% KSCN, 0.01% $(NH_4)_6Mo_7O_{24}$, 0.001% antimony sodium tartrate, 0.001% NH_4CuCl_3, 0.001% CuI_2, 0.01% sodium salicylate	+
0.01% KIO_3, 0.01% K_2SO_4, 0.01% CuO, 0.01% $BaCl_2$, 0.01% $Ba(NO_3)_2$, 0.01% $MnCl_2$, 0.01% $MnSO_4$, 0.01% H_3BO_3, 0.05% neutral red, 0.0001% crystal violet, 0.01% Nile blue, 0.01% Bismarck brown, 0.01%Congo red	d
Growth in the presence of:	
10 μg/disk methicillin	+
10 μg/disk ampicillin, 10 μg/disk colistin sulfate, 300 U/disk polymyxin B	d

(*continued*)

TABLE BXII.β.69. *(cont.)*

[a]For symbols see standard definitions.

[b]Data taken from Bradbury (1973, 1984), Panagopoulos (1969), Willems et al. (1987), and Van den Mooter and Swings (1990).

[c]All strains are negative for the following characteristics: oxidase; nitrate reduction; indole production; ammonia production; Voges–Proskauer test; phenylalanine deaminase; arginine dihydrolase; lysine and ornithine decarboxylase; lecithinase; hydrolysis of esculin, gelatin, casein, arbutin, sodium hippurate, and DNA; methyl red test; production of a fluorescent pigment on King's medium B; Simmons citrate; potato soft rot test; the following reactions in litmus milk: acid formation, coagulation, peptonization and reduction; β-glucosidase, lecithinase. None of the strains grew at 37°C, at pH 4.5, and 5.5, and in the presence of 30%, 20%, or 10% glucose, 2–10% NaCl, 0.1% actidione on GYEA medium (0.5% D-glucose, 0.1% yeast extract, 2% agar, trace of $FePO_4$), 0.1%, 0.05%, 0.01%, and 0.005% TTC. None of the strains produced acid from cellobiose, D-fructose, D-mannose, D-ribose, sucrose, D-xylose, salicin, *meso*-erythritol, raffinose, melibiose, trehalose, L-rhamnose, D-lactose, D-glucose, sorbitol, dulcitol, amygdalin, glycogen, inulin, dextrin, adonitol, D-mannitol, L-sorbose, α-methylglucoside, arbutin, and *meso*-inositol. None of the strains grew on D-xylose, D-mannose, D-ribose, sucrose, sorbose, lactose, raffinose, trehalose, maltose, cellobiose, L-rhamnose, D-fructose, melibiose, D-mannitol, D-sorbitol, inositol, dulcitol, adonitol, sodium-2-ketogluconate, salicin, inulin, glycogen, dextrin, arbutin, α-methylglucoside, glycerol, D-saccharic acid, mucic acid, D-glyceric acid, D-alanine, L-alanine, norleucine, L-valine, L-leucine, L-isoleucine, L-threonine, L-serine, L-asparagine, ethanolamine, *n*-butyric acid, ethanol, *iso*-butanol, formate, acetate (0.5%), calcium lactate, sodium propionate, malonate, maleate, oxalate, benzoate. All strains failed to grow on 0.5% peptone, on a medium containing NH_4Cl and D-glucose, and on a medium containing NH_4Cl, D-glucose, and mineral salts. None of the strains required L-methionine for growth or showed a stimulated growth in basal medium in the presence of L-cysteine; none used the following amino acids as sole nitrogen source: L-alanine, L-arginine, L-asparagine, L-aspartic acid, L-cysteine, L-glutamic acid, L-glutamine, L-histidine, L-hydroxyproline, L-isoleucine, L-leucine, L-methionine, L-phenylalanine, L-proline, L-serine, L-threonine, L-tyrosine, L-tryptophan, L-valine, and L-ornithine; use the following amino acids as sole nitrogen and carbon source: L-alanine, L-hydroxyproline, L-proline, and L-asparagine. All strains failed to grow in the presence of the following metal compounds and dyes: 0.01% $(NH_4)_2S_2O_8$, 0.001% $HgCl_2$, 0.001% $Hg(NO_3)_2$, 0.001% CuCl, 0.001% $CuCl_2$, 0.001% $CuSO_4$, 0.001% $Cd(CH_3COO)_2$, 0.0001% $Cd(CH_3COO)_2$, 0.01% $CoCl_2$, 0.01% $ZnCl_2$, 0.01% $Pb(CH_3COO)_2$, 0.001% pyronine Y, 0.005% safranine T, 0.001% methylene blue, 0.001% malachite green, 0.005% methyl green, 0.07% methyl green, 0.005% crystal violet, 0.05% Nile blue, 0.005% diamond fuchsine, 0.01% basic fuchsin, 0.0001% brilliant green, and 0.01% thionine, and the following antibiotics (disks): 10 μg erythromycin, 10 U bacitracin, 10 μg streptomycin, 30 μg nalidixic acid, 30 μg kanamycin, 100 μg sulfafurazole, 10 U penicillin G, 25 μg cephaloridin, 10 μg gentamicin, 30 μg chloramphenicol, 10 μg fucidin, 30 μg tetracycline, 30 μg novobiocin, 30 μg neomycin, 200 μg nitrofurantoin. None of the strains hydrolyzed the following substrates in API enzymatic tests: 2-naphthyl-α-D-glucopyranoside, 2-naphthyl-β-D-galactopyranoside, 2-naphthyl-α-L-fucopyranoside, 6-Br-2-naphthyl-α-D-galactopyranoside, 6-Br-2-naphthyl-β-D-glucopyranoside, 6-Br-2-naphthyl-α-D-mannopyranoside, 1-naphthyl-*N*-acetyl-β-D-glucosaminide, naphthol-AS-BI-β-D-glucuronic acid (6-bromo-2-hydroxy-3-naphthoic acid-2-methoxyanilide-β-D-glucuronate), naphthol-AS-BI-phosphodiamide (6-bromo-2-phosphodiamide-3-naphthoic acid-2-methoxyanilide, 2-naphthyl-myristate, 2-naphthyl-laurate, 2-naphthyl-palmitate, 2-naphthyl-stearate, L-cysteine-naphthylamide, β-alanine-naphthylamide, L-histidine-naphthylamide, L-hydroxyproline-naphthylamide, L-isoleucine-naphthylamide, L-valine-naphthylamide, L-threonine-naphthylamide, γ-L-glutamic acid-naphthylamide, L-proline-naphthylamide hydrochloride, *N*-benzoyl-L-leucine-naphthylamide, *N*-benzoyl-DL-arginine-naphthylamide, *N*-benzoyl-L-alanine-4-methoxy-naphthylamide, *N*-carbobenzyloxy-L-arginine-4-methoxy-naphthylamide, *N*-glutaryl-DL-phenylalanine-naphthylamide, glycyl-L-proline-naphthylamide, L-lysyl-L-lysine-naphthylamide, α-L-aspartyl-L-alanine-naphthylamide, aspartyl-L-arginine-naphthylamide, α-L-glutamyl-α-L-glutamic acid-naphthylamide, α-L-glutamyl-L-histidine-naphthylamide, L-histidyl-L-serine-naphthylamide, *N*-acetyl-glycyl-L-lysine-naphthylamide, L-lysyl-L-serine-4-methoxy-naphthylamide, L-alanyl-L-phenylalanyl-L-proline-naphthylamide, L-histidyl-L-leucyl-L-histidine-naphthylamide, L-valyl-L-tyrosyl-L-serine-naphthylamide, *N*-carbobenzyloxy-glycyl-glycyl-L-arginine-naphthylamide, L-alanyl-L-phenylalanyl-L-prolyl-L-alanine-naphthylamide, L-leucyl-L-leucyl-L-valyl-L-tyrosyl-L-serine-naphthylamide, *p*-nitrophenyl-α-D-galactopyranoside, *p*-nitrophenyl-β-D-galactopyranoside, *p*-nitrophenyl-β-D-galactopyranoside-6-phosphate, *p*-nitrophenyl-α-L-arabinofuranoside, *p*-nitrophenyl-α-D-glucopyranoside, *p*-nitrophenyl-β-D-glucopyranoside, *p*-nitrophenyl-β-D-galacturonide, *p*-nitrophenyl-β-D-glucuronide, *p*-nitrophenyl-α-maltoside, *p*-nitrophenyl-β-maltoside, *p*-nitrophenyl-*N*-acetyl-α-D-glucosaminide, *p*-nitrophenyl-*N*-acetyl-β-D-glucosaminide, *p*-nitrophenyl-α-L-fucopyranoside, *p*-nitrophenyl-β-D-fucopyranoside, *p*-nitrophenyl-β-L-fucopyranoside, *p*-nitrophenyl-β-D-lactoside, *p*-nitrophenyl-α-D-mannopyranoside, *p*-nitrophenyl-β-D-mannopyranoside, *p*-nitrophenyl-α-D-xylopyranoside, *p*-nitrophenyl-β-D-xylopyranoside.

[d]The following API test strips were used: API-ZYM, Osidases, Esterases, AP1, AP2, and AP3 (Biomérieux, France).

plicates isolation because fast-growing saprophytes may rapidly overgrow isolation cultures. Serfontein et al. (1997) reported the isolation of bacteria from infected material collected in hot and dry periods to be difficult. Under cool and wet conditions the same plants did yield large numbers of the bacterium. The most frequently used isolation materials are small pieces of infected wood taken aseptically from diseased vines and soaked in sterile water for 20 min. The resulting bacterial suspension is streaked onto nutrient agar (Panagopoulos, 1969; Erasmus et al., 1974; Grasso et al., 1979). Small pale-yellow colonies will appear after 5–6 d of incubation; after 8–10 d diameters of 0.4–0.6 mm are attained (Panagopoulos, 1969). An enrichment technique to improve isolation yields was proposed by Serfontein et al. (1997). Cuttings from diseased shoots that include a node were incubated in closed plastic bags together with wet cotton plugs. After 3 d in the dark at 15°C, extracts from the shoots contained significantly more *Xylophilus ampelinus* bacteria than controls analyzed before incubation. This method also permits isolation of bacteria from latently infected shoots with no apparent signs of disease (Serfontein et al., 1997). The most widely used isolation medium is nutrient agar, but better growth is obtained by adding 5% glucose to nutrient agar. YGC and GYCA medium also result in better growth, but because the $CaCO_3$ renders these media opaque they are less suitable for the study of colony morphology. YEGAL medium[3] is more convenient and also yields good growth (Starr et al., 1977). Repeated sterilization or re-melting of solid media inhibits growth of *Xylophilus* (Panagopoulos, 1969).

Maintenance Procedures

Cultures grown on screw-capped slants at 24°C for 2–3 d can be stored tightly closed at 4°C and should be transferred at least every 2 months. For long-term preservation, strains can be lyophilized.

Differentiation of the genus *Xylophilus* from other genera

The most typical feature of *Xylophilus* strains is their extremely slow and poor growth on most media at the optimal growth temperature of 24°C. They can be differentiated from most *Xanthomonas* species by the following characteristics: very low salt tolerance, inability to produce acid from numerous sugars, failure to hydrolyze gelatin and esculin, positive urease reaction, growth on K,Na-tartrate, L-glutamic acid, absence of growth on sucrose, and the use of L-glutamic acid as a sole carbon and nitrogen source (Van den Mooter and Swings, 1990). Other slow-growing organisms can also be isolated from grapevines but many of these are Gram positive. Gram reaction, catalase and oxidase tests, urease production, and lipolysis of Tween 80 have been proposed as preliminary confirmation tests to distinguish *Xylophilus ampelinus* from other slow growers (Serfontein et al., 1997).

3. YEGAL medium (g /l distilled water): yeast extract, 5.0; galactose, 10.0; K_2HPO_4, 4.01; NaH_2PO_4, 4.55; NH_4Cl, 1.0; $MgSO_4 \cdot 7H_2O$, 0.5; ferric ammonium citrate, 0.05; $CaCl_2$, 0.005. Yeast extract and galactose are each dissolved in 100 ml of water and autoclaved separately and added aseptically (Starr et al., 1977).

Serological tests with specific antisera are used for rapid identification of the pathogen (Erasmus et al., 1974; Ridé, 1996).

Taxonomic Comments

Xylophilus ampelinus was first classified in the genus *Xanthomonas* because it is a Gram-negative, aerobic, nonsporeforming plant pathogen with monotrichously flagellated rod-shaped cells, produces a yellow water-insoluble pigment and metabolizes sugars oxidatively (Panagopoulos, 1969). Later it became evident from additional data, such as pigment analyses (Starr et al., 1977), comparative studies of the biosynthesis of aromatic amino acids (Whitaker et al., 1981; Byng et al., 1983) and DNA–rRNA hybridization studies comparing *Xanthomonas ampelina* DNA with *Xanthomonas campestris* (De Vos and De Ley, 1983) that the vine pathogen was not a genuine *Xanthomonas*. As a result of a study of 34 strains from different geographic origins by means of SDS-polyacrylamide gel electrophoresis of whole-cell proteins, numerical analysis of 106 enzymatic features, and DNA–DNA and DNA–rRNA hybridization, we created a separate genus *Xylophilus* for these organisms (Willems et al., 1987). DNA–rRNA hybridization demonstrated that *Xylophilus* is a member of the family *Comamonadaceae* (previously called the "acidovorans rRNA complex"). Using this method none of the other diverse organisms of this family seemed especially closely related to the vine pathogen. Some phytopathogenic *Pseudomonas* species (now *Acidovorax*) and *Alcaligenes paradoxus* strains yielded slightly more stable DNA–rRNA hybrids when their DNA was hybridized with labeled rRNA of *X. ampelinus*, but when taking into account the experimental error, this was not considered significant (Willems et al., 1987). More recently the 16S rDNA sequences of *Xylophilus ampelinus* and various other members of the *Comamonadaceae* were determined, and these data revealed a closer relationship between *Xylophilus ampelinus* and *Variovorax paradoxus*. A sequence similarity of 97.9% was reported between both type strains (Wen et al., 1999). In other genera of the *Comamonadaceae* (*Acidovorax*, *Comamonas*, and *Hydrogenophaga*), this level of similarity is found between species within a genus. Together with the absence of DNA binding between the type strains of *Xylophilus* and *Variovorax* (Willems et al., 1991a), these would be arguments in support of a merger of these genera. Both are yellow-pigmented, although it is unknown whether these pigments have a similar structure. On the other hand, *Xylophilus* grows extremely slowly and is a phytopathogen with a rather restricted metabolic versatility, whereas *Variovorax* uses a wide variety of substrates and some of its strains are capable of chemolithotrophic growth using hydrogen oxidation as an energy source. In view of these differences and until further genotypic similarities are reported, the maintenance of separate genera may be justified for these organisms.

THE EDITORIAL BOARD

Hy.dro.ge.no′ phi.lus. Gr. n. *hydro* water; Gr. v. *genein* to produce; M.L. neut. n. *hydrogenum* hydrogen (that which produces water); Gr. adj. *philo* loving, friendly to; M.L. masc. n. *Hydrogenophilus* hydrogen lover.

Straight rods 0.5–0.8 × 1.0–3.0 µm during exponential growth. Occur singly. Motile or nonmotile. Gram negative. Nonsporulating. Aerobic or microaerophilic, having a strictly respiratory type of metabolism, with oxygen as the terminal electron acceptor. **Colonies are yellow. Thermophilic**; one species grows optimally at 50–52°C; and a second, at 60–65°C. **Facultatively chemolithoautotrophic**; can use H_2 as an electron donor and CO_2 as a carbon source. CO_2 is fixed via the Calvin-Benson cycle. Carbohydrates are not utilized. Acetate, pyruvate, DL-lactate, succinate, and DL-malate can be used as electron donors and carbon sources. Ammonium can be used as a nitrogen source. The major quinone system is ubiquinone 8. Isolated from hot springs and surrounding soil.

The mol% G + C of the DNA is: 61–65.

Type species: **Hydrogenophilus thermoluteolus** Hayashi, Ishida, Yokota, Kodama and Igarashi 1999, 785.

FURTHER DESCRIPTIVE INFORMATION

Hayashi et al. (1999) found the type strain (TH-1) of *H. thermoluteolus* to be nonmotile; however, Goto et al. (1978) reported the same strain to be motile. Reference strain TH-4 is nonmotile (Hayashi et al., 1999). The type strain of *H. hirschii* is motile by a single polar flagellum.

ENRICHMENT AND ISOLATION PROCEDURES

Isolation and culture conditions for *H. thermoluteolus* have been described by Goto et al. (1977). The isolation of *H. hirschii*—a microaerophilic organism—has been described by Stöhr et al. (2001); briefly, the autotrophic medium of Huber et al. (1992) was used lacking NaCl but containing 0.02% $CaCl_2 \cdot 2H_2O$. The medium was deoxygenated with N_2 and dispensed in 20-ml portions into 120 ml serum bottles under N_2. The gas phase in the bottles was changed to H_2/CO_2 (80:20, v/v), and the medium was sterilized at 100°C for 90 min and cooled. To each bottle was added 100 µl of a 10% sterile solution of $CaCO_3$ and 20 ml of filter-sterilized air. After several passages of serially diluted cultures, the cultures were plated onto the isolation medium solidified with 1.5% agar to obtain yellow colonies consisting of motile rods.

Differentiation of the genus *Hydrogenophilus* from other genera

The genus *Hydrogenophilus* differs from the genera *Calderobacterium* and *Hydrogenobacter* in that it consists of facultative hydrogen autotrophs instead of obligate hydrogen autotrophs. Moreover, the optimal growth temperatures of *H. thermoluteolus* and *H. hirschii* (50–52°C and 63°C, respectively) are lower than that of *Calderobacterium* (74–76°C; Kryukov et al., 1983) and of *Hydrogenobacter* (70–75°C; Kawasumi et al., 1984). In addition, the cell diameter of *H. thermoluteolus* and *H. hirschii* (0.5–0.6 μm and 0.6–0.8 μm, respectively) is greater than that of *Calderobacterium* (0.25–0.5 μm) and *Hydrogenobacter* (0.3–0.5 μm) cells.

Taxonomic Comments

Based on DNA–DNA hybridization experiments, Hayashi et al. (1999) found strain TH-1—the type strain of *H. thermoluteolus*—and reference strain TH-4 to have a hybridization value of 89%, indicating that the two strains belong to the same species. Moreover, 16S rDNA analysis indicated that, although the two strains belonged to the class *Betaproteobacteria*, they were sufficiently unrelated to this class as to warrant their placement in a new genus, *Hydrogenophilus* (Hayashi, et al., 1999). Analysis of 16S rDNA sequences by Stöhr et al. (2001) indicated that strain TH-1—the type strain of *H. thermoluteolus*—has a phylogenetic distance of 0.0257 from the type strain of *H. hirschii* (Yel5a); thus the two type strains should be placed within the same genus.

In this edition of the *Manual*, the genus *Hydrogenophilus* is classified in the Order *Hydrogenophilales* and the Family *Hydrogenophilaceae* within the Class *Betaproteobacteria*. The only other member of the family is the genus *Thiobacillus*, which differs markedly in its phenotypic properties from *Hydrogenophilus*. Other genera of Gram-negative, thermophilic, hydrogen chemolithotrophs include *Calderobacterium* and *Hydrogenobacter*, which are classified in the Phylum *Aquificae*, Class *Aquificae* Order *Aquificales*, and Family *Aquificaceae*.

Differentiation of the species of the genus *Hydrogenophilus*

Hydrogenophilus thermoluteolus grows optimally at 50–52°C, whereas *H. hirschii* grows best at 63°C. In regard to their relationship to oxygen, *H. thermoluteolus* grows best at 22% O_2, whereas *H. hirschii* is a microaerophile that grows best at 2.5% O_2 and fails to grow at O_2 levels higher than 5%.

List of species of the genus Hydrogenophilus

1. **Hydrogenophilus thermoluteolus** Hayashi, Ishida, Yokota, Kodama and Igarashi 1999, 785[VP]
ther.mo.lu.te′ o.lus. Gr. adj. *thermos* hot; L. adj. n. *luteolus* light yellow; M.L. masc. adj. *thermoluteolus* hot and light yellow.

Exponentially growing cells are 0.5–0.6 × 2.0–3.0 μm. Optimal temperature, 50–52°C. Optimal pH, 7.0. Aerobic. Other characteristics are as given for the genus, with the following additional information. Carbon sources include propionate, butyrate, and α-ketoglutaric acid. No growth occurs on lactose, D-glucose, D-galactose, sucrose, citrate, ethanol, benzoate, and *m*-hydroxybenzoate. Ammonium, nitrate, and urea can be used as sole nitrogen sources; nitrite and N_2 are not used. Major fatty acids: $C_{16:0}$, $C_{18:0}$. The major 3–hydroxy cellular fatty acid is $C_{10:0\ 3OH}$. Cyclic fatty acids have not been described in *H. thermoluteolus*. Isolated from soil around a hot spring in Izu peninsula, Shizuoka Prefecture, Japan (Goto et al., 1977).

The mol% G + C of the DNA is: 63–65 (T_m).
Type strain: TH-1, IFO 14978.
GenBank accession number (16S rRNA): AB009828.

2. **Hydrogenophilus hirschii** Stöhr, Waberski, Liesack, Völker, Wehmeyer and Thomm 2001, 488[VP]
hir′ schi.i. N.L. gen. n. *hirschii* in honor of Peter Hirsch, in recognition of his fundamental contributions to the taxonomy of unusual bacteria.

Cells are 0.6–0.8 × 1.0–2.0 μm. Motile by a single polar flagellum. Optimal growth temperature, 63°C; upper limit, 68°C. No growth at 45°C. Microaerophilic, growing best at 2.5% O_2 and failing to grow at O_2 levels higher than 5%. Other characteristics are as given for the genus, with the following additional information. Growth occurs anaerobically with nitrate. Growth occurs on yeast extract, peptone, meat peptone, and meat extract. Fumarate, glutamate, and gluconate can be used as carbon sources. No growth occurs on carbohydrates, aromatic compounds, L-alanine, L-proline, citric acid, methanol, or ethanol. Neither thiosulfate nor sulfur is used as an electron donor. Major fatty acids: $C_{16:0}$, $C_{17:0\ cyclo}$, and $C_{19:0\ cyclo}$. Isolated from a water sample from Angel Terrace in Yellowstone National Park, U.S.A.

The mol% G + C of the DNA is: 61 (HPLC).
Type strain: Yel5a, DSM 11420, JCM 10831.
GenBank accession number (16S rRNA): AJ131694.

Genus II. **Thiobacillus** *Beijerinck 1904b, 597[AL]*

Donovan P. Kelly, Ann P. Wood and Erko Stackebrandt

Thi.o.ba.cil′ lus. Gr. n. *thios* sulfur; L n *bacillus* a small rod; M. L. masc n. *Thiobacillus* sulfur rodlet.

Small, Gram-negative, rod-shaped cells (0.3–0.5 × 0.9–4.0 μm). Some species are motile by means of polar flagella. No resting stages known. Energy is derived by the oxidation of one or more reduced sulfur compounds, including sulfides, sulfur, thiosulfate, polythionates, and thiocyanate. Sulfate is the end product of sulfur-compound oxidation, but sulfur, sulfite, and polythionates may be accumulated by most species, sometimes transiently. All species can fix carbon dioxide by means of the Benson–Calvin cycle and are capable of autotrophic growth; some species are obligately chemolithotrophic, while others are chemoorganotrophic. The genus currently includes obligate aerobes and facultative denitrifiers. Optimal pH of 2–8 with optimal temperature of 28–43°C. Distribution is seemingly ubiquitous in marine, freshwater, and soil environments, especially where oxidizable sulfur

is abundant (e.g., sulfur springs, sulfide minerals, sulfur deposits, sewage treatment areas, and sources of sulfur gases, such as sediments or anaerobic soils releasing H_2S).

The mol% G + C of the DNA is: 62–67.

Type species: **Thiobacillus thioparus** Beijerinck 1904b, 597.

Further descriptive information

The chemolithotrophic, sulfur-compound-oxidizing, Gram-negative, rod-shaped members of the genera and species described (Table BXII.β.70) are usually 0.5 × 1.0–4.0 μm in size, occurring singly, in pairs or in short chains; some are motile by means of single polar flagella; some possess pili and other specialized surface features. All can obtain energy from the oxidation of reduced inorganic sulfur compounds, and, in most cases, elemental sulfur. Some species are obligately chemolithotrophic and autotrophic, others are facultatively heterotrophic, and, in some strains, optimal growth occurs mixotrophically. Both electron-transport-dependent and substrate-level phosphorylation occur during sulfur-compound oxidation, and reduction of NAD(P) requires an energy-dependent flow of electrons from cytochrome *c* (or *b*). Carbon dioxide fixation occurs mainly by means of the Benson–Calvin cycle, with some fixation occurring through pyruvate or phosphoenolpyruvate carboxylation. The obligately autotrophic species possess an incomplete tricarboxylic acid cycle (lacking 2-oxoglutarate dehydrogenase), which is used as a biosynthetic "horseshoe" pathway via oxaloacetate or succinate and 2-oxoglutarate, respectively, down each arm of the "horseshoe". Some species contain characteristic plasmids, and some have been shown to be susceptible to introduction of *Pseudomonas* plasmids. Little work on the genetics of *Thiobacillus* spp. is available, but it is known that autotrophic and drug-resistant mutants can be obtained and that mutations that decrease autotrophic efficiency can be induced. No species is known to be pathogenic. *Thiobacillus* spp. are ubiquitous, with the facultative species occurring in soil, freshwater, and marine environments as heterotrophs or mixotrophs. Sulfur-compound-oxidizing species have been isolated from Arctic, temperate, and tropical waters, soil, salt marshes, freshwater lakes, rivers, canals, hot springs, sulfur-rich mine or acid-mine wastewaters and other environments where oxidizable sulfur compounds occur naturally or anthropogenically.

Enrichment and Isolation Procedures

Most of the species can be isolated from natural habitats by the use of mineral media containing elemental sulfur or thiosulfate as the energy-yielding substrate. Use of media of different pH will assist in differential selection of the neutrophilic and acidophilic species, use of acid ferrous sulfate medium will frequently select for *Acidithiobacillus ferrooxidans*, and use of anaerobic thiosulfate medium (pH 7) supplemented with nitrate will select for *T. denitrificans*. A procedure has been described for the enrichment of facultatively autotrophic, mixotrophic strains, using a continuous-flow chemostat with both organic and inorganic substrates (Gottschal and Kuenen, 1980). This provides a means of avoiding the predomination by heterotrophs in standard batch enrichment media containing supplements such as thiosulfate and glucose or thiosulfate and acetate. In the latter medium, a mixture of obligately chemolithotrophic thiobacilli and chemoorganotrophs normally develops. *Acidiphilium acidophilum* was originally isolated as a commensal of *A. ferrooxidans*, although *"T. organoparus"* (now considered to be a strain of *A. acidophilum*) was enriched directly from an acid mine water environment. Media suitable for the different species are summarized in Kelly and Wood (1998) and are available from the original literature describing the species. In addition, culture collection catalogues also provide guidance for media suitable for their cultures.

Most strains are able to produce colonial growth on appropriate media solidified with agar. Some strains, especially those of *A. ferrooxidans*, grow poorly on agar media. In some cases, this difficulty is due to the toxicity of agar hydrolysis products and has been overcome in a number of ways (e.g., Tuovinen and Kelly, 1973). Toxic effects are generally avoided by the use of a minimal concentration of agar, screening of suitable brands of purified agars, use of agarose, and, in the case of *A. ferrooxidans*, use of a combination of media with low agar concentrations, at

[a]With inorganic sulfur compounds as sole energy substrates.

[b]Most species of the genus are not chemolithoautotrophic.

[c]Not all species exhibit all these features, and only *P. denitrificans* , *P. versutus*, and *P. pantotrophus* are facultative, sulfur-oxidizing chemolithoautotrophs.

[d]Most strains will grow on complex rich media, and some grow best mixotrophically with thiosulfate plus organic supplements.

[e]Denitrification to dinitrogen in one species only: *T. denitrificans*.

[f]*T. plumbophilus* grows only between pH 4.0–6.5.

[g]Optimum for *T. cuprinus* is pH 3.0–4.0.

pH 2.2–2.5, and with ferrous sulfate at only about 20 mM. The use of silica gel media as an alternative is normally unnecessary.

Maintenance Procedures

After cultivation on suitable media, most species survive storage at 5°C for periods of weeks to months, especially if the media for neutrophiles have not become too acidic before storage. *A. ferrooxidans* survives in culture on pyrite for very long periods when stored at 5 to 15°C, and *"T. plumbophilus"* survives for at least a year at room temperature on galena (Drobner et al., 1992). Many strains have been successfully lyophilized or have survived storage at −20°C, at liquid nitrogen temperature, or in glycerol suspension at −20°C.

Differentiation of the genus *Thiobacillus* from other genera

At the time of the previous edition of this *Systematics*, information on ubiquinone and fatty acid content, DNA base composition, and interspecific DNA–DNA hybridization had been obtained for the thiobacilli (Kelly and Harrison, 1989). This enabled division of the species into distinct groups on the basis of physiological and biochemical characteristics (Harrison, 1982, 1983; Katayama-Fujimura et al., 1982; Katayama-Fujimura and Kuraishi, 1983). It has also complicated consolidation of species, as DNA–DNA hybridization studies in some cases show considerable diversity among strains regarded as members of the same species, while also showing very high levels of similarity between putatively different species. The confirmation by 16S rRNA sequencing of the phylogenetic diversity of the formally approved species now forces major revision of this genus.

Primary separation of most of the former 21 species of *Thiobacillus* is relatively easy to achieve by virtue of differences in gross physiological characteristics, such as pH and temperature requirements for growth, ability or inability to grow heterotrophically as well as chemolithotrophically, and differences in the ability to grow anaerobically with denitrification or to use elemental sulfur. Most species designated as *Thiobacillus* may precipitate elemental sulfur into the medium during growth on sulfide, thiosulfate, and, in some cases, trithionate or tetrathionate. One of the exceptions is *T. versutus.* Sulfur precipitation is not a highly distinctive diagnostic characteristic, as it is a variable property influenced by growth conditions, such as oxygen availability or perturbation of steady state in chemostat culture. The precipitation of sulfur is superficially comparable to the extracellular precipitation observed with species of *Chlorobium* and contrasts with the intracellular accumulation of sulfur by members of the *Chromatiaceae* such as *Chromatium.* It is likely, however, that some species deposit sulfur internally, subsequently oxidizing it to sulfate. Thus, *T. albertensis* grown on thiosulfate is believed to contain a sulfur granule bounded by a membrane (Bryant et al., 1983), the appearance of which is correlated with the production of a large amount of extracellular elemental sulfur at the end of the growth phase. Morphologically, these inclusions resemble the sulfur found in *Beggiatoa* and *Thiothrix.* These granules do not appear during mid-log growth (Bryant et al., 1983), and had not been reported in earlier ultrastructural surveys of other thiobacilli (Mahoney and Edwards, 1966; Shively et al., 1970), but may have been observed in *"T. kabobis"* (Reynolds et al., 1981), which is now regarded as a synonym of *T. thiooxidans* (Kuenen et al., 1992). The possibility of both extracellular deposition and intracellular accumulation of elemental sulfur in some thiobacilli is somewhat of a physiological anomaly, possibly indicative of differing mechanisms or locations of sulfur compound oxidation. Extracellular sulfur precipitation is best explained as a consequence of the conversion of sulfide or the sulfane groups of thiosulfate (or polythionates) to sulfur at the surface of the cell, presumably in the periplasmic space and catalyzed by enzyme systems located in or external to the bounding membrane of the cell. This seems to be more plausible than intracellular generation of sulfur and its excretion to the outside (as has indeed been suggested). The physicochemical nature of the sulfur at the moment of formation is uncertain, and, of course, the cell wall would likely be a barrier to the excretion of large granules from inside the cell or even to their generation in the periplasmic space. The production of intracellular sulfur from a soluble substrate (thiosulfate) implies intracellular oxidation of that substrate and transport of S^0 across the membrane. Although it is clear that this process would involve membrane-associated electron transport systems in the oxidation of sulfur compounds to sulfate, the mechanism remains to be elucidated. Clearly, the present stage of our knowledge of the mechanism of transport of sulfur and its compounds and of the biochemistry of their conversion to sulfate is inadequate. Therefore, characteristics such as intracellular sulfur accumulation cannot be employed as reliable taxonomic features.

Taxonomic Comments

Since the description of *Thiobacillus* was published in the first edition of the *Systematics* (Kelly and Harrison, 1989), the genus has undergone a number of revisions and emendations. These changes are summarized in Table BXII.β.70 and Table BXII.β.71. Table BXII.β.71 also presents the DNA base composition and class within the *Proteobacteria* to which each species is now assigned, based on sequence analysis of either partial or complete 16S rRNA genes and recently proposed reassignments to new genera (Kelly and Wood, 2000a, b; Kelly et al., 2000). A phylogenetic tree illustrating the new and different genera to which most of the *Thiobacillus* species have been assigned is shown in Fig. BXII.β.60.

First, *T. versutus* and *T. acidophilus* (both members of the class *Alphaproteobacteria*) have been formally transferred from *Thiobacillus* into other genera (Katayama et al., 1995; Hiraishi et al., 1998; see the chapter by Hiraishi and Imhoff on the genus *Acidiphilium* in the family *Acetobacteraceae* in this volume), and each appears elsewhere within this edition. The remaining species group within the classes *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria.* The type species, *T. thioparus*, falls in the *Betaproteobacteria*, along with the closely related *T. denitrificans* and the moderate thermophile *T. aquaesulis* (McDonald et al., 1997; Kelly and Wood, 2000a, b). These three species are the only ones that can be justified based on molecular criteria to be members of the genus *Thiobacillus.* A fourth validly named species, *Thiobacillus delicatus*, is physiologically similar to members of the genus *Thiomonas* and may be reassigned to that genus when more data are available (Y. Katayama, personal communication). *Thiobacillus denitrificans* has been regarded as a close relative of *T. thioparus* since it was originally isolated by Beijerinck (1904a, b), and that view is now strongly supported by the confirmation that it is a member of the *Betaproteobacteria* (Lane et al., 1992; H.G. Trüper, personal communication, 1999; Kelly and Wood, 2000a). Of the remaining species, only *Thiobacillus novellus* has been shown to be a member of the *Alphaproteobacteria. T. novellus* is facultatively autotrophic (as are the *Alphaproteobacteria* species formerly classified as *T. versutus* (now *Paracoccus versutus*) and *T.*

TABLE BXII.β.71. Species of *Thiobacillus* recognized in the first edition of this *Manual* (Kelly and Harrison, 1989), or described subsequently, showing those species assigned, or proposed for assignment, to new or different genera

Basonym	Revised genus designations (published or proposed)
Thiobacillus thioparus [a]	*Thiobacillus thioparus*[T]
Thiobacillus denitrificans[b]	*Thiobacillus denitrificans*

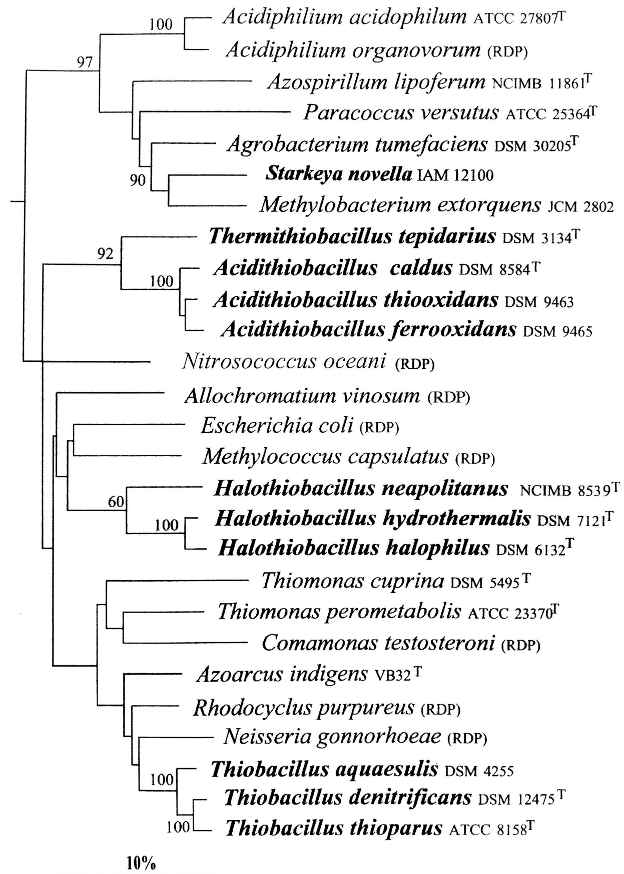

FIGURE BXII.β.60. Phylogenetic tree based on 16S rRNA gene sequences of representatives of the genera to which species formerly described as *Thiobacillus* are now assigned (*Thiobacillus*, *Acidiphilium*, *Starkeya*, *Thermithiobacillus*, *Acidithiobacillus*, *Halothiobacillus*, and *Thiomonas*). Reference species are taken from the Ribosomal Database Project (RDP) or from the sequence database libraries. *T* indicates the type strain of the species. Bar = 10 inferred nucleotide changes per 100 nucleotides. Numbers at some nodes indicate the number of times the species to the right occurred in 100 bootstrap replicates.

acidophilus (now *Acidiphilium acidophilum*), as well as *Thiosphaera pantotropha* (now *Paracoccus pantotrophus*) and has been proposed to be the type species of a new genus, *Starkeya* (Kelly et al., 2000). Of the other species in the *Betaproteobacteria*, four have been reassigned to the new genus *Thiomonas* (Moreira and Amils, 1997). A fifth acidophilic, lead-sulfide-leaching species reportedly also in the *Betaproteobacteria*, *"Thiobacillus plumbophilus"* (Drobner et al., 1992), has been too little studied to know if it should also be reassigned to *Thiomonas*, so for the present time it is retained in the genus *Thiobacillus*. Of the species within the *Gammaproteobacteria*, a broad division can be seen between two principal groups: one comprising the proposed new genus *Halothiobacillus* (McDonald et al., 1997; Kelly et al., 1998a; Kelly and Wood, 2000b), and the other (*Acidithiobacillus*) containing at least three of the acidophilic species, some of which also oxidize Fe^{2+} and sulfide minerals (Table BXII.β.71; Fig. BXII.β.60). The former *Thiobacillus tepidarius* also seems to be somewhat distantly related to this group (McDonald et al., 1997; Goebel et al., 2000), but we consider its moderate thermophily and lack of acidophily sufficient grounds to regard it as a distinct genus (*Thermithiobacillus*) at this time (Kelly and Wood, 2000b). *Thiobacillus albertis* (whose specific epithet is here corrected to *albertensis*) is also acidophilic and strictly chemolithotrophic, making it physiologically similar to *Acidithiobacillus thiooxidans*, but it differs from that species in possessing a glycocalyx and having a mol% G + C of 61.5, which is significantly higher than that of *A. thiooxidans* (50–52 mol% G + C). Based on 16S rRNA sequences, we confirm the placement of *T. albertensis* in *Acidithiobacillus* (Table BXII.β.71), whose members have DNA mol% G + C values ranging between 50–64 (Table BXII.β.71). *"T. prosperus"* is more difficult to define taxonomically, as it appears to be completely unrelated to the *T. ferrooxidans*–*T. thiooxidans*–*T. caldus* cluster based on 16S rRNA sequence comparisons (Goebel et al., 2000) and shows negligible DNA–DNA hybridization with other thiobacilli. We have reported the acidophilic species *T. ferrooxidans*, *T. thiooxidans*, and *T. caldus*, as well as *T. tepidarius*, to fall in the *Gammaproteobacteria*, whereas some reports in the literature assign these to the *Betaproteobacteria*. It seems clear to us from recent studies that these species, while close to the beta–gamma separation, are rightly placed in the *Gammaproteobacteria* (McDonald et al., 1997; Goebel et al., 2000; Kelly and Wood, 2000b).

Descriptions of the former *Thiobacillus* species *T. versutus* and *T. acidophilus* are found in the chapters on *Paracoccus* and *Acidiphilium*, respectively. Some characteristics of the genus *Thiobacillus* of the newly created genera, and of *Paracoccus* and *Acidiphilium* are given in Table BXII.β.70.

Differentiation of the species of the genus *Thiobacillus*

The characteristics of each of the six species are summarized in Table BXII.β.72.

List of species of the genus Thiobacillus

1. **Thiobacillus thioparus** Beijerinck 1904b, 597[AL]
thi.o'par.us. G. n. *thios* sulfur; M.L. adj. *thioparus* sulfur producing.

Rods, averaging 0.5 × 1.7 μm. Motile with a polar flagellum. Gram negative. Colonies grown on thiosulfate agar (1–2 mm in diameter) are circular and whitish-yellow due to precipitated sulfur. Turn pink, then brown on aging, especially in the center of old colonies. In static culture in liquid thiosulfate medium, sulfur is precipitated, and the medium becomes turbid with a pellicle of sulfur and cells. Sulfur granules and tetrathionate and/or trithionate may accumulate, accompanied by a pH drop to 4.5. In well-aerated or chemostat culture, sulfur oxidation of thiosulfate to sulfate may occur without precipitation. Some strains oxidize thiocyanate, thiosulfate, trithionate, tetrathionate, sulfur, and sulfide. Obligately chemolithotrophic and autotrophic. Ammonium salts and nitrates used as nitrogen sources. Aerobic. Optimal temperature: 28°C. Optimal pH: 6.6–7.2, with growth occurring between pH 4.5 and 7.8. Some strains are claimed to grow at pH 10.0. Found in mud, soil, canal water, and other freshwater sources. Presumably widely distributed.

The mol% G + C of the DNA is: 62–63 (Bd, T_m).

Type strain: ATCC 8158, DSM 505.

GenBank accession number (16S rRNA): M79426.

2. **Thiobacillus aquaesulis** Wood and Kelly 1995, 418[VP] (Effective publication: Wood and Kelly 1988, 342.)
a.quae.su'lis. L. n. *aquae* waters; L. n. *Sulis* pertaining to the Temple of Sulis Minerva (Minerva, the Roman goddess of wisdom); M.L. adj. *aquaesulis* from the waters of Sulis Minerva.

Short rods, 0.3 × 0.9 μm, containing some polyphosphate inclusions. Motile. Gram negative. Non-sporeforming. Chemolithoautotrophic growth on thiosulfate, trithionate, or tetrathionate. Colonies on thiosulfate agar at 43°C are small (1–2 mm), circular, convex, and smooth, becoming white or yellow with precipitated sulfur. In liquid batch culture, sulfur precipitation and a drop in pH without tetrathionate accumulation occur. Initiates growth at pH 7–9 (30–55°C), dropping the pH to 6–7. No growth at pH 6.4 or 9.4 or at 26°C or 58°C. Chemostat cultures do not accumulate sulfur or other intermediates during growth on thiosulfate, trithionate, or tetrathionate at pH 7.6 and 43°C. Facultatively heterotrophic on complex media (yeast extract or nutrient broth) but unable to grow on common sugars, organic acids, formate, or methylamine as single substrates. Uses ammonium salts as nitrogen sources. Capable of anaerobic, autotrophic growth during thiosulfate-dependent denitrification in batch culture, producing nitrite and sulfur from thiosulfate and nitrate. Optimal temperature: 40–50°C. Optimal pH: 7.5–8.0. Contains ubiquinone-8. Isolated from the thermal springs at Bath, Avon, England.

The mol% G + C of the DNA is: 65.7 (T_m).

Type strain: ATCC 43788, DSM 4255.

GenBank accession number (16S rRNA): U58019.

3. **Thiobacillus delicatus** (ex Mizoguchi, Sato and Okabe 1976)[VP] Katayama-Fujimura, Kawashima, Tsuzaki and Kuraishi 1984a, 142.
del.i.cat'us. L. masc. adj. *delicatus* delicate.

Rods, usually single, rarely in pairs, 0.4–0.6 × 0.7–1.6 μm. Nonmotile. Colonies grown on yeast extract–thiosulfate agar (1 mm. diameter) are smooth and circular and

TABLE BXII.β.72. Basic characteristics of species of the genus *Thiobacillus*

[a]Unable to grow on common sugars, organic acids or one-carbon organic substrates.

change from transparent to whitish-yellow with sulfur accumulation. Facultatively chemolithotrophic and mixotrophic. Grow autotrophically with sulfur, thiosulfate, or tetrathionate, but not with thiocyanate. Accumulates tetrathionate and trithionate transiently during growth on thiosulfate. Incapable of heterotrophic growth on single-carbon compounds. Grows mixotrophically in thiosulfate media supplemented with tricarboxylic acid cycle intermediates or amino acids. Optimal growth requires both organic and inorganic substances and thiosulfate or sulfur. Facultatively anaerobic; reduces nitrate and produces nitrite in mixotrophic and autotrophic media with thiosulfate or tetrathionate. Ammonium salts, nitrate, urea, glutamate, or aspartate can be used as the nitrogen source.

Optimal temperature 30–35°C, range 15–42°C (no growth at 10 or 45°C). Optimal pH 5.5–6.0, range 5.0–7.0. Isolated from mine water. Distribution unknown.

The mol% G + C of the DNA is: 66–67 (T_m, chemical analysis).

Type strain: IAM 12624.

Additional Remarks: Until 16S rDNA sequence data become available for this species, it cannot be firmly reassigned to the genus *Thiomonas*. Physiologically, the species is more similar to *Thiomonas perometabolis* than to the type species *Thiobacillus thioparus*.

4. **Thiobacillus denitrificans** (ex Beijerinck 1904b) Kelly and Harrison 1989, 1855 emend. Kelly and Wood 2000a, 548[VP]
de.ni.tri'fi.cans. M.L. v. *denitrifico* denitrify; M.L. part. adj. *denitrificans* denitrifying.

Short rods, 0.5 × 1.0–3.0 µm. May be motile by means of a polar flagellum. Under anaerobic conditions, colonies are clear or weakly opalescent when grown on thiosulfate–nitrate agar, On aging, colonies may become white with sulfur. Vigorous nitrogen production when grown under anaerobic conditions, leading to splitting of agar when solid media are used. Facultatively anaerobic. Grows autotrophically and aerobically on thiosulfate or tetrathionate, on which it produces growth yields approximately double those of *T. thioparus* or *T. neapolitanus*. Grows anaerobically on thiosulfate, tetrathionate, or sulfide by using nitrate, nitrite, or nitrous oxide as the terminal electron acceptor. Oxidizes sulfur, sulfide, thiosulfate, tetrathionate, and probably sulfite, but not thiocyanate. Chemostat culture can be switched easily and repeatedly between aerobic and anaerobic growth modes, with adaptation involving derepression of nitrate and nitrite reductase synthesis. Ammonium salts and, in at least some strains, nitrate are used as nitrogen sources.

Obligately chemolithotrophic and autotrophic. Optimal temperature: 28–32°C. Optimal pH: 6.8–7.4. Found in soil, mud, and freshwater and marine sediments, especially under anoxic conditions. Probably very widely distributed.

The original isolation of Beijerinck (1904a) may not have been a pure culture (Vishniac and Santer, 1957), and a viable sample is not available in the Delft Culture Collection (L.A. Robertson, personal communication) or in any other culture collection. Later work has demonstrated unambiguously that Beijerinck's designation was of a legitimate species exhibiting stable physiological characteristics (Lieske, 1912; Baalsrud and Baalsrud, 1954; Taylor et al., 1971; Justin and Kelly, 1978; Katayama-Fujimura et al., 1982). Earlier claims that the capacity of this organism to denitrify was lost on aerobic subculture and that it was facultatively heterotrophic were erroneous. The name has therefore been revived by Kelly and Harrison (1989, in Validation List No. 31), who suggested a neotype strain. It is now proposed that NCIB 9548 (the strain isolated by White and Hutchinson and used by Justin and Kelly, 1978; AB7, ATCC 23644, JCM 3870) be accepted as this reference strain (Kelly and Wood, 2000a).*

The mol% G + C of the DNA is: 63 (Bd, T_m).

Type strain: ATCC 23644, DSM 12475, NCIB 9548.

GenBank accession number (16S rRNA): AJ243144.

5. **"Thiobacillus plumbophilus"** Drobner, Huber, Rachel and Stetter 1992, 217.
plum.bo'philus. L. neut. n. *plumbum* lead; Gr. v. *philein* to love; M. L. adj. *plumbophilus* loving lead, referring to its ability to grow with lead sulfide as a sole energy source.

Cells are rod-shaped, Gram negative, 0.25 × 3 µm, and motile by one polar flagellum. Optimal growth between 21°C and 34°C, with growth occurring at up to 41°C. Growth between pH 4.0 and 6.5. Strictly chemolithoautotrophic and aerobic. Oxidation of galena (PbS), H_2S, and hydrogen. Sensitive to ampicillin and rifampicin. Possesses 96.5% ubiquinone Q-8. Isolated from a uranium mine in Germany. Insignificant DNA hybridization to *A. ferrooxidans* and *"T. cuprinus"*.

The mol% G + C of the DNA is: 66 (T_m, HPLC).

Deposited strain: DSM 6690.

6. **"Thiobacillus prosperus"** Huber and Stetter 1989, 484.
pros'pe.rus. L. masc. adj. *prosperus* prosperous, referring to its ability to gain precious metals by ore "leaching".

Cells are Gram-negative rods, 0.3 × 3–4 µm. Motile by one polar flagellum. Optimal growth around 37°C and up to 41°C. Growth from 0–3.5% NaCl (some strains tolerate 6% NaCl) and at pH 1.0–4.5. Strictly chemolithoautotrophic and aerobic. Growth on sulfidic ores, like pyrite, sphalerite, chalcopyrite, arsenopyrite, and galena, and on H_2S. Poor growth on elemental sulfur and ferrous iron. Produces sulfuric acid from reduced sulfur compounds. Sensitive to ampicillin and vancomycin. Possesses *meso*-diaminopimelic acid and ubiquinone Q-8. Lives in marine sediments in hydrothermal areas. Insignificant DNA hybridization to *T. ferrooxidans*, *T. thiooxidans*, *T. neapolitanus*, and *T. thioparus*. Member of the class *Gammaproteobacteria*.

The mol% G + C of the DNA is: 64 (T_m, HPLC).

Deposited strain: DSM 5130.

GenBank accession number (16S rRNA): AY034139.

Additional Remarks: "T. prosperus" will in due course be removed from the genus, as recent work has shown its closest phylogenetic relatives to be *"Acidihalobacter aerolicus"* (DSM 14174) and *"Acidihalobacter ferrooxidans"* (DSM 14175), with both of which it shares 95% 16S rRNA sequence identity (P.R. Norris, K.B. Hallberg and B. Johnson, personal communication, 2001).

**Editorial Note:* In the original description, the authors erroneously designated the neotype strain as NCIMB 8327.

Order III. **Methylophilales** *ord. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Me.thy.lo.phi.la′ les. M.L. masc. n. *Methylophilus* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Methylophilales* the *Methylophilus* order.

The order *Methylophilales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the family *Methylophilaceae*.

Description is the same as for the family *Methylophilaceae*.

Type genus: **Methylophilus** Jenkins, Byrom and Jones 1987, 447.

Family I. **Methylophilaceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Me.thy.lo.phi.la′ ce.ae. M.L. masc. n. *Methylophilus* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Methylophilaceae* the *Methylophilus* family.

The family *Methylophilaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Methylophilus* (type genus), *Methylobacillus*, and *Methylovorus*.

Aerobic respiratory metabolism. Oxidize methanol but not methane. Some grow on a limited range of other compounds. Found in a variety of habitats.

Type genus: **Methylophilus** Jenkins, Byrom and Jones 1987, 447.

Genus I. **Methylophilus** *Jenkins, Byrom and Jones 1987, 447*[VP]

THE EDITORIAL BOARD

Me.thy.lo.phi′ lus. Fr. n. *méthyle* the methyl radical; Gr. adj. *philos* loving; M.L. masc. n. *Methylophilus* methyl radical loving.

When grown on methanol–mineral salts agar or in methanol–mineral salts liquid medium, the cells are straight or slightly curved rods, usually 0.3–0.6 × 0.8–1.5 μm, occurring singly or in pairs. Gram negative, but the stain is often not taken up well. **Motile by polar flagella or nonmotile**. Endospores are absent. **No cellular inclusions**. No sheaths or prosthecae detected. No capsules formed, but **slime may be produced by some strains**. Colonies on methanol–mineral salts agar plates incubated for 2 days at 30°C or 37°C are **nonpigmented**, circular, 1–2 mm in diameter, with entire edge, convex, translucent to opaque. Pyocyanin and fluorescein are not produced. No, or extremely poor, growth on nutrient agar and in nutrient broth incubated at 30°C or 37°C for 2 days. No, or extremely poor, growth on blood agar; no hemolysis. Optimal temperature, 30–37°C; no growth occurs at 4°C or 45°C. Optimal pH, 6.5–7.2. **Aerobic**. **Metabolism respiratory**; very little or no acid is produced from glucose. **Methanol is oxidized as the sole carbon and energy source by all strains**. In addition, a limited range of other carbon compounds such as methylamines, formate, glucose, and fructose may be utilized as sole carbon and energy sources. Methane is not used. Nutritionally nonexacting; nitrate and ammonium salts serve as nitrogen sources. Catalase positive and **oxidase positive**. The fatty acid composition is primarily of the nonhydroxylated straight-chain saturated and monounsaturated types with $C_{16:0}$ and $C_{16:1}$ predominating. The major isoprenoid quinone components are ubiquinones with eight isoprene units (Q-8). Isolated from activated sludge, mud, and river and pond water.

The mol% G + C of the DNA is: 50 (T_m).

Type species: **Methylophilus methylotrophus** Jenkins, Byrom and Jones 1987, 447.

FURTHER DESCRIPTIVE INFORMATION

Hexulose phosphate synthetase and hexulose phosphate isomerase, key enzymes of the ribulose monophosphate pathway (RMP) for methanol assimilation, are present (Beardsmore et al., 1982; ElRayes et al., 1991). Methanol dehydrogenase, and NAD^+-linked formaldehyde and formate dehydrogenases also occur (Beardsmore et al., 1982). A variant of the ribulose monophosphate cycle of formaldehyde fixation occurs that involves cleavage of hexose phosphate by 2-keto-3-deoxy-6-phosphogluconate aldolase and a rearrangement sequence involving transketolase and transaldolase (Beardsmore et al., 1982).

Hydroxypyruvate reductase, isocitrate lyase, malyl-CoA-lyase, and glyoxylate aminotransferase, which are characteristic of the serine assimilation pathway, are absent (ElRayes et al., 1991).

A glucose-6-phosphate dehydrogenase is present that is active with both $NADP^+$ and NAD^+. Two separate 6-phosphogluconate dehydrogenases occur, one active with both $NADP^+$ and NAD^+ and the other active only with NAD^+ (Beardsmore et al., 1982).

Ammonia is assimilated via the glutamate dehydrogenase pathway (ElRayes et al., 1991). Acetamide and acrylamide are hydrolyzed by a cytoplasmic amidase (Silman et al., 1991).

The most positive redox potential ever recorded for a flavin adenine dinucleotide-containing protein has been measured for an electron-transfer flavoprotein (ETF) synthesized by *Methylophilus methylotrophus* (Byron et al., 1989).

Urea is hydrolyzed to ammonia by a cytoplasmic urease that is inducible by urea and short-chain amides and repressed by excess ammonia (Greenwood et al., 1998).

TAXONOMIC COMMENTS

Studies of the type strain by 16S rRNA analysis have placed the genus in the class *Betaproteobacteria* (Tsuji et al., 1990).

List of species of the genus Methylophilus

1. **Methylophilus methylotrophus** Jenkins, Byrom and Jones 1987, 447^{VP}
me.thy.lo.tro′phus. M.L. n. *methyl* the methyl radical; Gr. adj. *tropho* pertaining to nutrition; M.L. adj. *methylotrophus* methyl radical-consuming.

The cells are motile by single flagella. Colonies on methanol–mineral-salts agar are grayish-white. In addition to growth on methanol as the sole carbon and energy source, good growth occurs on glucose and may or may not occur on methylamines as sole carbon and energy sources. Different strains give different results with fructose as the sole carbon and energy source. Poor growth, which varies between strains, may occur on lactose, sucrose, D-ribose, D-xylose, ethanol, propanol, butanol, acetate, and formate. Acid is not produced from glucose. Acetoin, tested by the Voges–Proskauer method, may or may not be produced. Tween 20, 40, and 60 are hydrolyzed. Tween 80 is not hydrolyzed. Urease is produced. Leucine arylamidase is produced. Phosphatase production is weak and differs between different strains. Sulfatase is not produced. H_2S is not produced. Gelatin is not liquefied. Extracellular DNase and RNase are not produced. 2,3,5-Triphenyltetrazolium chloride (0.01%) is reduced. No growth occurs in the presence of 0.01% potassium tellurite, or with 5% NaCl. Resistant to penicillin, oleandomycin; sensitive to nalidixic acid, streptomycin, and a number of other antibiotics.

The type strain produces significant amounts of a low-viscosity extracellular polysaccharide from methanol under conditions of nitrogen limitation in chemostat culture.

The mol% G + C of the DNA is: about 50 (T_m), 50.3 (T_m) (NCIB 10515^T), 49.8 (T_m) (ATCC 31226^T).

Type strain: AS1, ATCC 53528, DSMZ 46235, NCIB 10515.

GenBank accession number (16S rRNA): L15475.

2. **Methylophilus leisingeri** corrig. Doronina and Trotsenko 2001b, 1^{VP} (*Methylophilus leisingerii* (sic)) (Effective publication: Doronina and Trotsenko 1994, 529.
lei.sing′e.ri. M. L. gen. n. *leisingeri* named after the Swiss microbiologist, Thomas Leisinger, who isolated the organism.

Gram-negative rods 0.4–0.6 × 1.1–1.7 μm. Nonmotile (unlike *M. methylotrophus*). A slender polysaccharide capsule is present. Colonies on methanol salt agar are circular, 1–4 mm in diameter, white or pale pink in color, opaque, convex, with even edges and a smooth surface. Temperature range, 10–37°C; optimum, 30–35°C. pH range, 6.5–7.8; optimum, 6.8–7.2. The generation time is 2 h on media with methanol or dichloromethane, 10 h with glucose. No vitamins or other growth factors are required. Cellulose is not digested; gelatin is not liquified; starch is weakly hydrolyzed. Acetoin, indole, hydrogen sulfide, and ammonia are not produced. Oxidase, catalase, and urease positive. Strictly aerobic, although able to reduce nitrates to nitrites. Carbon and energy sources include methanol, dichloro- and dibromomethane, glucose, and galactose; methylated amines are not used. Nitrogen sources include ammonium and nitrate. No growth occurs on media with 3% NaCl.

One-carbon units are assimilated via the 2-keto-3-deoxy-6-phosphogluconate (KDPG) variant of the ribulose monophosphate pathway. The Krebs cycle lacks an α-ketoglutarate dehydrogenase. Glyoxylate shunt enzymes are not present. Ammonium is assimilated via the glutamate cycle; glutamate dehydrogenase is lacking. Cells contain a constitutive methanol dehydrogenase (PQQ) and may produce an inducible dichloromethane dehalogenase and hexokinase. Palmitic ($C_{16:0}$) and palmitoleic ($C_{16:1}$) acids predominate among the cellular fatty acids. Cardiolipin is absent from cellular phospholipids. The major ubiquinone is Q-8. The type strain exhibits a DNA hybridization value of 26% with the type strain of *M. methylotrophus.* The type strain was isolated from wastewater in Switzerland.

The mol% G + C of the DNA is: 50.2 (T_m).

Type strain: VKM B-2013, DM11, DSM 6813.

Genus II. **Methylobacillus** *Yordy and Weaver 1977, 254^{AL}, emend. Urakami and Komagata 1986a, 509*

THE EDITORIAL BOARD

Meth.yl.o.ba.cil′lus. Fr. *méthyle* the methyl radical; L. dim. n. *bacillus* a small rod; M.L. masc. n. *Methylobacillus* methyl rodlet.

Rods 0.3–0.6 × 0.8–2.0 μm. **Motile by means of a single polar flagellum or nonmotile.** Gram negative. **Most strains are obligate methylotrophs that grow on one-carbon compounds other than methane**; however, some strains can also use fructose. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. The major cellular fatty acids are straight-chain saturated $C_{16:0}$ and unsaturated $C_{16:1}$. The major quinone is Q-8; Q-7 and Q-9 are minor components.

The mol% G + C of the DNA is: 50–56.

Type species: **Methylobacillus glycogenes** Yordy and Weaver 1977, 254; emend. Urakami and Komagata 1986a, 510.

MAINTENANCE PROCEDURES

Cultures of *M. glycogenes* have been maintained on Medium B[1] at 30°C.

1. Medium B (Urakami and Komagata, 1986a) contains (per liter of distilled water): $(NH)_2SO_4$, 3.0 g; KH_2PO_4, 1.4 g; Na_2HPO_4, 3.0 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; ferric citrate, 0.03 g; $CaCl_2 \cdot 2H_2O$, 0.03 g; $MnCl_2 \cdot 4H_2O$, 0.005 g; $ZnSO_4 \cdot 7H_2O$, 0.005 g; $CuSO_4 \cdot 5H_2O$, 0.0005 g; yeast extract, 0.2 g; vitamin solution, 1.0 ml; methanol, 10.0 ml. The vitamin solution contains (per liter of distilled water): biotin, 2 mg; calcium pantothenate, 400 mg; pyridoxine hydrochloride, 400 mg; *p*-aminobenzoic acid, 200 mg; folic acid, 2 mg; inositol, 2 g; nicotinic acid, 400 mg; riboflavin, 200 mg.

Differentiation of the genus *Methylobacillus* from other genera

Table BXII.β.73 lists characteristics differentiating *Methylobacillus* from other nonmethane-utilizing methylotrophs.

Taxonomic Comments

In this edition of the *Manual*, the genus *Methylobacillus* is placed in the class *Betaproteobacteria*, the order *Methylophilales*, and the family *Methylophilaceae*. This family includes three genera: *Methylophilus*, *Methylobacillus*, and *Methylovorus*.

List of species of the genus Methylobacillus

1. **Methylobacillus glycogenes** Yordy and Weaver 1977, 254[AL]; emend. Urakami and Komagata 1986a, 510.
gly.co′gen.es. Gr. adj. *glykus* sweet; Gr. v. *gennairo* to produce; Gr. adj. *glycogenes* sweet-producing, intended to mean sugar-producing, glycogen-producing.

Gram-negative rods with rounded ends, 0.3–0.5 × 0.8–2.0 μm, occurring singly or rarely in pairs. Motile by means of single polar flagella. Do not form spores. Do not form capsules. Do not accumulate poly-β-hydroxybutyrate. No growth occurs in nutrient or peptone broth. Colonies are shiny, smooth, raised, entire, white to light yellow, 1–3 mm in diameter after 3 days at 30°C on methanol-containing agar. Nitrate reduced to nitrite. Methyl red and Voges–Proskauer negative. Do not produce indole, hydrogen sulfide, or ammonia. Do not hydrolyze gelatin or starch. No denitrification. No acid from D-glucose or D-fructose. Utilize methanol but not methane as the sole carbon source. Obligate methylotroph. Do not utilize L-arabinose, D-xylose, D-glucose, D-mannose, galactose, maltose, sucrose, lactose, trehalose, D-sorbitol, D-mannitol, inositol, glycerol, soluble starch, succinic acid, citric acid, acetic acid, ethanol, or hydrogen. Variable utilization of D-fructose and methylamine. Utilize ammonia, urea, and nitrate as sole nitrogen sources. Urease and oxidase negative. Catalase positive. Growth at 30°C (most strains also grow at 37°C) and pH 6–8. Most strains do not grow in the presence of 3% NaCl.

The mol% G + C of the DNA is: 50–56; type strain 54 (Bd).

Type strain: T-11, ATCC 29475, DSM 5685, JCM 2850, NCIB 11375.

GenBank accession number (16S rRNA): M95652.

2. **Methylobacillus flagellatus** Govorukhina, Kletsova, Tsygankov, Trotsenko and Netrusov 1998, 631[VP] (Effective publication: Govorukhina, Kletsova, Tsygankov, Trotsenko and Netrusov 1987, 676.)

TABLE BXII.β.73. Characteristics differentiating *Methylobacillus* species from each other and from other nonmethane-utilizing methylotrophs[a,b]

[b]Data from and Yordy and Weaver (1977), Urakami and Komagata (1986a), Govorukhina et al. (1987),Jenkins et al. (1987), Govorukhina and Trotsenko (1991), Holt et al. (1994), Padden et al. (1997).

fla.gel.la′ tus. L. *flagellum;* L. *flagellatum* for attached flagella, flagellated.

Gram-negative rods, 0.5–0.6 × 1.4–1.8 μm. Motile. Reproduce by division. Do not form spores or capsules. Colonies on agar with methanol are round, translucent, with milky color, smooth, convex, with an even edge and viscous consistency. Obligate methylotroph. Methanol and methylamine are used as carbon and energy sources. Methylamine, ammonia salts, dimethylamine, nitrates, and peptone are used as nitrogen sources. Optimal temperature 42°C; range, 10– 52°C. Optimal pH 7.2–7.3; range 5.8–8.4. Generation time is 2 h. Vitamins are not required. No acid or gas is produced from glucose. Urease, oxidase, and catalase positive. Nitrate reduced to nitrite. Hydrolyze starch but not cellulose, gelatin, or Tween 80. Major fatty acids are $C_{16:0}$ and $C_{16:1}$. The ratio of *cis*-vaccenic acid to palmitoleic acid is 0.32.

The mol% G + C of the DNA is: 55.5.

Type strain: KT, ATCC 51484, DSM 6875, VKM B-1610.

GenBank accession number (16S rRNA): M95651.

Genus III. **Methylovorus** *Govorukhina and Trotsenko 1991, 161*^{VP}

THE EDITORIAL BOARD

Me.thyl.o′ vo.rus. Fr. *méthyle* the methyl radical; L. v. *voro* to consume; M.L. adj. *methylovorus* methyl-consuming.

When grown on methanol–mineral salts medium, cells are straight or slightly curved rods, usually 0.5–0.6 × 1.0–1.3 μm, occurring singly or in pairs. Gram negative. **Motile** by a single polar flagellum. Endospores are absent. No complex intracellular membranes. No sheaths or prosthecae detected. No capsules formed, but slime may be produced by some strains. Colonies on methanol–mineral salts agar incubated for 2 days at 30°C are circular, 1–2 mm in diameter, with entire edge, convex, and translucent to opaque; may be pink, creamy, or milky in color. Pyocyanin and fluorescein not produced. Cells multiply by binary fission. No aggregation or pigmentation occurs in liquid medium. No growth or extremely poor growth occurs on nutrient agar and in nutrient broth at 30–37°C; no growth occurs under an atmosphere of CH_4/O_2 or $H_2/CO_2/O_2$. Optimal pH for growth, 7.0–7.2; temperature, 35–37°C. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Only methanol and glucose are used as carbon and energy sources.** In addition, some strains are able to grow slowly on methylated amines and betaine. Nitrates, ammonium salts, methylated amines, glutamate, and peptone serve as nitrogen sources. Acetoin, indole, H_2S, and NH_3 are not produced in test medium. Milk is not hydrolyzed. **Oxidase positive.** Urease and catalase positive. Peroxidase variable. Arginine dihydrolase negative. Strains may hydrolyze starch, but not cellulose, gelatin, or Tween 80. Acid, but not gas, is produced from glucose. Isolated from activated sludge, mud, soil, and pond water.

The mol% G + C of the DNA is: 56–57.

Type species: **Methylovorus glucosotrophus** Govorukhina and Trotsenko 1991, 162.

FURTHER DESCRIPTIVE INFORMATION

All strains assimilate methanol carbon through the ribulose monophosphate (RuMP) pathway and ammonia via the glutamate cycle (glutamate synthase and glutamine synthetase). Neither α-ketoglutarate dehydrogenase nor glyoxylate shunt enzymes are present. The fatty acid composition is primarily of the nonhydroxylated straight-chain saturated and monounsaturated types with $C_{16:0}$ and $C_{16:1\ \omega7}$. Branched C_{17} fatty acids are absent. The major phospholipids are phosphatidylethanolamine and phosphatidylglycerol. The strains also possess diphosphatidylglycerol.

DIFFERENTIATION OF THE GENUS *METHYLOVORUS* FROM OTHER GENERA

Table BXII.β.74 indicates some features that differentiate *Methylovorus* from *Methylophilus* and *Methylobacillus*.

TAXONOMIC COMMENTS

Results of DNA–DNA hybridization and 5S rRNA sequencing studies on some strains of obligately and restricted facultatively methylotrophic bacteria support the establishment of *Methylovorus* as a genus separate from other methylotrophs (Wolfrum and Stolp, 1987; Bulygina et al., 1993). The genus is closely related to *Methylobacillus* and *Methylophilus* and belongs to the class *Betaproteobacteria*.

TABLE BXII.β.74. Characteristics differentiating *Methylovorus* from related genera[a,b]

Characteristic	*Methylovorus*	*Methylophilus*	*Methylobacillus*
Presence of:			
6-Phosphogluconate dehydrogenase (NADP-linked)	−	+	+
Branched C_{17} fatty acids	−	+	−
Diphosphatidyl glycerol	+	−	+
Assimilation of NH_3 occurs by:			
Glutamate cycle (glutamate synthase and glutamine synthetase)	+	+	−
Glutamate dehydrogenase	−	−	+
Mol% G + C of the DNA	56–57	50–53	50–56

[a]For symbols see standard definitions.

[b]Data from Govorukhina and Trotsenko (1991).

List of species of the genus Methylovorus

1. **Methylovorus glucosotrophus** Govorukhina and Trotsenko 1991, 162^{VP}

glu.co.so.tro′ phus. M.L. n. *glucosum* glucose; Gr. adj. *tropho* pertaining to nutrition; M.L. adj. *glucosotrophus* glucose-consuming.

The characteristics are as described for the genus. In addition, generation times when grown on methanol and glucose are 2 and 17 h, respectively. Vitamins and co-factors are not required.

The mol% G + C of the DNA is: 56–57 (T_m).

Type strain: 6B1, DSM 6874, UCM B-1475.

Order IV. **Neisseriales** *ord. nov.*

TONE TØNJUM

Neis.se.ri.a' les. M.L. fem. n. *Neisseriaceae* type family of the order; *-ales* ending to denote an order; M.L. fem. pl. n. *Neisseriales* the *Neisseriaceae* family.

Organisms are coccal, coccoid, or distinctly rod-shaped, occurring singly, in pairs, in masses, or in short chains. Cells of *Aquaspirillum* are helical, while *Simonsiella* and *Alysiella* may exhibit a characteristic multicellular micromorphology. Endospores are not formed. Gram-negative, but there may be a tendency to resist decolorization. Flagella and swimming motility are absent except in the genus *Aquaspirillum.* The cells are nonmotile in liquid media but surface-bound motility ("twitching motility") is frequently observed. Fimbriae (pili) are often present.

All species grow aerobically. Strains of all recognized species usually have an optimal growth temperature of approximately 32–36°C. Capsules may be present. Colonies of most genera are not pigmented, with the exception of strains of *Vogesella* and *Chromobacterium.* Several species have complex growth factor requirements, while some species grow readily in simple defined media containing a single organic carbon and energy source.

The mol% G + C of the DNA is: 46–67.

Type genus: **Neisseria** Trevisan 1885, 105.

TAXONOMIC COMMENTS

The order *Neisseriales* comprises a major branch of the *Betaproteobacteria* with the single family *Neisseriaceae* as the type family. *Neisseriaceae* consists of the type genus *Neisseria* as well as the heterogeneous genera (in alphabetical order) *Alysiella, Aquaspirillum, Catenococcus, Chromobacterium, Eikenella, Formivibrio, Iodobacter, Kingella, Microvirgula, Prolinoborus, Simonsiella, Vitreoscilla,* and *Vogesella.* In order of decreasing relatedness to the type genus *Neisseria* the genera included in *Neisseriaceae* include *Kingella, Eikenella, Alysiella, Simonsiella* (Rossau et al., 1986, 1989; Dewhirst et al., 1989), *Microvirgula* (Patureau et al., 1998), *"Laribacter"* (Yuen et al., 2001), *Vogesella* (Grimes et al., 1997), *Vitreoscilla* (Joshi et al., 1998), *Chromobacterium* (Dewhirst et al., 1989), *Aquaspirillum* (Rossau et al., 1989; Wen et al., 1999), *Prolinoborus* (Pot et al., 1992b), *Formivibrio* (Hippe et al., 1999), and *Iodobacter* (Fig. BXII.β.61). Other entities that, based on 16S rRNA phylogenetic analysis, show the closest relatedness to *Neisseriales* are *Taylorella* spp. encompassing *Taylorella equigenitalis* and *Taylorella asinigenitalis* (Bleumink-Pluym et al., 1993; Jang et al., 2001) and *Pelistega europaea* (Vandamme et al., 1998), through their relationship to *Iodobacter fluviatilis*; these genera appear closer to the *Neisseriaceae* type genus *Neisseria* than does the genus *Catenococcus.* However, the genera *Taylorella* and *Pelistega* are currently placed in the new family *Alcaligenaceae* in the order *Burkholderiales.*

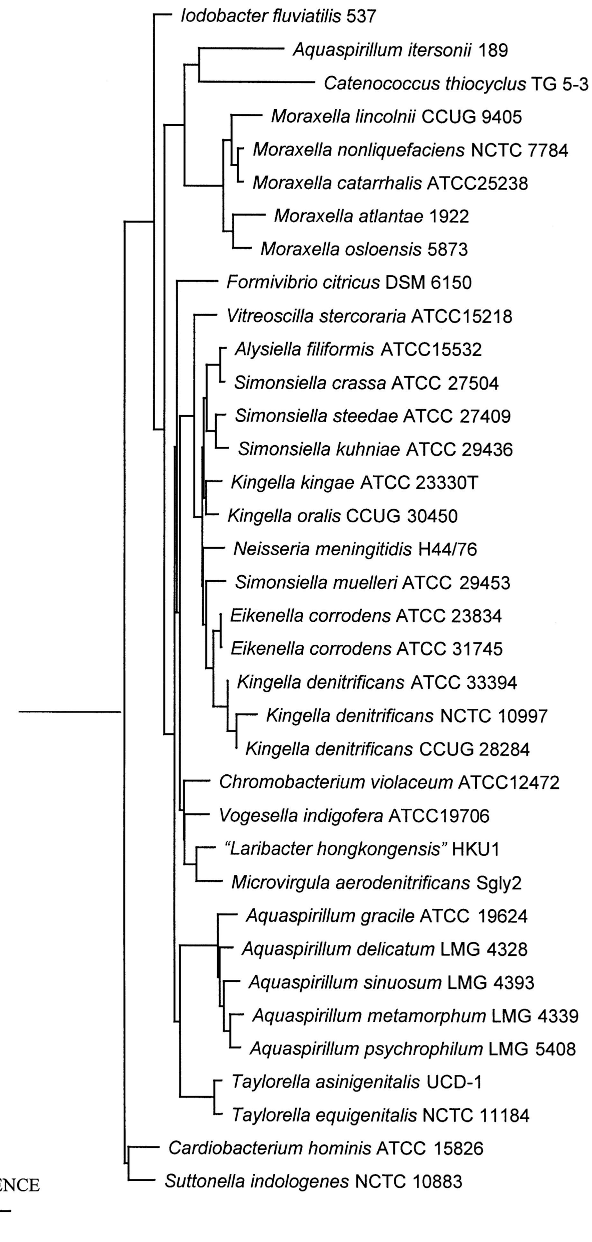

FIGURE BXII.β.61. Phylogenetic neighbor-joining tree of the family *Neisseriaceae* based on 1355 nucleotide positions of the 16S rRNA genes. *Oligella urethralis* CIP 103 116 was used as an outgroup (K.K. Garborg, S.A. Frye, B. Pettersson and T. Tønjum, unpublished studies).

Family I. **Neisseriaceae** Prèvot 1933, 119[AL] emend. Dewhirst, Paster and Bright 1989, 265

TONE TØNJUM

Neis.se.ri.a′ ce.ae. M.L. fem. n. *Neisseria* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Neisseriaceae* the *Neisseria* family.

Organisms are coccal, occurring singly, in pairs, or in masses, often with adjacent sides flattened (different planes of division), or distinctly rod-shaped or coccoid (one plane of division), frequently occurring in pairs or short chains. Cells of *Aquaspirillum* are helical, while *Simonsiella* and *Alysiella* may exhibit a characteristic multicellular micromorphology. Endospores are not formed. Gram negative, but there may be a tendency to resist decolorization. Flagella and swimming motility are absent. The cells are nonmotile in liquid media but surface-bound motility ("twitching motility") is frequently observed. Fimbriae (pili) are often present.

All species grow aerobically. Strains of all recognized species usually have an optimal growth temperature of approximately 32–36°C. Capsules may be present. Colonies are not pigmented. Several species have complex growth factor requirements, while some species grow readily in simple defined media containing a single organic carbon and energy source.

All strains except those of *Formivibrio* are oxidase positive. Usually catalase positive. Indole is not produced. True waxes are not present. Fatty acid profiles show the presence of mainly unbranched saturated and mono- or di-unsaturated fatty acids composed of 16 and 18 carbon atoms. Most strains reside indigenously on mucosal membranes of humans and animals, although environmental species were recently included in this family.

The mol% G + C of the DNA is: 46–67.

Type genus: **Neisseria** Trevisan 1885, 105.

FURTHER DESCRIPTIVE INFORMATION

Since the 1980s, mainly as a result of the application of new molecular techniques, major changes have occurred within the taxonomy and classification of the family *Neisseriaceae*. This family comprises a major branch of the *Betaproteobacteria*. Studies with DNA–DNA and DNA–rRNA hybridizations, and subsequently 16S rRNA sequence comparisons, have redefined the relationships among species belonging to the *Neisseriaceae* (Dewhirst et al., 1989; Rossau et al., 1989; Enright et al., 1994; Tønjum et al., 1995a; Harmsen et al., 2001). Findings from DNA-mediated transformation to streptomycin resistance, DNA base composition data, DNA–DNA and DNA–rRNA hybridization, and rRNA sequencing have revealed differences that mandate the separation of the genera *Moraxella* and *Acinetobacter* (belonging to the *Gammaproteobacteria*) from *Neisseriaceae* (Stackebrandt et al., 1988b; Dewhirst et al., 1989). In addition, using transformation analysis, the four coccal species of the "false neisseriae" (previously "*N. catarrhalis*", *N. caviae*, *N. ovis*, and *N. cuniculi*) have been transferred from *Neisseria* to the *Gammaproteobacteria* (Catlin, 1970; Bøvre, 1979). The moraxellae, including the "false neisseriae", psychrobacters, and acinetobacters, were grouped to form the new family *Moraxellaceae* (Catlin, 1991; Rossau et al., 1991; Pettersson et al., 1998b), leaving the genera *Neisseria*, *Kingella*, and *Simonsiella*, the genospecies *Eikenella corrodens* and *Alysiella filiformis*, and the CDC groups EF-4 and M-5 as members of *Neisseriaceae* (Fig. BXII.β.61; Dewhirst et al., 1989; Rossau et al., 1989). Currently, *Aquaspirillum*, *Catenococcus*, *Chromobacterium*, *Formivibrio*, *Iodobacter*, *Microvirgula*, *Prolinoborus*, *Vitreoscilla*, and *Vogesella* are also assigned to *Neisseriaceae*. Table BXII.β.75 lists some differential characteristics of the genera of the family.

Many species of *Neisseriaceae* contain strains that are highly competent for genetic transformation (see Table BXII.β.77 in the *Neisseria* chapter). In addition to representing the most important form of genetic exchange causing genomic heterogeneity (Spratt et al., 1992), transformation also provides a tool for definite identification of numerous, although not all, species of the *Neisseriaceae*, and also forms an important basis for allocation of species within the genera of this family (Bøvre, 1980; Bøvre and Hagen, 1981; Tønjum et al., 1995b).

Genetic taxonomy in *Neisseriaceae* was pioneered by Catlin and Cunningham in 1961 when they demonstrated close relationships between most *Neisseria* species (except the species then misnamed "*N. catarrhalis*") and by Bøvre and Henriksen in 1962. That a genus may contain both coccal and rod-shaped species was shown for genus *Neisseria* by the detection of the rod-shaped organism known as *Neisseria elongata* (Bøvre and Holten, 1970). More recently, another rod-shaped organism, *N. weaveri*, has been included in the genus *Neisseria* (Andersen et al., 1993; Holmes et al., 1993). The genus *Kingella* was proposed by Henriksen and Bøvre in 1976 for the organism known previously as *Moraxella kingae* (now *Kingella kingae*), and was subsequently enlarged by the proposed inclusion of two more species, *K. denitrificans* and *K. indologenes* (Snell and Lapage, 1976). The genus *Kingella* now consists of the species *K. kingae*, *K. denitrificans*, and *K. oralis* (Dewhirst et al., 1993), while *K. indologenes* was transferred to the family *Cardiobacteriaceae* as *Suttonella indologenes* (Dewhirst et al., 1990). A slight genetic affinity between *K. kingae* and *N. elongata* has been demonstrated by genetic transformation and DNA–DNA hybridization (Bøvre and Holten, 1962; Tønjum et al., 1989).

The cellular lipid composition of *Neisseriaceae* is characterized by the absence of branched fatty acids. The quantitative and qualitative distributions of straight-chain fatty acids, including hydroxy acids, generally distinguish the genera as genetically circumscribed and can also be important in differentiation among several species (Jantzen et al., 1974, 1975; Bøvre et al., 1976). True waxes, i.e., simple esters of fatty alcohols and fatty acids, are absent in the genera *Neisseria* and *Kingella*, while activities corresponding to the enzymes thymidine phosphorylase, nucleoside deoxyribosyltransferase, and thymidine kinase have been shown to be present in the genus *Kingella*, but absent in the genus *Neisseria* (Jyssum and Bøvre, 1974). Carbonic anhydrase has been detected in all *Neisseria* species (Berger and Issi, 1971).

TAXONOMIC COMMENTS

The taxonomic placement of *Neisseriaceae* corresponds to rRNA superfamily III according to DNA–rRNA hybridizations performed by Rossau et al. (1986, 1989). Based on 16S rDNA phylogeny, *Neisseriaceae* consists of the type genus *Neisseria*, as well as the genera (in alphabetical order) *Alysiella*, *Aquaspirillum*, *Caten-*

[a]Symbols: +, positive for the majority of strains and some strains of each species; [+], positive for all strains of the majority of species (only one species uniformly negative); D, positive and negative species (or strains of *Acinetobacter*) about equally represented; −, all strains negative.

[b]Only two species, *N. elongata* and *N. weaveri*, consist of rods.

[c]*K. denitrificans* may be negative or weakly positive with the least sensitive test reagent, dimethyl-*p*-phenylenediamine, whereas it is distinctly positive when tetramethyl-*p*-phenylenediamine is used. For other organisms of this table (including *K. kingae*) the result is the same with either reagent.

ococcus, *Chromobacterium*, *Eikenella*, *Formivibrio*, *Iodobacter*, *Kingella*, *Microvirgula*, *Prolinoborus*, *Simonsiella*, *Vitreoscilla*, and *Vogesella*. In order of decreasing relatedness to the type genus *Neisseria* the genera included in *Neisseriaceae* encompass *Kingella*, *Eikenella*, *Alysiella*, *Simonsiella* (Rossau et al., 1986, 1989; Dewhirst et al., 1989), *Microvirgula* (Patureau et al., 1998), *"Laribacter"* (Yuen et al., 2001), *Vogesella* (Grimes et al., 1997), *Vitreoscilla* (Joshi et al., 1998), *Chromobacterium* (Dewhirst et al., 1989; Martin and Brimacombe, 1992; Duran and Menck, 2001), *Aquaspirillum* (Rossau et al., 1989; Wen et al., 1999), *Prolinoborus* (Pot et al., 1992b), *Formivibrio* (Hippe et al., 1999), and *Iodobacter* (Fig. BXII.β.61). Other entities that, based on 16S rRNA phylogenetic analysis, show the closest relatedness to *Neisseriales* are *Taylorella* spp., encompassing *Taylorella equigenitalis* and *Taylorella asinigenitalis* (Bleumink-Pluym et al., 1993; Jang et al., 2001), and *Pelistega europaea* (Vandamme et al., 1998) through their relationship to *Iodobacter fluviatilis*. These genera appear closer to the genus *Neisseria* than does the genus *Catenococcus*. The phylogenetic maps obtained by 16S rDNA sequence analysis show that species within *Neisseriaceae* are polyphyletic. This is due to the high frequency of horizontal gene transfer by transformation combined with frequently occurring recombination events and a relatively high spontaneous mutation rate (Spratt et al., 1992). These factors contribute to the limitations of the use of 16S rDNA sequences as the basis for taxonomy in this bacterial family.

Microvirgula aerodenitrificans (Patureau et al., 1998) are denitrifying and very motile curved rods isolated from activated sludge. Although phenotypically similar to *Comamonas testosteroni*, phylogenetic analysis based on the 16S rRNA sequence shows that *Microvirgula aerodenitrificans* is most closely related to the genus *Vogesella*. Another recent addition to the genera in *Neisseriaceae* is the genus *"Laribacter"*, represented by *"Laribacter hongkongensis"* (Yuen et al., 2001). This bacterium was isolated from the blood and empyema of a cirrhotic patient. The cells are seagull shaped or spiral rods. Phylogeny based on 16S rDNA sequence analysis shows that *"L. hongkongensis"* is most closely related to *Microvirgula aerodenitrificans*, *Vogesella indigofera*, and *Chromobacterium* species, respectively.

Vogesella indigofera (Grimes et al., 1997) has blue-pigmented colonies with a metallic copper-colored sheen. These blue-pigmented bacteria were isolated from freshwater samples, and numerical analysis of morphological and biochemical characteristics has revealed 90.0% relatedness between *Vogesella* spp. and *Burkholderia cepacia* and *Janthinobacterium lividum*. A phylogenetic analysis in which both 5S rRNA and 16S rRNA were used also revealed that the *Vogesella* strains were closely related to *Chromobacterium violaceum*, but sufficiently distinct to warrant placement in a separate genus, *Vogesella*, named in honor of Otto Voges, who first isolated and described this blue-pigmented eubacterium in 1893.

Selected strains/biovars currently classified as *Aquaspirillum* spp., *Aquaspirillum gracile*, *Aquaspirillum delicatum*, *Aquaspirillum sinuosum*, *Aquaspirillum metamorphum*, and *Aquaspirillum psychrophilum* also belong to the *Neisseriaceae* (Wen et al., 1999), together with *Prolinoborus* (Pot et al., 1992b). *Iodobacter fluviatilis* (previously *Chromobacterium fluviatile*) (Wen et al., 1999) and *Catenococcus thiocycli* (partial 16S rDNA sequence submitted by Tourova, T.P. and Kuznetsov, B.B., Moscow, Russia) are the entities most distantly related to the type genus *Neisseria* (Fig. BXII.β.61).

Acknowledgments

Stimulating discussions with Kjell Bøvre and Bertil Pettersson are deeply appreciated. The information provided in the first version of *Bergey's Manual of Systematic Bacteriology* (1984) by Kjell Bøvre is gratefully acknowledged.

Genus I. **Neisseria** *Trevisan 1885, 105*[AL]

TONE TØNJUM

Neis.se′ri.a. M.L. fem. n. *Neisseria* named after Albert Neisser, who discovered the etiological agent of gonorrhea in the pus of patients in 1889.

Cocci 0.6–1.9 µm in diameter, occurring singly but often in pairs with adjacent sides flattened; two species (*Neisseria elongata* and *N. weaveri*) are exceptions and consist of short rods 0.5 µm wide, often arranged as diplobacilli or in chains. Division of the coccal species is in two planes at right angles to each other, sometimes resulting in tetrads. Capsules and fimbriae (pili) may be present. Endospores are not present. Gram negative, but there is a tendency to resist decolorization. Swimming motility does not occur and flagella are absent. Aerobic. Some species produce a yellow carotenoid pigment. Some species are nutritionally fastidious and hemolytic. Optimal temperature, 35–37°C. Oxidase positive. Catalase positive except most strains of *N. elongata*. Carbonic anhydrase is produced by all species. All species reduce nitrite except *N. gonorrhoeae* and *N. canis*. *Neisseria* spp. produce acid from carbohydrates by oxidation, not fermentation. Chemoorganotrophic. Exotoxins are not produced. Some species are saccharolytic. Inhabitants of the mucous membranes of mammals. Some species are primary pathogens of humans. The genus *Neisseria* belongs to the family *Neisseriaceae* of the *Betaproteobacteria*.

The mol% G + C of the DNA is: 48–56.

Type species: **Neisseria gonorrhoeae** (Zopf 1885) Trevisan 1885, 106 (*Merismopedia gonorrhoeae* Zopf 1885, 54.)

FURTHER DESCRIPTIVE INFORMATION

Cells of most *Neisseria* spp. are cocci that divide in two planes at right angles to each other, often resulting in the formation of diplococci and tetrads. However, cells of the species *N. elongata* and *N. weaveri* are short, slender rods (Bøvre and Hagen, 1981; Andersen et al., 1993). *Neisseria* spp. produce oxidase and catalase, carbonic anhydrase, and nitrite reductase, but do not produce thymidine phosphorylase, nucleoside deoxyribosyl transferase, or thymidine kinase. In contrast to *Moraxella* spp., the cell walls of *Neisseria* spp. do not contain true waxes. Summaries of the occurrence and isolation (Bøvre and Hagen, 1981), phylogeny and taxonomy (Bøvre and Hagen, 1981), biochemistry, physiology, and identification (Morse and Knapp, 1989; Knapp and Koumanis, 1999), and clinical significance (Cartwright, 1995; Knapp and Koumanis, 1999) of neisseriae are available.

Phylogeny and classification The genus *Neisseria* contains 17 species and biovars that may be isolated from humans including six species that may be isolated from animals (Table BXII.β.76). The taxonomy of the species of human origin has undergone many changes; these and the names by which individual species have been known have been summarized (Rossau et al., 1989; Tønjum et al., 1995b; Knapp and Koumanis, 1999). *Neisseria* spp. may be identified by phenotypic characteristics including their patterns of acid production from carbohydrates, production of polysaccharide from sucrose, and reduction of nitrate (Table BXII.β.76), as well as 16S rDNA sequence analysis (Fig. BXII.β.62).

Based on conventional characterization and 16S rDNA sequence analysis, *Neisseria* spp. can be divided into three major groups. The first group includes the closely related species *N. gonorrhoeae*, *N. meningitidis*, *N. lactamica*, *N. cinerea*, and *N. polysaccharea*. Strains of these species grow as nonpigmented, translucent colonies. Members of the second group, which consists of *N. subflava* (including biovar flava, biovar perflava, and biovar subflava), *N. sicca*, and *N. mucosa*, referred to as the saccharolytic species, usually grow as opaque, yellow-pigmented colonies on solid media. Some strains of *N. subflava* biovar perflava have translucent colonies. Although asaccharolytic, *N. flavescens* grows as yellow, opaque colonies and appears to be a member of this group (Kingsbury, 1967; Rossau et al., 1989). The third group contains *N. elongata* and the animal species *N. weaveri*, *N. denitrificans*, *N. animalis*, *N. canis*, *N. macacae*, *N. iguanae*, and *N. dentiae*. However, based on 16S rDNA sequence analysis, *N. denitrificans* is just as related to *Simonsiella muelleri* and *Kingella denitrificans* as to *Neisseria* spp., and *N. canis* and the other animal neisserial species are related to *K. kingae* and *K. oralis*. The genetic basis for interrelatedness of strains of *Neisseria* and other genera of the *Neisseriaceae* is addressed below.

Cell morphology Although the genus *Neisseria* has traditionally consisted only of cocci (Fig. BXII.β.63), two rod-shaped species, *N. elongata* and *N. weaveri*, are currently included in the genus.

Cell wall composition Neisserial cell surface variation serves as an adaptive mechanism that can modulate tissue tropism, immune evasion, and survival in the changing host environment.

Outer membrane The outer membrane of the neisseriae is typical for a Gram-negative bacterium and consists of phospholipids, several proteins, and LPS. The gonococcal outer membrane is more permeable to hydrophobic compounds such as fatty acids, detergents, and certain antibiotics than the membranes of other Gram-negative bacteria (Miller et al., 1977). This may be due in part to the presence of phospholipids in the outer leaflet of the outer membrane (Lysko and Morse, 1981).

Outer membrane proteins *N. gonorrhoeae* and *N. meningitidis* possess several outer membrane proteins that have been studied at the molecular level and found to be analogous to one another. The nomenclature of these proteins has been devised to reflect the genetic relatedness of these organisms (Hitchcock, 1989).

PORINS The gonococcal (protein I, PI) and meningococcal (class 1, 2, and 3 proteins) outer membranes contain trimeric proteins that form hydrophilic pores (porins) termed Por (Newhall et al., 1980a; Douglas et al., 1981; Derrick et al., 1999; Müller et al., 1999). The porin function is necessary for the survival of the bacterium, allowing nutrients and other solutes to enter the cell. The neisserial porin proteins are important as serotyping antigens, putative vaccine components, and for their proposed role in the intracellular colonization of humans. Gonococci express one of two classes of porins, termed PIA and PIB or PorA and PorB (Sandstrøm et al., 1982), which are encoded by alleles of the same gene (Gotschlich et al., 1987b; Carbonetti et al., 1988). Antigenic heterogeneity in the PIA and PIB molecules provides the basis for gonococcal serotyping. In contrast to gonococci, many meningococcal strains express two porin molecules, one encoded by *porA* (designated the PorA or class I protein) and a second encoded by *porB* (designated as the PorB or class II/III). PorB is the meningococcal counterpart of gonococcal porin with class II corresponding to PIA and class III corresponding to PIB, while PorA/class I expression is unique to meningococci. Evidence of interspecies recombination of *porB*

[b]Only two species, *N. elongata* and *N. weaveri*, consist of rods.

[c]Nitrite in low concentrations can be reduced by *N. gonorrhoeae* and by serogroups A, D, and Y of *N. meningitidis* (Berger, 1970).

[d]*N. subflava* biovar perflava is positive; the reaction differs among strains of *N. subflava* biovar subflava.

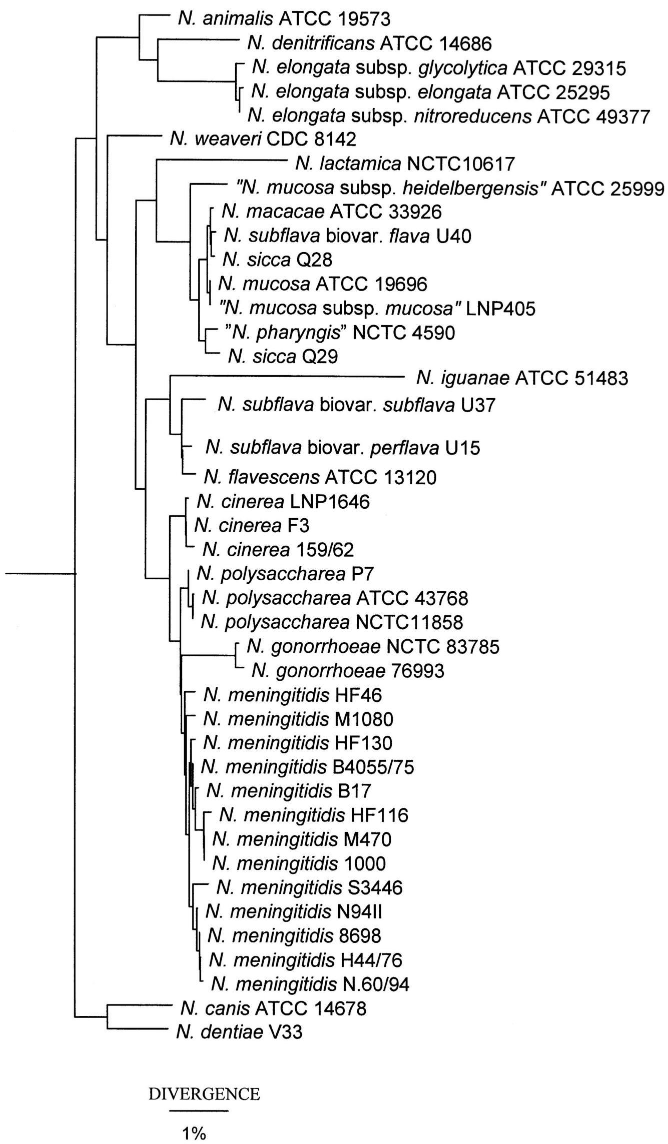

FIGURE BXII.β.62. Neighbor-joining tree of the genus *Neisseria* based on 1355 nucleotide positions of the 16S rRNA genes. *Moraxella nonliquefaciens* NCTC 7784 was used as an outgroup (Reproduced with permission from K.K. Garborg., S.A. Frye, B. Pettersson and T. Tønjum, unpublished studies).

has been documented in the isolation of a meningococcal stain whose *porB* allele was virtually identical to that of gonococcal allele (Vazquez et al., 1995). Although gonococci fail to express PorA/class I protein, they carry a complete but defective copy of the *porA* gene (Feavers and Maiden, 1998). The PorB of *N. gonorrhoeae* is able to translocate from the outer bacterial membrane into host cell membranes where it modulates the infection process (Müller et al., 1999). Most evidence suggests that meningococcal PorB/class II/III proteins behave analogously in function and structure to the gonococcal counterpart, while PorA/class I is structurally distinct but with overlapping function. For example, meningococcal strains lacking PorA/class I protein can be constructed as long as they express PorB/class II/III protein and vice versa (Tommassen et al., 1990). In the case of both porins, immunization has been demonstrated to be capable of engendering bactericidal (van der Voort et al., 1996) and opsonic antibodies (Lehmann et al., 1999). PorA/class I protein appears to be an important component for noncapsular meningococcal vaccines, but like PorB/class II/III is polymorphic due to horizontal gene exchanges (Bart et al., 1999). Moreover, the efficacy of vaccines composed solely of PorA/class I protein may be compromised because strains failing to express the PorA/class I molecule have been shown to arise due to 1) phase variation owing to slipped strand mispairing within its promoter region (van der Ende et al., 1995), 2) complete deletions of the gene (van der Ende et al., 1999), and 3) gene inactivation via insertion of IS1301 (Newcombe et al., 1998). Phase variation appears to account for the absence of PorA expression in most strains (Bart et al., 1999).

Several studies have demonstrated the association of particular PI serotypes with either disseminated or localized gonococcal infections (Cannon et al., 1983; Sandstrøm et al., 1984; Brunham et al., 1985). Strains of *N. gonorrhoeae* isolated from patients with disseminated disease (PIA strains), and strains of *N. meningitidis* were more efficient at porin insertion than strains isolated from a mucosal site (PIB strains). PIA has also been shown to be specifically associated with increased bacterial invasiveness for human cells, which may explain its association with invasive disease (van Putten et al., 1998). Treatment with PI also decreased the ability of human neutrophils to exocytose granules and affected other cellular functions (Haines et al., 1988). PI has been considered as a potential vaccine candidate against gonococcal disease. Antibodies against PI are effective in both bactericidal and opsonic assays (Virji et al., 1986, 1987), and infection with one PI serotype appears to provide protection against subsequent infection with the same serotype (Buchanan et al., 1980). However, even the use of a meningocccal hexavalent PorA vaccine candidate in a clinical trial did not result in adequate protection (Rouppe van der Voort et al., 2000).

Opacity-associated (Opa) proteins Both *N. gonorrhoeae* and *N. meningitidis* express a family of closely related but size-variable surface-exposed outer membrane proteins termed opacity-associated or Opa proteins. The gonococcal proteins have been named protein IIs while those from meningococci are referred to as class 5 proteins. A similar protein has been identified in *N. lactamica* and *N. cinerea* (Aho et al., 1987). Most, but not all, gonococcal opacity-associated proteins are associated with pronounced colony opacity because they increase the aggregation of gonococcal cells and thereby contribute to autoagglutination and adherence (Blake et al., 1995). There is no relationship between colony opacity and expression of the opacity-associated proteins in *N. meningitidis* (Hagman and Danielsson, 1989). With regard to function, gonococcal and meningococcal opacity-associated protein expression have been demonstrated to promote adherence and uptake into mammalian cells by virtue of their ability to engage cell surface receptors including CD66 (Chen et al., 1997a) and proteoglycan receptors (van Putten and Paul, 1995).

The opacity-associated proteins undergo phase variation, are immunogenic, and appear to have an important role in bacterial adherence and invasion. The *in vivo* importance of opacity-associated protein expression for neisserial infection is suggested by the findings that gonococci recovered after urogenital infection are typically Opa^{+}, as are bacteria recovered after the inoculation of human volunteers with transparent (Opa^{-}) bacteria (Swanson et al., 1988). In *N. gonorrhoeae*, *N. meningitidis*, and *N. lactamica*, 11, 3–4, and 2 unlinked chromosomal alleles, respec-

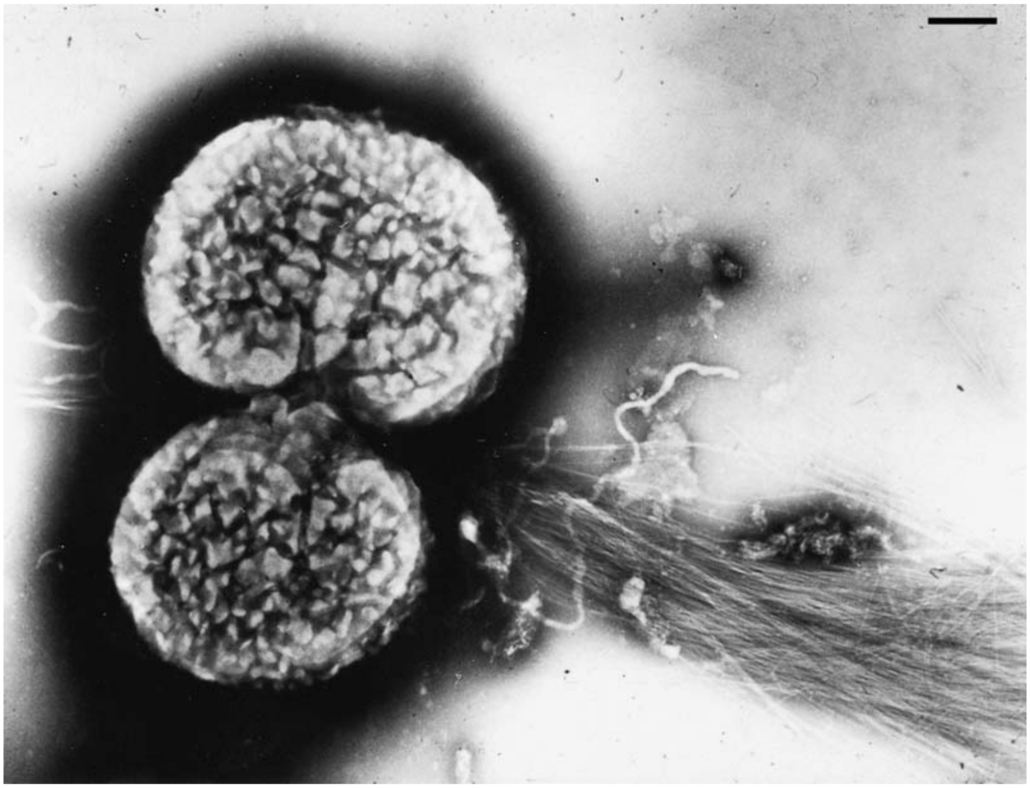

FIGURE BXII.β.63. Electron microscopic image of negatively stained *Neisseria meningitidis* strain M1080. Bar = 0.25 mm.

tively, have been identified that encode distinct opacity-associated protein variants (Meyer and van Putten, 1989). Each of these is a complete gene with a functional promoter and is transcribed (Stern and Meyer, 1987). Phase variable expression results from slipped strand mispairing DNA rearrangements, which occur at high frequencies and alter the number of pentanucleotide CTCTT coding repeat units in the N-terminal part of the open reading frames (Murphy et al., 1989). The opacity-associated proteins of *N. gonorrhoeae* and *N. meningitidis* can undergo phase variation during natural infection (Zak et al., 1984; Tinsley and Heckels, 1986).

Opa proteins also display antigenic variability and diversity within strains occurring by recombinational reassortment, which has been documented both in gonococci (Connell et al., 1988) and meningococci (Hobbs et al., 1998).

Opc The meningococcal Opc outer membrane protein and its gene were first identified in a genetic cloning study using antibodies to the meningococcal Class 5C protein (Olyhoek et al., 1991). Further analysis revealed, however, that Opc is structurally and antigenically unrelated to the Class 5 proteins (Merker et al., 1997). Most meningococcal strains are capable of expressing Opc, and intrastrain phase variation occurs owing to changes in the number of contiguous cytosine residues that separate the *opc*-10 promoter and the start codon sequences (Sarkari et al., 1994). Although originally thought to be meningococcal-specific, gonococci carry an allele of *opc* in their genome and Opc is weakly expressed in gonococci (Zhu et al., 1999). Meningococcal Opc promotes binding to and uptake by mammalian cells by virtue of binding proteoglycan receptors (de Vries et al., 1998). The potential benefits of a humoral immune response to Opc remain unclear (Thiesen et al., 1997).

H.8 protein The DNA sequence predicts that the H.8 protein is a lipoprotein based on the presence of a lipoprotein signal-peptide processing site and an N-terminal cysteine residue. The predicted protein is 71 amino acids in length and is composed entirely of 13 repeats of the AAEAP consensus sequence that was also present in another neisserial protein, the lipid-modified azurin (Gotschlich et al., 1987a; Kawula et al., 1987). This protein is not essential for the growth and survival of gonococci in a complex medium, and the function of this protein remains unknown.

PilQ PilQ was first identified as the outer membrane protein-macromolecular complex (OMP-MC), a major protein component of the outer membrane suggested to account for about 10% of its protein mass (Newhall et al., 1980b; Hansen and Wilde, 1984). This protein is required for type IV pilus biogenesis in the pathogenic neisseriae and was renamed PilQ based on its homology to the *Pseudomonas aeruginosa* PilQ protein (Drake and Kommey, 1995; Tønjum et al., 1998). Neisserial mutants expressing defective forms of the protein are devoid of pili and pilus-associated phenotypes. The PilQ complex has a molecular mass of 800–900 kDa and is composed of 12 identical subunits of 76–80 kDa (Tsai et al., 1989; Drake and Koomey, 1995; Tønjum et al., 1998). The C-terminus of PilQ shares identity with members of a large family of proteins associated with membrane translocation of macromolecular complexes, termed secretins. PilQ appears to function in pilus biogenesis in its complex form by serving as a pore through which pili are extruded. The PilQ

monomer exhibits in its N-terminus a polymorphic region in which an octapeptide repeat occurs 4–7 times in *N. meningitidis* and only 2–3 times in *N. gonorrhoeae*. Antibodies against PilQ are produced during a natural infection (Tønjum and Koomey, personal communication), and PilQ antibodies are bactericidal for both homologous and heterologous gonococcal and meningococcal strains in a complement-dependent assay system (Corbett et al., 1986; Tønjum et al., 1998).

PilC A 110-kDa protein termed PilC was originally identified by virtue of its co-purification with the neisserial pilus fibers has also been identified in the neisserial outer membrane (Jönsson et al., 1991). Neisserial mutants failing to express PilC were reported to show a dramatic reduction in piliation (Jönsson et al., 1991; Nassif et al., 1994). More recently, PilC has been implicated as the molecule responsible for pilus-associated epithelial cell adherence (Rudel et al., 1995a, b).
